(iii.) **The Indirect Fick Principle.** It is also possible, by indirect methods, to find the CO_2, or O_2, in the arterial and venous bloods without the use of operative procedures. In Field's method, the tension of CO_2 in the arterial blood is obtained by determining the amount of this gas in ordinary alveolar air, since the alveolar and arterial tensions of CO_2 are identical. This tension must be converted into percentage content by reference to a CO_2-dissociation curve of the same blood (Ch. XL).

The content of CO_2 in the venous blood coming into the lungs is determined by a procedure which brings the alveolar air up to the same tension. The subject having expired deeply, takes, from a 5 l. bag, three deep breaths in succession of a mixture containing about 94 per cent. oxygen and 6 per cent. CO_2, *i.e.* just above what is known to be the tension of CO_2 in arterial blood. The large amount of oxygen is supplied in order to prevent errors due to anoxæmia. These three breaths are taken within fifteen seconds, and the last one is held for a few seconds. As the total circulation time in a man at rest is assumed to be about thirty seconds, there is no time for the blood which has taken up CO_2 from the lungs to come back to the lungs, *i.e.* equilibrium is established between the air in the alveoli and the continually renewed venous blood arriving at the alveoli by the pulmonary artery. After holding the third breath the alveolar air is collected and analysed so that its tension of CO_2 can be calculated.† This is converted into percentage of CO_2 in the venous blood by reference to the CO_2-dissociation curve, as was done for arterial blood. In this way we find the difference between the CO_2 content of the blood leaving and of the blood entering the lungs. Before these determinations are carried out, the total CO_2 given off by the individual is measured by collecting his expired air. Suppose that the difference in CO_2 content of arterial and venous blood was 40 c.c. per litre blood, while the total amount of CO_2 given off from the lungs in the course of a minute was 200 c.c. the total amount of blood would be $\frac{200}{40} = 5$ litres, which would thus be the "minute" volume of the heart. In other methods the arterio-venous oxygen difference is determined.

Krogh and Lindhard ‡ devised a method for determining the blood flow through the lungs by finding how much nitrous oxide is taken from a mixture of nitrous oxide and air with which the lungs are filled. Knowing the solubility coefficient of nitrous oxide in blood at the tension and temperature at which this gas is present in the pulmonary alveoli, and determining the amount of this gas which has disappeared from the mixture breathed during a certain time, it is possible to estimate the volume of blood which has passed through the lungs during the same time. In another method the soluble gas used is acetylene.§

(iv.) **By Calculation.** It has been claimed that the cardiac output can be computed from the arterial blood pressure and the pulse wave velocity.||

(v.) **The Ballistocardiogram.** When the heart expels its blood into the arteries, a recoil (comparable with that of a rifle, together, sometimes, with the rifleman, when a bullet is fired) is given to the heart and to the whole body. If one stands on a delicate spring

weighing-machine, the pulsation due to this ballistic recoil, is clearly shown as a pulsation. A curve, the ballistocardiogram, can be recorded by having the subject lie on a suspended support movable in the long axis of the body.* It shows important changes with altered heart output.

CARDIO-PNEUMATIC MOVEMENTS. Since the ventricle during systole becomes smaller, the space thus provided in the chest cavity is taken up by an expansion of the veins, auricles, and lungs. To this systolic diminution of intrathoracic pressure are due the "cardio-pneumatic" movements. These are recorded by connecting one nostril to a tambour, while the other nostril and the mouth are kept closed. If a carotid pulse tracing be taken at the same time, it will be found that there is a fall of the pressure in the nasal cavity, synchronous with the rise of the pressure in the arteries, both being due to the expulsion of blood from the heart.

CHAPTER XXXII

FACTORS WHICH MODIFY THE HEART'S ACTION

The performance of the heart is subject to considerable alterations, due to the operation of numerous factors capable of affecting either the frequency or the extent of its contractions. With the heart *in situ* these factors are difficult to analyse, owing to their number and complex interactions, particularly those of the mutual effects of the systemic circulation and the heart beat upon one another. In order to study the conditions which can control the filling and emptying, and also the rate, of the heart in the absence of the complications normally introduced by the presence of a delicately poised and constantly changing peripheral circulation, it is of importance to be able to replace the latter by an artificial circulation, the resistance of which can be controlled at will. This can be effected by the use of the heart-lung preparation.

The Heart-Lung Preparation. With the use of this preparation, devised by Starling,* it is possible to study the action of the cat or dog heart under very varying conditions of systemic arterial resistance, venous pressure, rate of filling, or temperature. One arrangement of the apparatus is shown in Fig. 372. Artificial respiration being maintained, the chest is opened under an anæsthetic. The arteries coming from the arch of the aorta—in the dog, the brachio-cephalic and the left subclavian—are then ligatured, thus cutting off the whole blood supply to the brain. Cannulæ are placed in the brachio-cephalic artery and the superior vena cava. The cannulæ and the large venous reservoir are filled beforehand with defibrinated blood. The descending aorta, azygos vein, and inferior vena cava are ligated. The only path left for the blood is by the ascending aorta and the cannula *CA* in the brachio-cephalic artery. The arterial cannula communicates with a

passes to the resistance *R*. This consists of a thin-walled rubber tube (part of a rubber fingerstall) which passes through a wide glass tube provided with two lateral tubulures W_1, W_2. One of these, W_2, is connected with an air reservoir into which air can be pumped.

When air is injected into the outer tube, the tube *R* collapses, and will remain collapsed until the pressure of the blood within it is equal or superior to the pressure in the air surrounding it. It is thus possible to vary at will the resistance to the outflow of the blood from the arterial side. From the peripheral end of *R* the blood passes at a low pressure through a spiral warmer into a glass reservoir. From the reservoir a wide india-rubber tube leads to the cannula in the superior vena cava *SVC*. This cannula is provided with a thermometer. A tube placed in the inferior vena cava and connected with a water manometer M_3 shows the pressure in the right auricle. On the recording surface we thus have a record of the arterial pressure, and of the pressure within the right auricle The rate of inflow from the reservoir into the right auricle is controlled by an adjustable screw-clamp. The output through the aorta can be measured at any time by opening the tube *X*, clamping *Y*, and allowing the blood to flow for a given number of seconds. into a measure. The course of the circulation is shown in Fig. 373.

This method, although of considerable value in giving information as to the conditions which determine the output of the left ventricle and the maximum capacity of the heart as a pump, tells us nothing as to the output in the intact animal. The output as measured represents the ventricular output minus the blood flow through the coronary arteries. It is possible, however, to insert a cannula into the coronary sinus, and so to measure the blood flow through the heart muscle.* The coronary circulation must be added to the flow through the arterial resistance in order to arrive at the correct total output of the left ventricle. An essential in this preparation is that the output from the left ventricle and the pressure in the aorta must be sufficient to maintain a circulation through the coronary vessels.

Output and Inflow. It is self-evident that, provided the venous inflow remains constant, the minute output over a reasonable interval of time must also be constant, equal to the inflow, and unaffected by considerable alterations of arterial resistance or heart rate. Thus, in the heart-lung preparation with a moderate and constant venous inflow the output remains constant whether we maintain the average arterial pressure at 60 mm. Hg or at 160 mm. Hg. It is also unaffected by altering the rate of the heart from 80 beats per minute up to 160 or even 200 beats per minute. On the other hand, the output must at once be altered by changes in the venous inflow and can in fact be varied in a dog's heart weighing 50 gms. from 100 c.c. up to 3,000 c.c. per minute.

With increasing inflow of blood into the heart, the auricles and ventricles become more filled during diastole ; and during systole of the ventricles the incoming blood must accumulate in the big veins and auricles to a still greater extent. The venous pressure in the intact animal therefore rises, with increased venous inflow. In so far as venous pressure is an index of venous inflow, we may say that the output of the heart increases with the venous pressure, so long as the heart is functionally capable of dealing with the blood it receives during diastole. And since the minute output in the isolated heart is practically independent of the frequency of the beat, it follows that with a constant venous inflow the venous pressure tends to fall, and diastolic volume to diminish, as the heart rate increases. The optimum venous pressure is that which fills the ventricle during its diastole to the maximum extent from which it is able to empty. As the rate of the heart increases, the inflow of blood can also be increased without causing over-distension of the ventricles. An increase of heart rate must therefore be, in the intact animal, an important factor in enabling this organ to deal with the maximum amount of blood. Although increase of rate cannot alter the minute output with constant venous inflow, it does increase the *maximum* inflow which the heart is able to expel. At the same time, the lowering of pressure in the great veins aids the venous inflow into the chest.

As might be expected, the alterations in the vigour of the circulation depend in the first instance on the venous flow. The greater the volume of the blood that is brought up to the heart by the accessory factors of the circulation, the greater will be the output of this organ. The changes in rate and force of the heart which accompany its increased activity and increased output, *e.g.* during exercise, represent merely the response by which this organ is able to deal in the most advantageous manner with the increased inflow.

The cardiac output, like the oxygen consumption of the individual, is definitely increased after ingestion of food (Fig. 374). It is also greater in man by 10 or 12 per cent. when lying supine, than when sitting, and becomes still smaller when standing erect.*

---

* EVANS and STARLING. *J. Physiol.*, 1913, **46**, 413.

The Work of the Heart. The energy of the ventricular contraction is expended in two ways: first, in forcing a certain amount of blood into the already distended aorta against the resistance presented by the arterial blood pressure; and secondly, in imparting a certain velocity to the mass of blood so thrown out. Thus the energy of the muscular contraction is converted partly into potential energy in the form of increased distension of the arterial wall and partly into the kinetic energy represented by the momentum of the moving column of blood. The work done at each beat by each ventricle may be calculated from the formula:

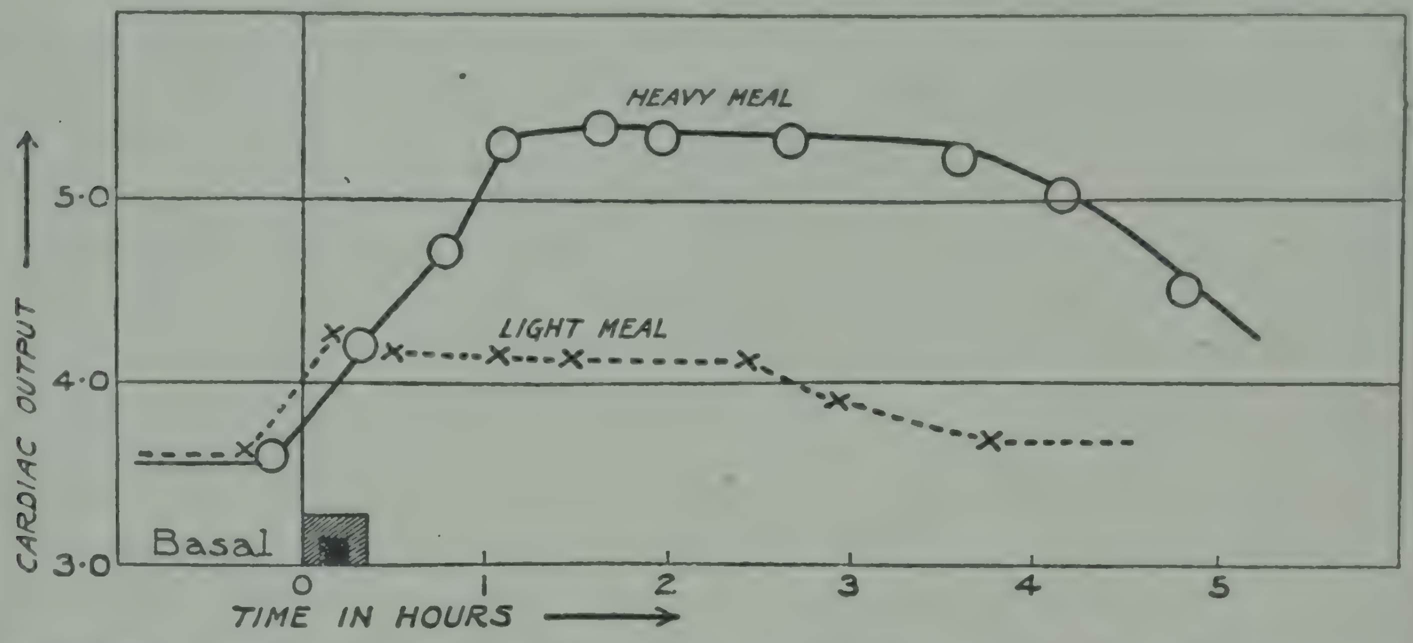

FIG. 374. Effect of food on cardiac output. (GROLLMAN.) (From MARSHALL.)

$$W = QR + \frac{wV^2}{2g}$$

where W stands for work, w for the weight, and Q for the volume of blood expelled at each contraction; R is the average arterial resistance in terms of height of a column of blood, during the outflow of blood from the heart, and V is the mean velocity at which the blood is expelled. In this equation QR is the work done in overcoming the resistance, and $\frac{wV^2}{2g}$ the energy expended in imparting velocity to the blood.

If we take 60 c.c. as the average output of each ventricle, 100 mm. Hg as the average pressure at the beginning of the aorta, and 500 mm. per second as the velocity imparted to the blood thrown into the aorta, we can roughly calculate the work done by the human left ventricle at each beat :—

$$QR = 60 \times 0{\cdot}100 \text{ m.} \times 13{\cdot}6 = 81{\cdot}6 \text{ gram-metres,}$$

or roughly 80 gram-metres. On the other hand, the expression

$$\frac{wW^2}{2g} = \frac{60 \times (0{\cdot}5)^2}{2 \times 9{\cdot}8} = 0{\cdot}7 \text{ gram-metres.}$$

It is evident that this latter factor is negligible, and that with small outputs we may regard the work of the heart as sufficiently expressed by the output multiplied by the average arterial blood pressure. Taking the average pressure in the pulmonary artery at 20 mm. Hg, the work of the right ventricle at each beat would amount to about 16 gram-metres, a total for the two ventricles of about 100 gram-metres per beat, which is equivalent to about 10,000 kilogram-metres in twenty-four hours for a man at rest.

During muscular work this figure would be largely increased. Not only does QR become much larger, but the velocity factor is no longer negligible, since the work done in imparting velocity to the blood increases as the cube of the output per minute. If we take, as an example, a maximum effort on the part of an athlete, we may assume an output per beat of 180 c.c. and a pulse rate of 180 per minute (an output per minute of 32·4 litres) and an average arterial pressure of 120 mm. Hg.

---

* DONAL, GAMBLE and SHAW. *Amer. J. Physiol.*, 1934, **109**, 666; MCMICHAEL. *Q. J. Exp. Physiol.*, 1937, **27**, 55.

Then

$$QR = 180 \times 0{\cdot}120 \times 13{\cdot}6 = 294 \text{ gram-metres.}$$

To determine the velocity of output, we assume that 180 c.c. of blood are thrown out into the aorta during $\frac{1}{8}$ second. This gives a velocity of 2·3 metres per second, assuming a cross section of 625 mm.^{2} at the root of the aorta. Therefore

$$\frac{wV^2}{2g} = \frac{180 \times (2{\cdot}3)^2}{2 \times 9{\cdot}8} = 49 \text{ gram-metres.}$$

The total work of both sides of the heart will be :

$$\underset{\text{Left side.}}{294 + 49} + \underset{\text{Right side.}}{59 + 49} = 451 \text{ gram-metres per beat, or 81 kilogram-metres per minute.}$$

It will be noted that now the velocity-factor accounts for nearly one-quarter of the total work.

Since the period of systolic output occupies not more than $\frac{3}{8}$ of the cardiac cycle, the mean velocity during expulsion must be $2\frac{2}{3}$ times greater than the mean aortic velocity : the following general formula $W = \frac{7QR}{6} + \frac{w(VC)^2}{gE^2}$, (where V is the mean aortic velocity, C the duration of the cardiac cycle and E the duration of period of expulsion) gives the work of both ventricles.* The expression QR is also only approximately correct. Supposing the pressure in the aorta at the beginning of systole is 50 mm. Hg, and at the end of systole 150 mm., the work could not be deduced accurately from the average pressure, but would need a simple application of the integral calculus for its determination. This has been made by Katz,† who finds that the expression employed above deviates from the real value by a variable amount, and tends to underestimate the work done, especially that due to the kinetic factor.

It is important to remember that the strain or tension, which is thrown on the cardiac fibres and which resists their contraction, will be determined not only by the blood pressure which has to be overcome, but also by the size of the ventricle cavities. If we regard the ventricle as a sphere, it is evident that, in order to produce a pressure p per unit area, in its interior, the total pressure exerted by the walls must be $4\pi r^2 p$, *i.e.* it must be proportional to the surface area of the inside of the ventricle or to the squareof its radius. Moreover, with increasing distension, the wall of the heart becomes thinner and the number of muscle fibres in a given area fewer, so that the larger the heart the more strongly will each fibre have to contract in order to produce a given tension in the contained fluid. At the beginning of systole the distended heart must therefore contract more strongly than at the end of the systole, if it is to develop an endocardiac pressure sufficient to overcome that in the aorta.

Adjustment of Output to Inflow. The heart in the heart-lung preparation has a marvellous power of regulating its activity according to the mechanical demands which are made upon it. Thus, if we keep the venous inflow constant, it makes no difference to the output of the heart whether the average arterial pressure be maintained at 80 or 160 mm. Hg, although in the latter case the heart must do twice as much work in order to keep the outflow at the same level. We could compare this behaviour with that of an automobile with an automatic throttle designed to give a constant velocity, whatever the load or the gradient. Again, if we maintain the arterial pressure constant and alter the venous inflow, we find that within very wide limits the heart is able to expel against the arterial resistance the whole of the blood which flows into it from the veins. In this way we can alter the output of a small heart of 50 grammes from 300 to 3,000 c.c. per minute. To use our automobile analogy again, the throttle is now designed to enable it to perform any reasonable journey, long or short, in the same time.

---

* Lovatt Evans. *J. Physiol.*, 1918, **52**, 6.

† Katz. *Amer. J. Physiol.*, 1932, **99**, 579.

Oxygen Usage and Efficiency. As we should expect, this variation in the work done by the heart is associated with corresponding variations in the chemical changes which occur at each heart beat. It is easy with the heart-lung preparation to determine the actual work done and to vary this at will. Then, knowing that each cubic centimetre of oxygen used represents the liberation of about 2 kg.-m. of energy, it is easy to calculate at what mechanical efficiency the heart is working over any given period of observation. Thus, if a heart uses 3,000 c.c. of oxygen in a given period it has liberated as heat and work about 6,000 kg.-m. of energy; if in that time it performed 600 kg.-m. of work the efficiency was 0·1 (or 10 per cent.). In this way it was found that the efficiency of the heart is probably never greater than 30 per cent.—more usually it is from 5 to 10 per cent. In this respect the heart shows much the same mechanical performance as the skeletal musculature. The respiratory exchange of the heart increases *pari passu* with the work it has to do.* Thus in an isolated dog's heart, weighing 70 grammes, with a constant output of 35 litres per hour, raising the arterial pressure from 80 mm. Hg to 140 mm. Hg increased the oxygen consumption from 228 to 404 c.c. per hour. In another experiment with a heart of 59 grammes, in which the arterial pressure was maintained constant at 80 mm. Hg, increasing the output from 9·3 to 92 litres per hour raised the oxygen consumption from 155 to 649 c.c. per hour. An increase of work effected by a rise of arterial resistance is attended by a greater increase of oxygen usage than is the same increase of work effected by a rise of output. When the efficiency of the heart at various levels of work is plotted against the mechanical work done, it is seen to reach a maximum with increasing work, and then to decline (Fig. 375). Increase of the work beyond this point soon leads to insufficiency: over a certain further range more work can be accomplished but at rapidly increasing cost, and with still further increase of resistance or inflow the mechanical work done also declines and failure is then imminent.

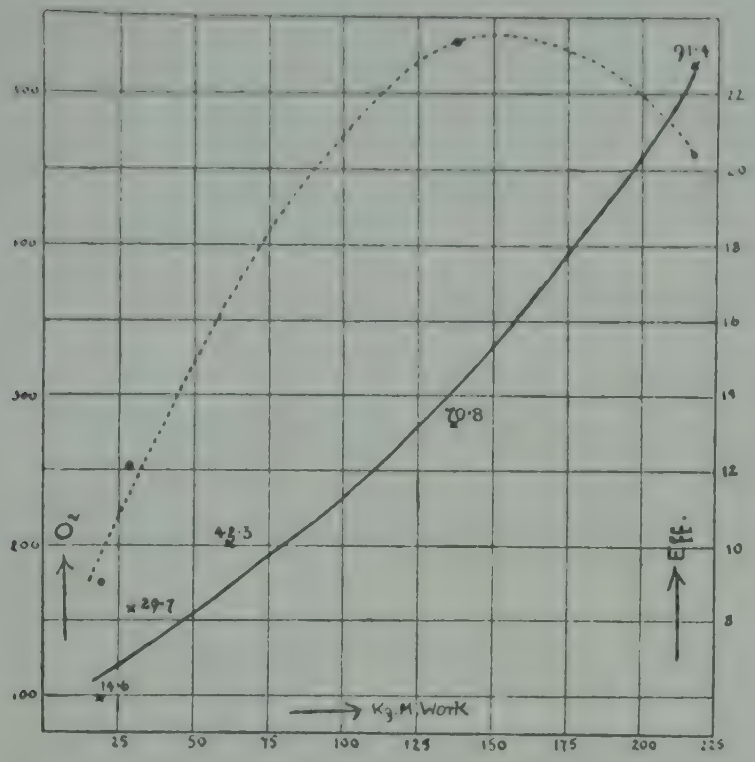

FIG. 375. Oxygen Usage and Efficiency of Dog's Heart (H–L–P), showing their Relation to Work done. Arterial pressure, 80 mm. Hg. throughout. Continuous line, oxygen usage, c.c. p. hr: the figures on the oxygen curve show the output in l. p. hr. Dotted line, efficiency. (LOVATT EVANS, 1918.)

The Law of the Heart. Investigation of the volume and pressure changes of the heart under varying conditions of arterial resistance and venous filling throws light on the mechanism of the adaptation.† Let us take first the changes in volume as recorded by the cardiometer, and suppose a heart is contracting 100 times per minute, forcing out at each beat 10 c.c. of blood into the aorta against an average pressure of 100 mm. Hg, with systolic and diastolic pressures respectively of 110 and 90 mm. Hg (Fig. 376). The aortic valves will open as soon as the pressure rises above 90 mm. Hg. In order that the left ventricle may force out 10 c.c. of blood the pressure in its interior must rise at each heart beat above the maximum systolic pressure in the aorta, *e.g.* to 120 mm. Hg. Suppose the arterial resistance is now increased so as to bring the average pressure up to 130 mm. Hg. The heart now may raise the pressure in its interior to 130 mm. Hg. This will be higher than the diastolic pressure in the aorta and a certain amount of blood will escape, but the outflow of blood will cease as soon as the pressure in the aorta is equal to that in the ventricle. Diastole will then occur, the ventricle will relax before it has emptied out 10 c.c. of blood. Let us assume it has forced out 3 c.c. of blood, so that the excess of 7 c.c. remains at the end of systole. Meanwhile, the venous inflow is proceeding at the same rate as before, so that at the end of diastole its diastolic volume will be increased by 7 c.c. At the next beat we find that the contraction of the ventricle is much more forcible. The maximum pressure now rises to 140 mm. Hg and 8 c.c. of blood are sent out into the aorta. At the end of this beat the heart will be still fuller than before, containing an excess of 9 c.c. of blood. The third beat is still more forcible, the intraventricular pressure rising to a maximum of 145 mm. Hg, and now 10 c.c. of blood are expelled. After this, the heart goes on beating regularly, expelling 10 c.c. of blood at each beat, *i.e.* the same amount as it receives from the veins. But the heart remains more dilated than it was previously (Fig. 376), since it contains an excess of 9 c.c. of blood. If now the arterial resistance be suddenly reduced to its previous amount, the first beat after the change may send out 17 c.c. of blood, the second beat 12 c.c. of blood and the third beat 10 c.c. as before. It is similar with alterations of the rate of inflow, with constant arterial pressure, as shown in Fig. 377. We see, therefore, that an increased liberation of energy results from the contraction of the heart muscle when there is an increased diastolic volume of the heart and *vice versâ* ; but increased diastolic volume means greater length of the muscular fibres composing its wall, so we arrive at a statement that, as in voluntary muscles, the *energy of contraction is a function of the length of the muscle fibres.* This important generalisation is commonly called Starling's "Law of the Heart." †

* EVANS and MATSUOKA. *J. Physiol.*, 1914, **49,** 378.

† PATTERSON and STARLING. *J. Physiol.*, 1914, **48,** 357; PATTERSON, PIPER and STARLING, *ibid.*, p. 465.

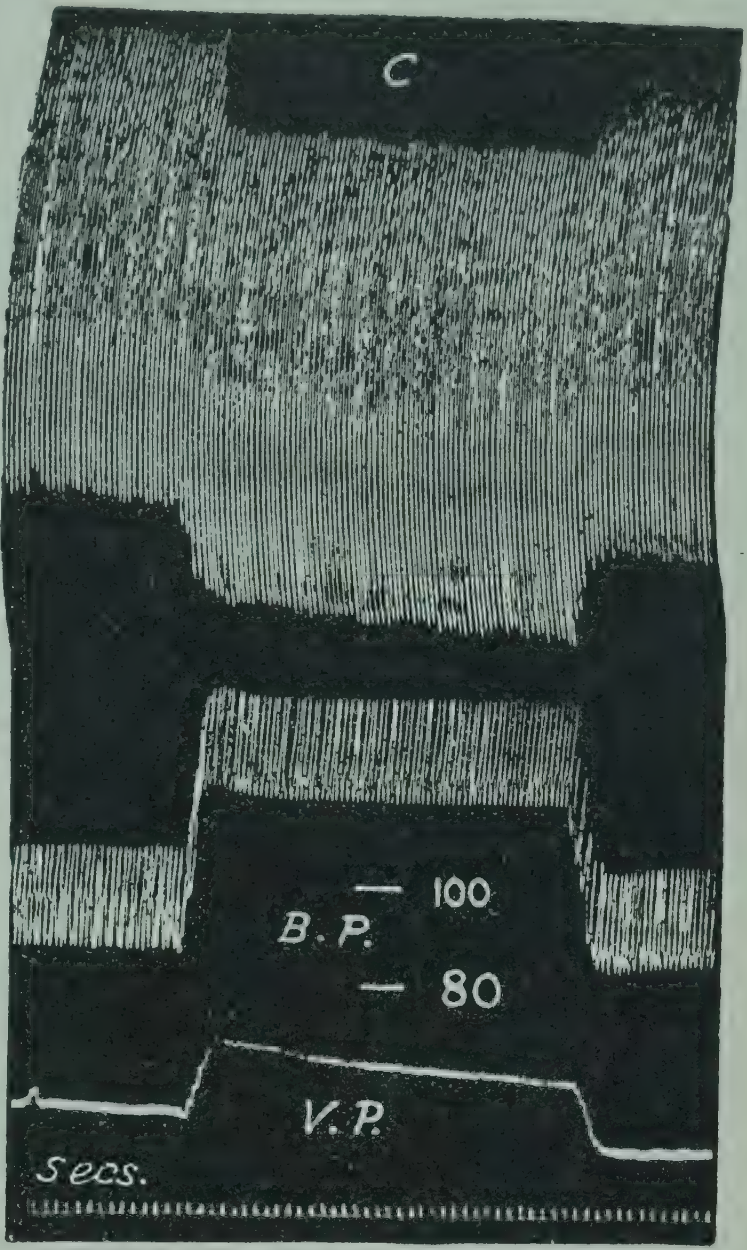

Fig. 376. Effect of Increased Arterial Pressure on the Volume Changes of the Heart, with a steady inflow of 154 c.c. Blood per 10 seconds.

C. = cardiometer curve; downstroke is diastole. BP = arterial blood pressure. V.P. = pressure in the inferior vena cava. The lines 100 and 80 are calibrations for the blood pressure in mm. Hg. (Patterson, Piper and Starling.)*

In a resting heart increasing distension of its cavities will tend to stretch its muscle fibres and therefore to exert a tension on them. By accurately recording the pressure changes within the contracting ventricle under varying conditions, it has been found that the tension on the fibres is not the determining factor. In a heart beating regularly, the inflow of blood is proceeding during the relaxation of the ventricles, *i.e.* the muscles are giving before the inflowing blood. The latter is therefore able to distend the heart without exercising more than a minimum pressure on its walls. With a small inflow it is found that the pressure in the ventricles may be approximately zero at the end of diastole, whether the heart is contracting against a resistance of 80 mm. Hg or a resistance of 120 mm. Hg, or, with a moderate arterial resistance, whether it is receiving 5 c.c. or 0 c.c. during the period of diastole. With a still larger outflow or a bigger resistance there is an appreciable rise of tension within the ventricles at the end of diastole. But that the change in *distension*, *i.e.* in the diastolic length of the muscle fibres, is the chief factor in determining the energy of the subsequent contraction is evident on reference to Fig. 378 which shows the reaction to increasing filling of the tortoise ventricle contracting isometrically. It will be seen that as the diastolic filling increased from 0 to 1·5 c.c., the intraventricular pressure developed during systole increased from 0 to 45 mm. Hg. The maximum systolic pressure (48 mm. Hg) was developed with a filling of 3 c.c. and an initial tension within the heart of 3 mm. Hg. Further increasing the filling to 4 c.c. caused for the first time a considerable rise of initial tension to 13 mm. Hg, but the result was to *diminish* the tension developed during systole. This means that, up to a certain optimum length, the energy of contraction increases with every increase in initial length of the fibres. Beyond this point it requires considerable tension to cause a further increase in length, but this is associated with a diminution in the effectiveness of the contractions.

A	124	95	86
B	130	145	140
C	124	55	33

The curved line at the side represents the value of the cardiometer excursions, *i.e.* of alterations of ventricular volumes, in cubic centimetres. (Patterson, Piper and Starling, 1914.)

The capacity of the heart for adapting itself to changes in mechanical demands made upon it will be limited by its inability to dilate further; in the intact animal its dilatation is limited by the pericardium, and by the mechanical disadvantage at which the further dilated heart acts. The greater its diastolic volume, and the more nearly globular its form, the greater the mechanical disadvantage of the muscle fibres in raising the pressure in the interior of the ventricles, so that by continually increasing the demands on the heart, we shall finally arrive at a stage at which it is unable to deal with the blood supplied to it.

Evidence of a relation between heart volume and total energy consumption was furnished by the demonstration, by Evans and Matsuoka, that there is a parallel between heart volume and oxygen usage. Determinations of the oxygen usage of the heart * also show that, within limits, when the diastolic volume is the same, the oxygen usage is the same, whatever may be the amount of work done (Fig. 379): in other words, the oxygen utilisation and the diastolic volume are closely correlated over rather wide ranges.‡ Beyond the point of maximal performance diastolic volume and oxygen utilisation show a further increase, but the work accomplished diminishes; this holds good in general whenever, with an increased volume in diastole, there is a reduced efficiency, as is the case when the heart fails. This was confirmed by Stella,§ who used the tortoise heart and found that the relationship between diastolic volume and oxygen usage depends upon the conditions under which the heart works.

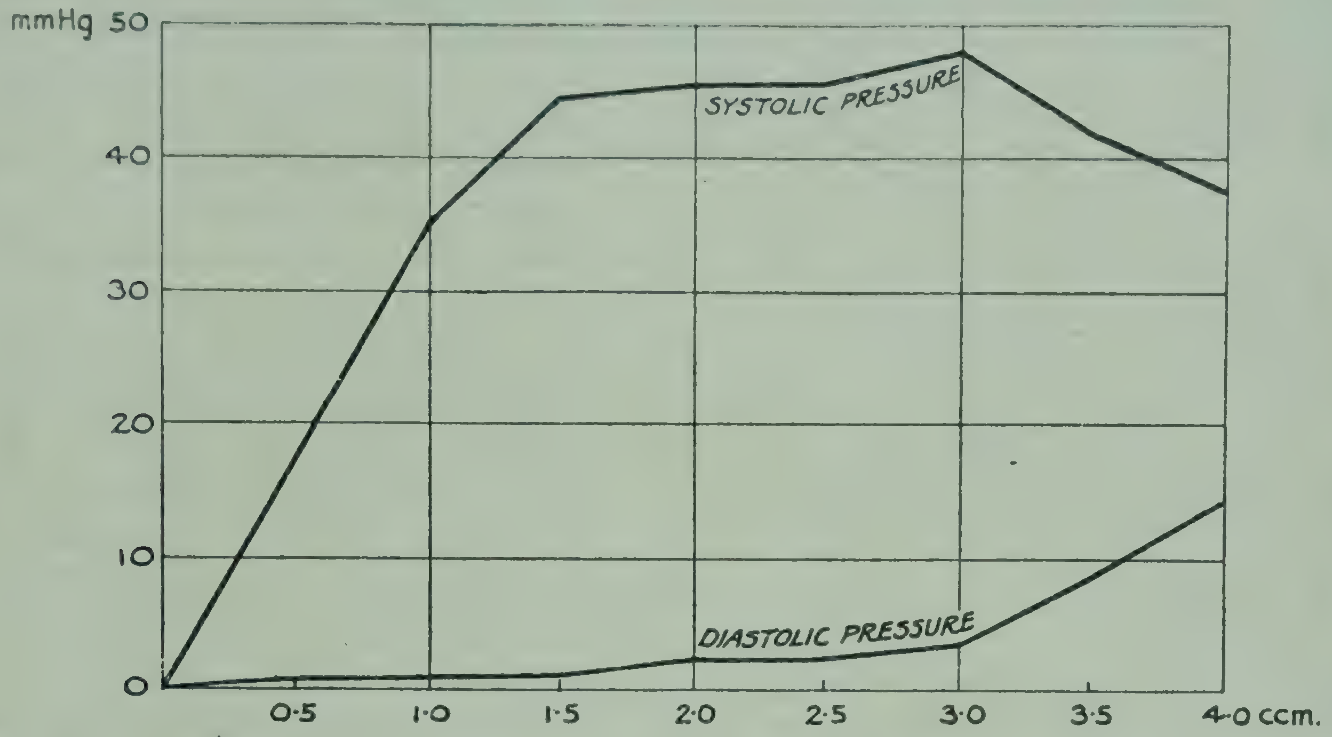

FIG. 378. Relation of the Tension developed during Isometric Contraction of the Tortoise Ventricle to the Filling (*i.e.* initial length of fibres) of the Ventricle. (KOZAWA.)†

The physiological condition of the heart is measured by the maximum pressure which it is able to produce in its cavities when it contracts, starting from a certain initial size or length of fibres. As the heart becomes fatigued this pressure falls, so that the heart must dilate in order that each contraction shall produce the same maximum pressure as before. Dilatation is therefore a measure of fatigue.

THE HYPODYNAMIC OR INSUFFICIENT HEART is unable properly to cope with the work which it is set to do. Sooner or later all isolated hearts become insufficient, a condition which is revealed by a rising intra-auricular pressure. As the heart approaches insufficiency it tends to do less work, and to dilate. The dilatation is always accompanied by an increased oxygen usage. If now the work conditions are lightened the dilatation and oxygen consumption may be reduced, and the heart may be competent to carry on at the easier level. If, on the contrary, still further work is offered to an already insufficient heart the mechanical work done *may* be restored to its former level, but only at the cost of a still further dilatation, rise of intra-auricular pressure, and greatly augmented oxygen usage. Like all pathological phenomena, these effects are nothing more than exaggerations of normal properties, and insufficiency is mainly a reduced mechanical efficiency; of the expended chemical energy (as judged by oxygen usage) at a given diastolic volume, a smaller fraction is converted into mechanical work by the failing than by the normal heart.

Addition of digitalis or strophanthin to the blood leads to a real improvement of the insufficient heart, *i.e.* at a given task the diastolic volume and oxygen consumption of the spontaneously insufficient heart are reduced and hence the efficiency is increased.

TONE. Many authors speak of a "tone" of the heart muscle, generally meaning thereby a tendency to resist distension during diastole. This term is ambiguous, and has been used in so many meanings that it would be better to avoid the word altogether. The "tone of the heart" is really synonymous with physiological condition. A heart in good condition has a "high tone." It empties itself almost completely at each beat, even when receiving a considerable quantity of blood during diastole. A heart with a "low tone" is in the condition of a fatigued heart. It is greatly dilated and at the end of systole still contains a large amount of residual blood.

COMPENSATION. This property of the cardiac muscle is responsible for the power of "compensation" possessed by a diseased heart. We may take as an example the destruction of one aortic valve, a lesion which can be produced experimentally in a dog. Immediately after the lesion is established, no additional resistance is offered to the expulsion of the blood, and the ventricle will send the normal amount into the aorta. During the succeeding diastole the blood at a high pressure in the aorta will leak back into the ventricle through the damaged valve. The arterial pressure therefore falls rapidly, and the ventricle receives blood from two sides, *i.e.* by regurgitation through the aortic valves, and in the normal way from the auricles and veins. At the end of diastole the ventricle is therefore overfilled. Increased stretching of its fibres, however, has the effect of producing an increased contraction, and the heart, at its next systole, throws out not only the normal quantity of blood, but also that which it has received back from the aorta. The arterial system thus receives at each beat the normal quantity of blood *plus* the amount which leaks back into the ventricle after each systole; so that the amount of blood remaining in the aorta and available for passage on to the capillaries is the same as in the normal animal. On this account, after a lesion of the aortic valves has been established, the mean arterial pressure remains the same as before, although the pulse pressure at each heart beat is increased in amplitude. The augmented output by the ventricles naturally involves increased work on the part of their muscular walls, which react to increased work by hypertrophy. The final effect, therefore, is a heart bigger than normal, with hypertrophied and thickened walls, but capable of maintaining an adequate circulation throughout all parts of the body; in other words, complete compensation has taken place.

MEEK (1927). The Question of Cardiac Tonus. *Physiol. Rev.*, **7**, 259.

Influence of Temperature on the Heart. Warming the heart quickens the rhythm, and cold slows it. In the isolated heart beating in normal sequence, the shortening of the contractions of the different cavities with rise of temperature may be ascribed to the quickening of the sinus rhythm. The changes, however, *i.e.* the shortening of the contraction with rise and the lengthening with fall of temperature, are more marked than when the rhythm is changed by direct excitation of the sino-auricular node itself. The increase of rhythm with temperature is almost proportional to the temperature, and over a limited range this proportionality may be linear.* At 40° C. the isolated mammalian heart may beat four times as frequently as 25° C. Warming the heart beyond 44° C. may cause stoppage of the heart or send it into fibrillation.

---

* KNOWLTON and STARLING. *J. Physiol.*, 1912, **44**, 206.

Similar effects are produced on conduction, both in the heart muscle itself and in the special conducting tissues. Thus, cooling of the heart leads to an increase in the A.V. interval.

The contraction of cardiac muscle is affected in the same way, a rise of temperature lessening the duration both of the contraction and of the refractory period.

As in a skeletal muscle, the slow contraction of the heart at low temperatures is more efficient than the quick contraction at high temperatures, *i.e.* when the muscle contracts slowly and maintains the intraventricular tension for a longer time, less energy is required for the expulsion of a certain volume of blood than at a higher temperature.

Influence of the Composition of the Surrounding Medium on the Heart Muscle. All the cells of the body require a definite osmotic environment. This is equivalent to a 0·7 per cent. sodium chloride solution for the frog's heart, and to a 0·9 per cent. solution for the mammalian heart. As Ringer first showed, the nature of the salts employed for making up the isotonic solution is all-important to heart muscle.* Thus, a strip of muscle from the apex of the tortoise's ventricle immersed in a 0·7 per cent. solution of sodium chloride, begins to beat rhythmically. The contractions soon reach a maximum and then die away in a condition of relaxation. Sodium chloride therefore acts as a stimulus to contraction, but is unable to maintain the beats for any considerable length of time. On now adding to the solution a trace of calcium chloride the contractions begin again (Fig. 380). The relaxations after each contraction then become more and more incomplete, until finally the heart

[*] RINGER. *J. Physiol.*, 1883, **4**, 29.

stops in a tonically contracted condition. If now a trace of potassium chloride be added, the contractions recommence and may last for many hours, although the solution contains nothing which can furnish energy to the contracting muscle (Fig. 381).

The exact significance of the different ions for the functions of cardiac and other forms of muscular tissue must still be regarded as an open question.

Fluids containing the three ions mentioned above in slightly varying proportions, are commonly used to maintain the beat in an excised heart either of a cold- or of a warm-blooded animal (Ringer's fluid, etc., *v.* p. 62). In the case of the latter, it is necessary to keep the fluid warm, and saturated with oxygen. Locke* showed that the addition of glucose to the solutions enables the beats to go on for a longer period of time, and will in fact renew the rhythm of a heart which has ceased beating while being fed with pure saline solution. Addition of sodium lactate is even better.

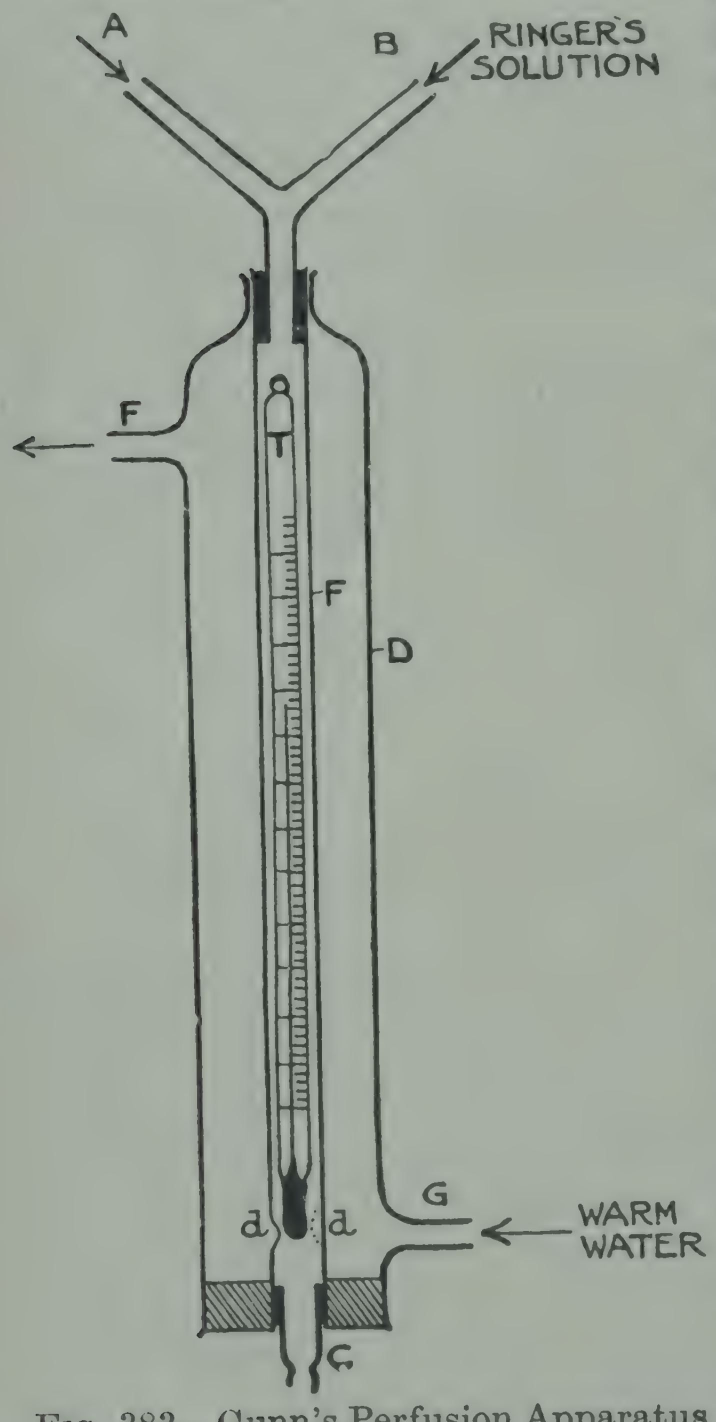

FIG. 383. Gunn's Perfusion Apparatus for the Mammalian Heart.

The influence of the chemical composition of the medium on the contraction of the heart may be investigated in the following ways:

One of the simplest methods of investigating the heart of cold-blooded animals is by perfusing the heart cavities with the fluid under investigation.

In one method, the fluid is allowed to flow through the whole heart, passing in by the sinus and out by the aortæ, or, as in Symes' method,† in by a cannula tied in the auricle, and out by the aortæ (Fig. 382). It is usual to start with Ringer's fluid, and then to omit or increase the constituents one by one, in order to demonstrate their influence.

The heart of warm-blooded animals can also be investigated by a somewhat similar method. It was shown by Porter ‡ that the mammalian heart could be kept alive by perfusing oxygenated blood serum through the coronary vessels, and Locke § found that the same results could be obtained by using warm oxygenated Ringer's solution of the same tonicity as mammalian blood. A simple apparatus for this purpose is shown in Fig 382.‖ It consists of an outer jacket, D, through which a constant stream of water at a little above body temperature is passed. The inner tube, F, is made of thin glass, and at its lower end three small indentations, d, d, serve to support a thermometer, T, of such a thickness that only a small space is left between it and the inner tube. Into the lower end of the inner tube the cannula, C, is fixed by a rubber sleeve, while at the upper end a Y-shaped tube delivers either oxygenated Ringer's solution by B, or any other solution which is to be perfused by A. The proper perfusion pressure is provided by placing the reservoir of Ringer's, or other, solution at the desired height, and these reservoirs are immersed in a bath kept at body temperature. The heart having been excised and washed well in cold saline, the cannula is tied into the stump of the aorta, and the perfusion started. The pressure of the fluid closes the aortic valves, so that the solution only passes into the coronary vessels. After passing through the heart, it reaches the right side, and flows away. A thread is attached to the apex of the heart, and the beats are recorded by means of a lever attached to the thread.

HYDROGEN ION CONCENTRATION. The reaction of the perfusing fluid has considerable influence on the frog's heart. When weak acids are perfused through this heart, it dilates, the beats become smaller, slower, and finally at about pH 2 or 3, disappear. A similar relaxation may be obtained as the result of the action of carbon dioxide. On perfusing with weak alkalies on the other hand, the relaxation during diastole becomes more and more incomplete, so that the heart is finally arrested at pH 11 or 12 * in a contracted condition. There will thus be some reaction, actually at pH 8·3,† which will represent the optimum reaction for the beat of the frog's heart. This optimum reaction is not the same for the different cavities of the heart, nor for the hearts from various animals.

In the mammal under normal conditions, the chief variable factor affecting the reaction of the blood is the tension of carbon dioxide in this fluid; and any change in the carbon dioxide of the blood produces corresponding alterations in the heart's action. The effective factor is probably always the hydrogen ion concentration, so that a deficiency of CO_2 may be partially compensated for by reduction of the $NaHCO_3$, *e.g.* by an increased amount of lactic acid in the blood. The optimum pH is 7·5 to 8·0. Decreased pH (reduced alkalinity) causes (1) Slowing of the cardiac rhythm, from its action on the sino-auricular node. (2) Slower propagation and deficient spread of the excitatory wave through the auricular muscle and the A.V. bundle.‡ (3) Dilatation of the ventricles, which is greater than can be accounted for by the slowing of the heart and the greater filling thereby induced (cp. Fig. 384). (4) Dilatation of coronary vessels.

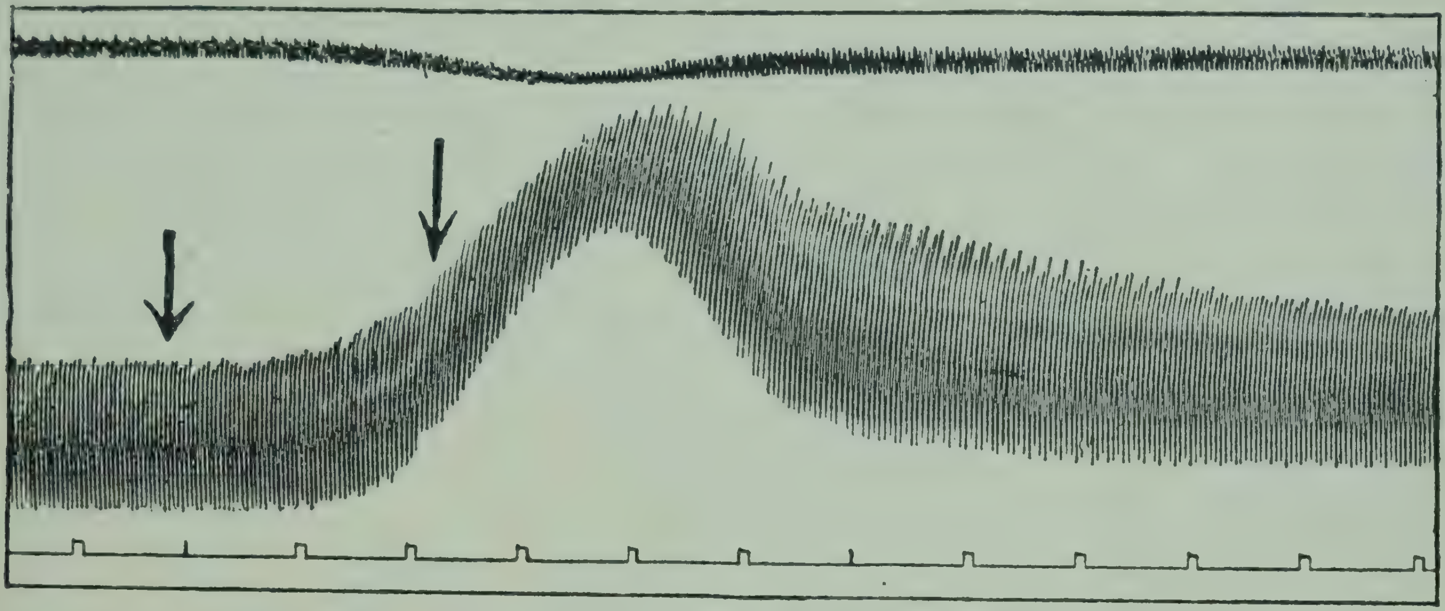

Fig. 384. Volume Curve of Ventricles (Cat) (lower curve).

The upper curve is the arterial pressure, maintained by an adjustable resistance at 130 mm. Hg. Between the arrows the air used for artificial respiration was replaced by a mixture containing 20 per cent. CO_2 and 25 per cent. oxygen. Note the dilatation with impaired contraction, followed by increased amplitude of contraction as the heart recovers. (Jerusalem and Starling, *J. Physiol.*, 1910, **40**, 279.)

Yandell Henderson § found that vigorous artificial ventilation of the lungs brought about a condition in which the heart's contraction was very forcible but its cavities almost empty. He ascribed this condition to the hypertonicity of the heart muscle produced by washing the carbon dioxide out of the blood. The condition of low CO_2 content of the blood (and consequent raised pH) is known as "*acapnia.*" Dale and Evans ‖ showed that, in the condition of acapnia there is paralysis of the spinal vasomotor centres and a large fall of arterial pressure. The inflow of blood to the heart is therefore decreased, and the heart, having only a small amount of blood to contract on, looks "hypertonic," *i.e.* reduced in size. The conditions may be at once removed by adding 5 per cent. CO_2 to the air used for the artificial ventilation. When the heart is perfused with a saline fluid of very alkaline reaction (pH 8·4) the coronary flow is so reduced, by constriction of the vessels, that the heart fails owing to oxygen lack. Up to pH 8·0 there is much less effect.

THE NERVOUS REGULATION OF THE HEART

So far we have considered the action of the heart as a separate organ, but, in order that it may be adapted to the needs of the body as a whole, its automatic mechanism must be subject to the central nervous system, which must be able, in the general interest, to regulate the heart by increasing or diminishing its activity.

The regulation is effected through the intermediation of various afferent nerves, and of efferent nerve fibres to the heart. The afferent supply from the heart itself is in afferent fibres in the right vagus and in the aortic nerve; the efferent, the vagus and sympathetic. They are not essential to life. Thus a dog, in which all the nerves of the heart had been divided, survived the operation for eight months, the pulse rate during the time not having appreciably altered and the animal being in a fair condition of health, though less capable of carrying out work, such as running, since the mechanism for adjusting the action of the heart in response to the needs of the muscles had been lost.

The Efferent Cardiac Nerves. The heart in vertebrates is supplied with efferent nerve fibres from two sources: from the medulla oblongata along the vagus nerve, and from the upper dorsal region of the spinal cord through the mediation of the sympathetic system (Fig. 385).

The Vagus. In the frog, the fibres which leave the vagus to pass to the heart make connection with the cells of Remak's ganglion, and probably with other intrinsic cardiac ganglia, whence non-medullated fibres carry their impulses to the heart muscle. The site of these synapses can be demonstrated by the nicotine method. After painting nicotine on the heart in the region of Remak's ganglion, stimulation of the vagus is without effect on the heart; stimulation of Remak's ganglion or of the fibres leaving it is, however, still effective.

The fibres of the vagus in the mammal arise from the dorsal nucleus of the vagus, and various branches pass to the heart by way of the superficial and deep cardiac plexuses, the anatomical arrangements of which are intricate. In the mammal, the right vagus arborises in the sino-auricular node, and the left nerve in the auriculo-ventricular node. As in the frog, the vagus fibres relay with ganglion cells at the places named, there being numerous scattered ganglia in both auricles and in the auriculo-ventricular groove, but few, if any, in the ventricles.* From these nerve cells, fibres are distributed to auricles, to the bundle of His and to the base of the ventricles.

THE SYMPATHETIC. The fibres from the sympathetic system take a somewhat different course in the frog and the mammal. In the frog (Fig. 386) the sympathetic fibres leave the spinal cord by the anterior root of the third spinal nerve; they then pass through the ramus communicans to the corresponding sympathetic ganglion, whence they run up through the second ganglion and the annulus of Vieussens to the first ganglion; they then pass into the cervical sympathetic strand to the *ganglion trunci vagi;* here they join the vagus and pass down as a vago-sympathetic to the heart.

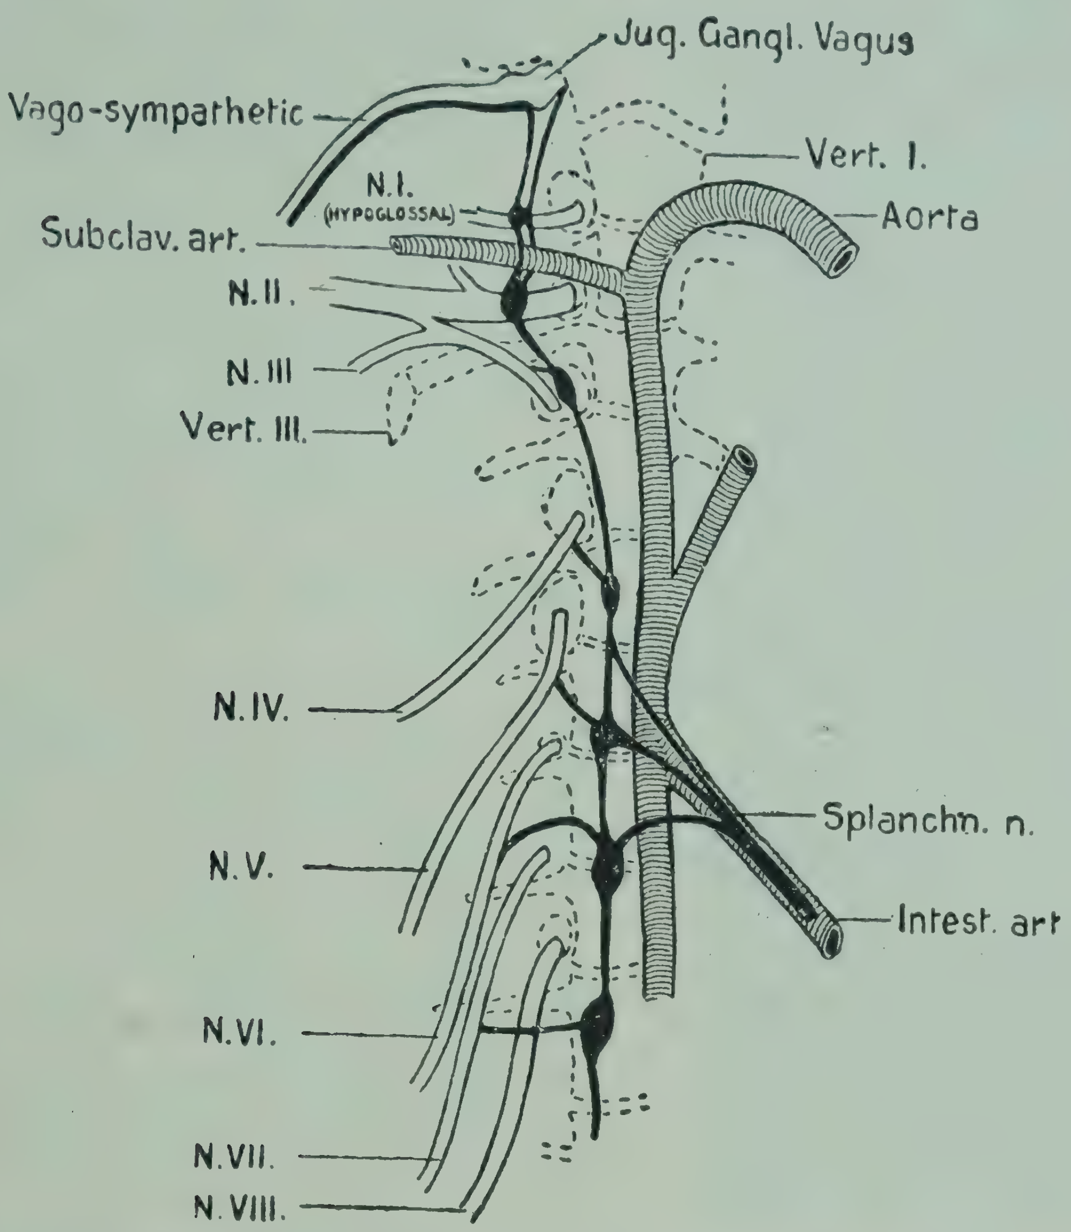

FIG. 386. Sympathetic Chain of Frog (right side) to show Connection with Vagus Nerve.

The sympathetic ganglia with their branches are black. Of the peripheral branches only the splanchnic nerve is represented. (Modified from ECKER.)

In most mammals the principal sympathetic fibres leave the spinal cord by the ventral roots of the upper 5, but chiefly the second and third thoracic nerves, run in white rami communicantes to the stellate ganglion or its equivalent (= inf. cerv. g. + 1–4 thoracic g.), and thence by the annulus of Vieussens to the middle cervical ganglion. Cardiac branches convey the sympathetic fibres to the heart, and are given off from the stellate ganglion, the middle cervical ganglion and the annulus. These branches run to the superficial and deep cardiac plexuses, in which they cannot be distinguished from the vagus branches.

By the nicotine method it is possible to trace out the cell connections of these fibres. As they leave the cord they are medullated, and similar to the other fibres making up the visceral outflow throughout the thoracic region; the white fibres pass along the ramus communicans to the stellate or other sympathetic ganglion, where they end, forming *synapses* with the cells of the ganglion. Here fresh relays of fibres, which are non-medullated, start and carry the impulses to the heart along the various cardiac nerves just mentioned. In the heart these fibres are distributed to the muscle fibres without the intervention of any other ganglion cells.

Although the principal supply of sympathetic fibres to the heart is as stated above, there are subsidiary supplies derived from the white rami of the thoracic spinal nerves down to the 6th or 7th, while cardiac branches from the sympathetic chain run from the superior, middle and inferior cervical ganglia as well as from the upper thoracic ganglia, to the heart. This probably applies also to man (Fig. 387), though it is not certain that all these branches are cardio-accelerator in function.

---

* WOOLLARD. *J. Anat.*, 1926, **60**, 345.

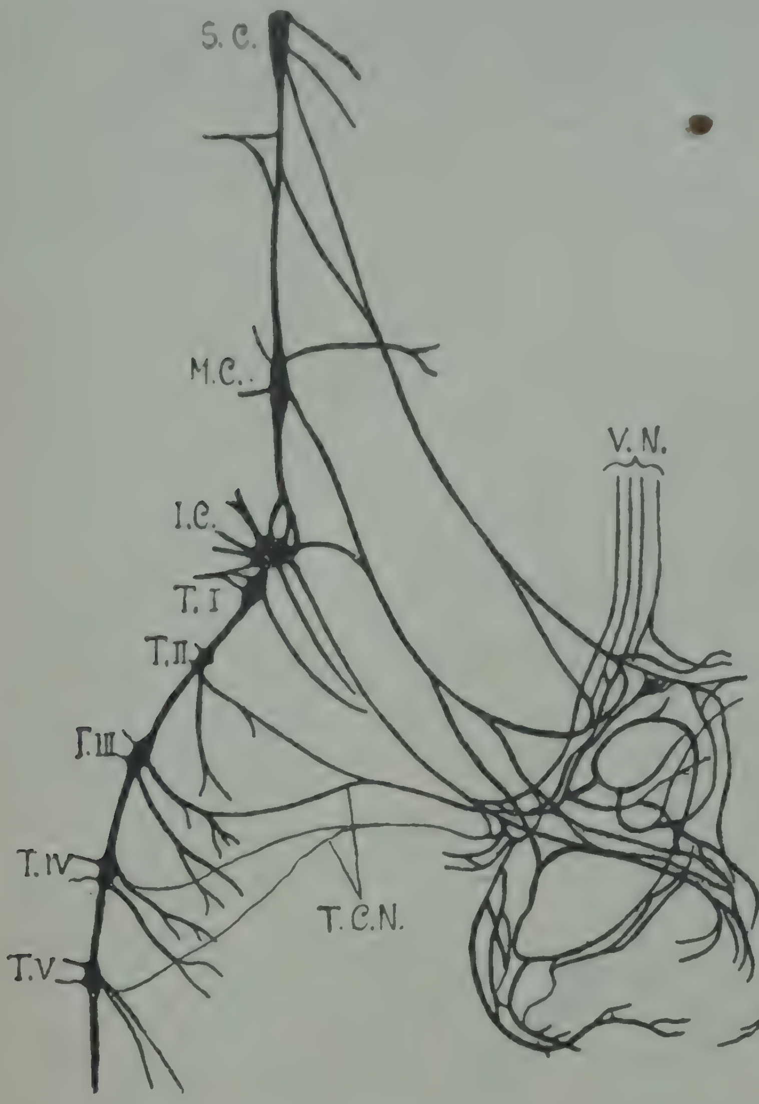

FIG. 387. Diagram of Sympathetic and Vagus Supply to the Cardiac Plexuses (Man). S.C., M.C., I.C., superior, middle and inferior cervical ganglia. T. I, II, III, IV, V, thoracic sympathetic ganglia. T.C.N., thoracic cardiac nerves. V.N., cardiac branches of vagus. (KUNTZ.)

Action of the Vagus. The action of the vagus fibres on the heart is almost identical in frog and mammal and is exerted primarily on the auricle. Since the auricle normally drives the ventricle, this also is affected. If in the dog the peripheral end of the cut vagus be stimulated, while the arterial blood pressure is being recorded, diastole is lengthened almost immediately, the pulse is seen to become slower, or, with a stronger stimulus, to cease altogether, and the blood pressure falls towards zero. On discontinuing the stimulus, the heart begins to beat again and the pressure rises after a few beats to normal (Fig. 388).

If the stimulation of the vagus be prolonged, the blood pressure, on discontinuance of the stimulus, may rise above normal owing to the asphyxia of the vaso-motor centres produced by the prolonged cessation of the circulation.

When the arterial system is dilated, so that the mean systemic pressure during cardiac inhibition is low, or when the asphyxial gasps of the animal are prevented by section of the spinal cord, the heart may fail to recover from the inhibition produced by stimulation of the vagus.

To study the influence of the vagus on the auricles and ventricles respectively, it is necessary to record separately the contractions of the different chambers of the heart, or the electrocardiogram may be used as an index to the changes in the heart under the action of nerve stimulation or section. The vagi may affect the heart in one of several ways. Their chief action is on the venous end. Vagus stimulation may cause auricular standstill, slowing, flutter or fibrillation. The right vagus, since it connects with the sino-auricular node, has the greater effect in lowering the rate. If its action is confined to the sino-auricular node, the sole effect of the vagus on the auricles and ventricles will consist in an alteration of rhythm. They may cease to beat altogether, or they may give beats of normal strength but at a slower rhythm than before. Often, indeed, under these conditions the beats of the ventricles may be increased in size, since the strength and extent of their contractions will be greater with any prolongation of the diastolic period and consequent increased diastolic filling of the ventricle.

If the vagus (especially the left) acts on the auricles without affecting the sino-auricular node, the rhythm will be unaltered, but the strength and duration of systole, and the refractory period of the auricles, will be diminished. Under such circumstances the rhythm of the ventricles will be unchanged.

Generally, strong vagus stimulation stops the action of all parts of the auricles ; in such cases the ventricles also cease beating. Very often after a short pause the ventricles commence to beat at a slow (" idioventricular ") rhythm. This is called " vagus escape." This escape is generally confined to the ventricles, the auricles remaining in a state of diastole. Vagus escape is favoured by distension of the right side of the heart, and is often synchronous with the respiratory efforts which supervene after a certain duration of inhibition, as a result of asphyxia. It appears to be due in part to an accelerating reflex from a distended right auricle,* and from the carotid sinus in which pressure has fallen, and in part to independent contraction of a ventricle temporarily cut off from auricular control. That the ventricle can initiate the escape beat is shown by the fact that occasionally one may observe a contraction of the auricle following each ventricular contraction.

Whether the vagus has a direct action on the mammalian ventricle is still doubtful; its effect is, at any rate, very slight as compared with that on the auricle. The fact that stimulation of the vagus, like division of the bundle of His, usually causes merely temporary cessation of the ventricular beat, also indicates that this nerve has its chief action on the auricles.†

In the frog, it appears that the vagus has a direct inhibitory action on the ventricle, diminishing the strength of its contraction in response to the stimuli transmitted to it from the venous end. This action of the vagus on the ventricle is, however, not found in the tortoise. In both these animals the auricles show the same effects as in the mammal, viz. an influence limited to the rhythm when only the sinus is affected, or a diminution of the strength of contraction when the sinus is unaffected and when the chief action is on the auricular muscle.

Finally, the vagi may affect the conduction of the excitatory process from auricles to ventricles and to all parts of the ventricles.‡ Under weak vagus stimulation this is shown by increase in the P–R interval of the electrocardiogram, and in more pronounced effects the ventricles may beat at a slower rhythm than the auricles, a block having been produced in the auriculo-ventricular bundle.

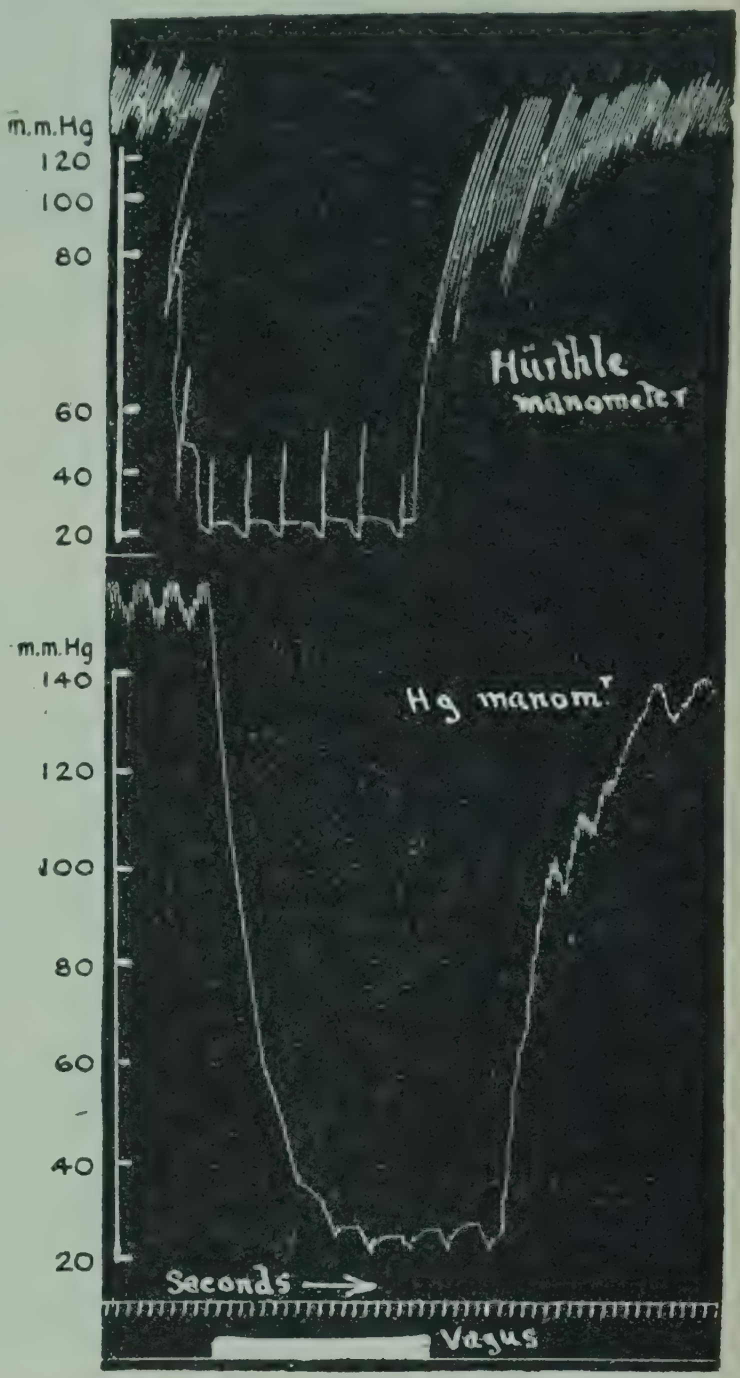

FIG. 388. Blood Pressure Tracing from Carotid of Dog (taken simultaneously with Hürthle's Manometer and Mercury Manometer), showing effect of Excitation of Vagus. (The Mercury Manometer gives very imperfect records of the pulsations during rapid changes of blood pressure.) (C. L. E.)

It is evident that these various effects are chiefly due to differences in the place affected. Thus, if the vagus fibres which are distributed to the remains of the sinus are specially active, we shall get alterations of rhythm affecting the whole heart. If those which supply the A.V. bundle are excited, the most pronounced effect will be on the propagation of the excitatory process from auricles to ventricles.

It is remarkable that the excitability of the vagus fibres is dependent on the condition of the cells in the medullary centres. Thus, if the centres are depressed by narcotics, the vagus fibres become more excitable, and similarly if the vagi are sectioned, so that the fibres are cut off from the centres, their excitability steadily increases to a maximum.§

The vagus nerve usually contains also some cardio-accelerator fibres, which arise directly from the medulla.||

THE TONIC ACTION OF THE VAGUS. If both vagi of a mammal be divided, or if a small dose of atropine be given, the heart as a rule beats more frequently,

showing that, under normal circumstances, tonic impulses are constantly descending the vagi and holding the heart's action in check. The extent of the quickening produced by section of the vagi varies in different species and is associated with its powers of carrying out prolonged muscular exertion. Thus, in the dog, hare, or horse the pulse, which is normally slow, may be doubled in frequency by section of the vagi. In the rabbit, which has a rapid pulse, division of both vagi causes very little alteration in the pulse rate. In man, especially in the athlete, vagus tone is high.

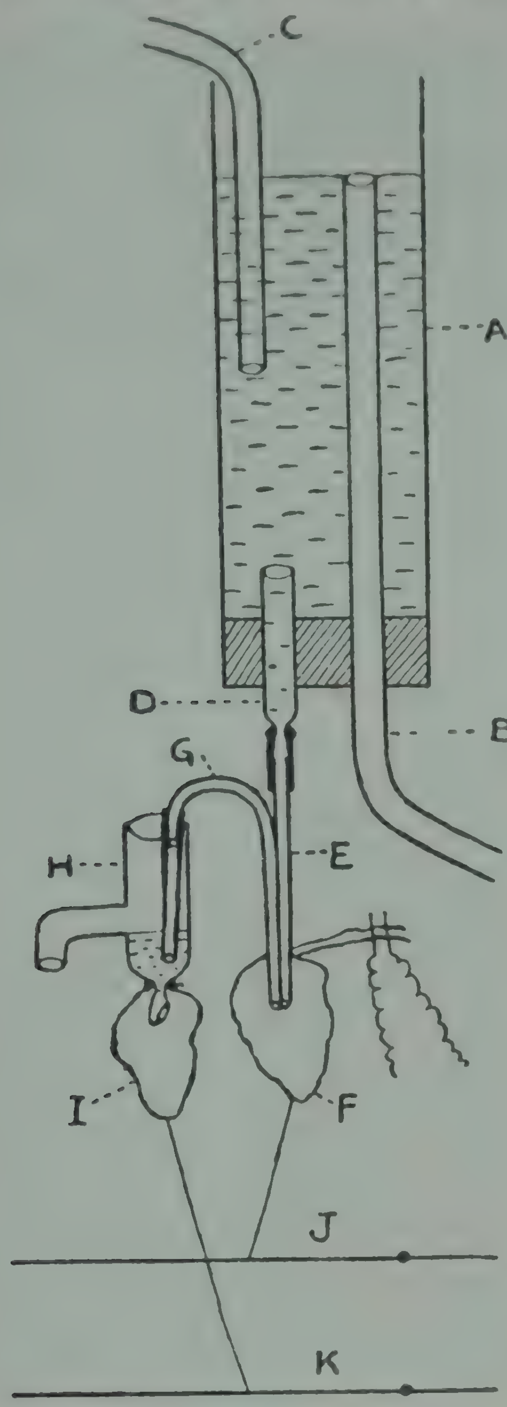

FIG. 389. The fluid from perfusion apparatus A passes to E which supplies the donor heart F. After irrigating the inside of the donor heart, the fluid passes to the glass cannula tube H, to which is attached the recipient heart I. J and K are the levers to which the hearts are attached. (BAIN. *Q. J. Exp. Physiol.*, 1932, **22**, 269.)

This tonic action may be increased by morphia. Reflex alteration of the tone may also be induced in various ways to be described later, and is normally the chief cause of alteration in heart rate.

MODE OF ACTION OF VAGUS. Ever since the discovery in 1845 by the brothers E. H. and E. F. Weber * of the action of the vagus on the heart, much work has been expended with a view to determining the intimate nature of the inhibitory process. Atropine is known to paralyse the effect of stimulation of either the vagus trunk or the ganglion of Remak in the frog. It therefore exerts its action at or beyond the post-ganglionic terminations. Muscarine or acetyl choline produces the same effect as stimulation of the inhibitory fibres, and when applied to the isolated auricle or ventricle causes weakening of the beat and finally complete inhibition; this action is also prevented by atropine.

Although various views as to the nature of inhibition have been put forward from time to time, the present tendency is to ascribe both the excitatory and the inhibitory effects of all nervous stimulation to the liberation, at the nerve ending, of small amounts of highly active substances, which exert their effects on, and are quickly destroyed in, the tissues.

It was shown by Loewi † that the vagus acts by producing in the heart a chemical substance which has the power of inhibiting it. The "humoral" transmission of the effect of vagus stimulation can be demonstrated as in Fig. 389. When a frog's heart perfused with saline solution is brought to a standstill by stimulation of its vagus, the fluid if passed on into a fresh heart will produce on the latter the same effect as if the vagus nerve to the second heart were stimulated (Fig. 390). It is now generally accepted that the mediating substance is acetyl choline, and that the effect of vagus excitation is to produce or liberate this substance in the immediate vicinity of the vagus endings.

† LOEWI. *Pflüger's Arch.*, 1921, **189**, 239.

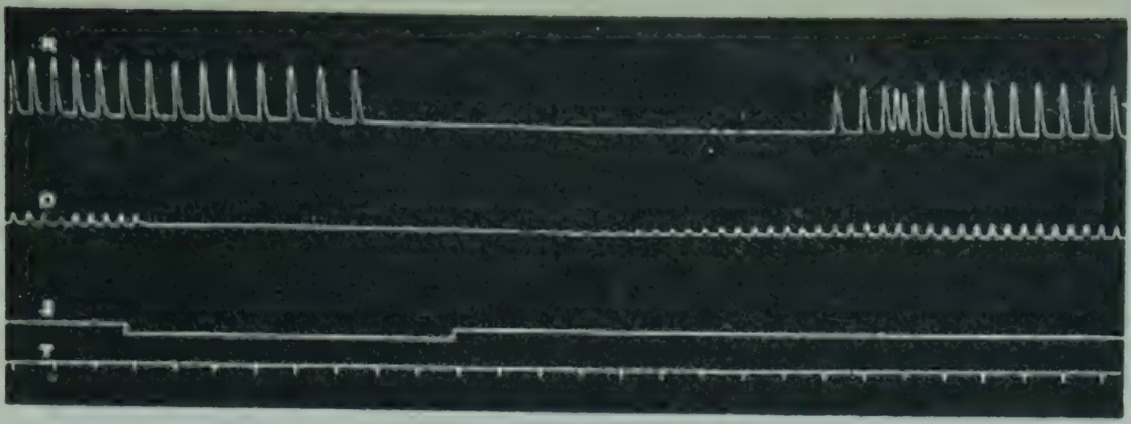

FIG. 390. Tracings from hearts of *Rana esculenta* perfused by method illustrated in Fig. 389. Upper line, recipient heart (R); second line, donor (nerve-stimulated) heart (D); third line, signal; bottom line, time in five-second intervals. Vagus of donor heart stimulated during forty seconds. Arrest of donor heart followed by slowing and then by standstill of recipient heart. (BAIN. *Q. J. Exp. Physiol.*, 1932, **22**, 269.)

The action of acetyl choline is antagonised by atropine, but augmented and prolonged by eserine. The latter effect is due to the fact that eserine paralyses the activity of the enzyme choline esterase, which is prevalent in the blood and tissues, and which normally very rapidly destroys the acetyl choline, so shortening the time over which its effects will last.

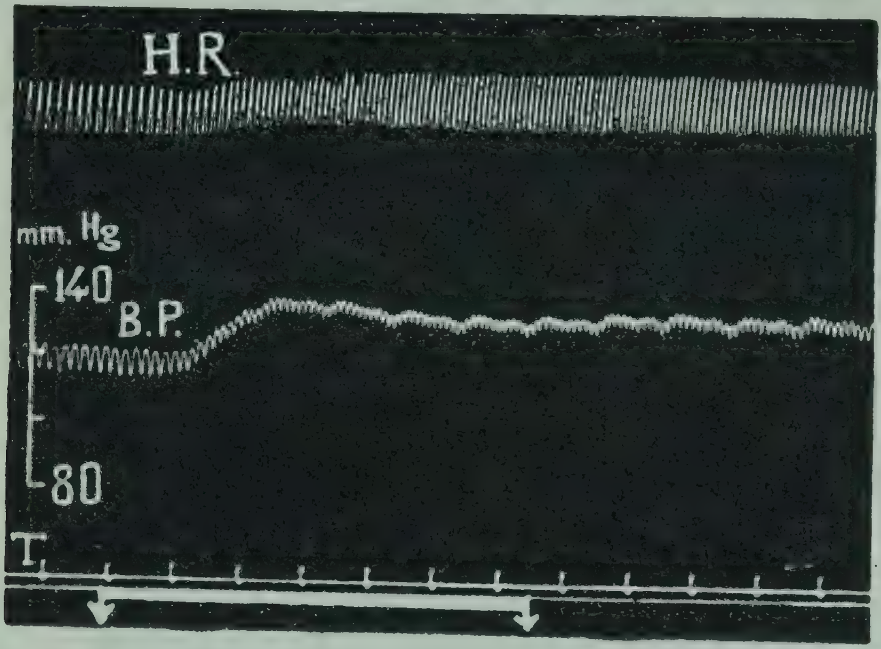

FIG. 391. Heart rate (H.R.) as recorded by Hürthle manometer, and arterial pressure (B.P.) of decerebrate dog, with suprarenals removed and all cardiac nerves cut. Between the arrows stimulation of cardiac nerves from right stellate ganglion causes acceleration of 93 beats per minute and rise of arterial pressure. T = 3-second intervals. Note the latent period of about 6 seconds. (SAMAAN. *J. Physiol.*, 1935, **83**, 332.)

Action of the Sympathetic. Stimulation of the sympathetic cardiac nerves at any part of their course has an effect on the heart the reverse of that produced by stimulating the vagi.* In most cases the pulse frequency is increased in consequence of the action of these nerves on the "pace-maker" of the heart. The frequency attained by maximal stimulation of the accelerator nerves is independent of the previous rate of the heart beat. The increase in rate involves a shortening of the diastolic period. The size of the auricular and ventricular contractions may be increased at the same time as their rate. In fact, like the vagus nerves, the sympathetic fibres of the heart can influence rhythm, strength of contraction, or conduction from auricle to ventricle, according to the part of the heart muscle which is affected.

The augmentor effect on the strength of the ventricular beats is often great. The sympathetic fibres are much less easily tired than the vagus fibres, and have a longer latent period. Whereas the latent period of the vagus in the mammal is considerably less than one second, that of the accelerator nerves may amount to ten seconds (Fig. 391). If the vago-sympathetic of the frog be stimulated, the first effect is inhibition due to vagus action. The vagus nerve endings then become fatigued, and the influence of the accelerator fibres makes

a. Under influence of adrenaline.
b. Under simultaneous influence of adrenaline and CO_2 (15 per cent.).

THE ACTION OF ADRENALINE ON THE HEART. Adrenaline has a powerful action both on the heart and blood vessels and plays an important part in the regulation of the circulation. The action is practically identical with that of excitation of the sympathetic nerve supply. Indeed, as a parallel to the functions of acetyl choline in the parasympathetic system, it is probable that the action of the sympathetic nerves is actually due to the liberation of small amounts of adrenaline at the nerve endings, so that a local effect is produced. Its action on the heart is well shown in the heart-lung preparation. On adding $\frac{1}{10}$ mgm. of adrenaline to the 500 c.c. of blood circulating through the preparation, a maximum accelerator and augmentor effect is produced and lasts for 15 to 20 minutes. Through its influence on the sino-auricular node, the rhythm of the heart is greatly increased, in the dog to about 240 per minute. At the same time the energy of each contraction is augmented. This is especially shown in a heart which is beginning to fail and is therefore showing dilatation. Directly the adrenaline reaches the heart, the contractions become extremely energetic so that the heart rapidly diminishes in volume, the venous pressure falls, and the blood is thrown out with violence into the aorta. The more powerful contraction enables the output of the heart at each beat to be maintained or even increased, in spite of the shorter duration of the systole. With each beat the maximum pressure in the ventricle therefore rises (*see* Fig. 393). The stimulating effect of adrenaline is shown, moreover, by the fact that the oxygen usage is increased two or three times above that which obtained before the administration * ; it also dilates the coronary vessels, so ensuring an increased supply of blood to the heart. The action of adrenaline, therefore enables the heart to cope with a bigger strain, either in the shape of arterial resistance or increased inflow, than it could otherwise do.

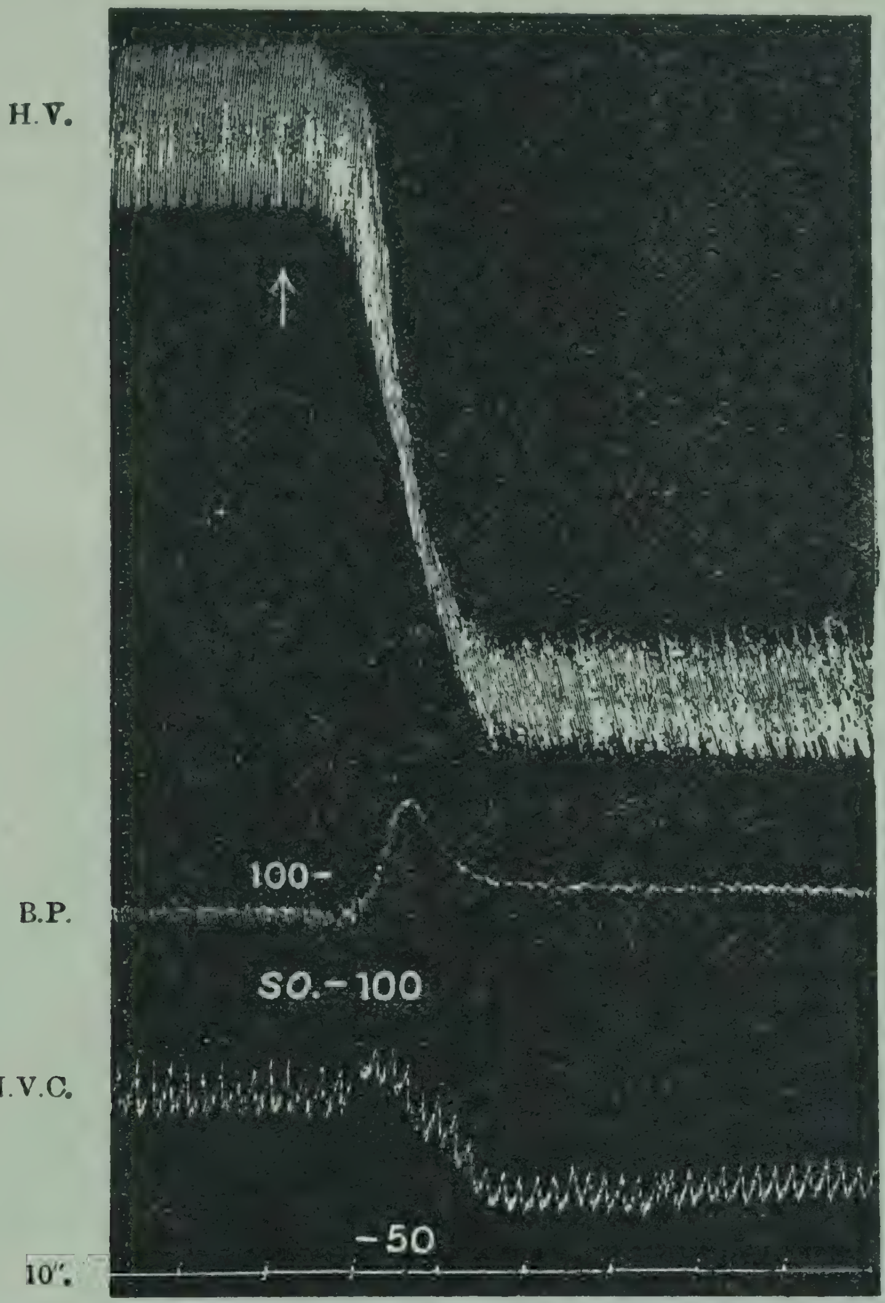

FIG. 394. Effect of Adrenaline on Heart Volume and Venous Pressure. Dog Heart-lung preparation. H.V. = heart volume ; B.P. = arterial pressure ; I.V.C. = venous pressure. At arrow adrenaline added to give a concentration of 1 : 3,500,000 in the blood. (PATTERSON, *Proc. R. S.*, 1914, **88B,** 371.)

There is an antagonism in the influence on the heart of the two substances set free during general muscular activity. Carbon dioxide in excess causes diminished activity, dilatation of the heart and slowing of rhythm. Adrenaline causes increased activity, diminution of cardiac volume and increased rhythm (Fig. 394). The action is so pronounced that if adrenaline be added at the same time,* it is possible to administer 20 or 30 per cent. carbon dioxide to a heart-lung preparation without altering its output, and the beat is maintained and contraction is effective.

THE HEART REFLEXES

Centres. These are in the medulla oblongata. Here, in the dorsal nucleus of the vagus, we find the *cardio-inhibitory centre, i.e.* the neurone pool giving origin to the efferent fibres of the vagus, and also in which the afferent fibres of the vagus terminate.† Direct stimulation of the vagus centre may cause slowing or stoppage of the heart. The tonic influence of the vagi is abolished by destruction of this centre. In this region we also find the vasomotor centre, and the two centres are often affected together, though in opposite directions, excitation of the cardio-inhibitory centre for instance being accompanied by a reduced activity of the vasomotor centre. The cardio-inhibitory centre may be played upon by impulses, arriving at it through various afferent nerves or from the higher parts of the brain, which give rise to the changes of the pulse rate associated with emotional conditions, or it may be directly affected by the composition of the blood circulating through its capillaries.

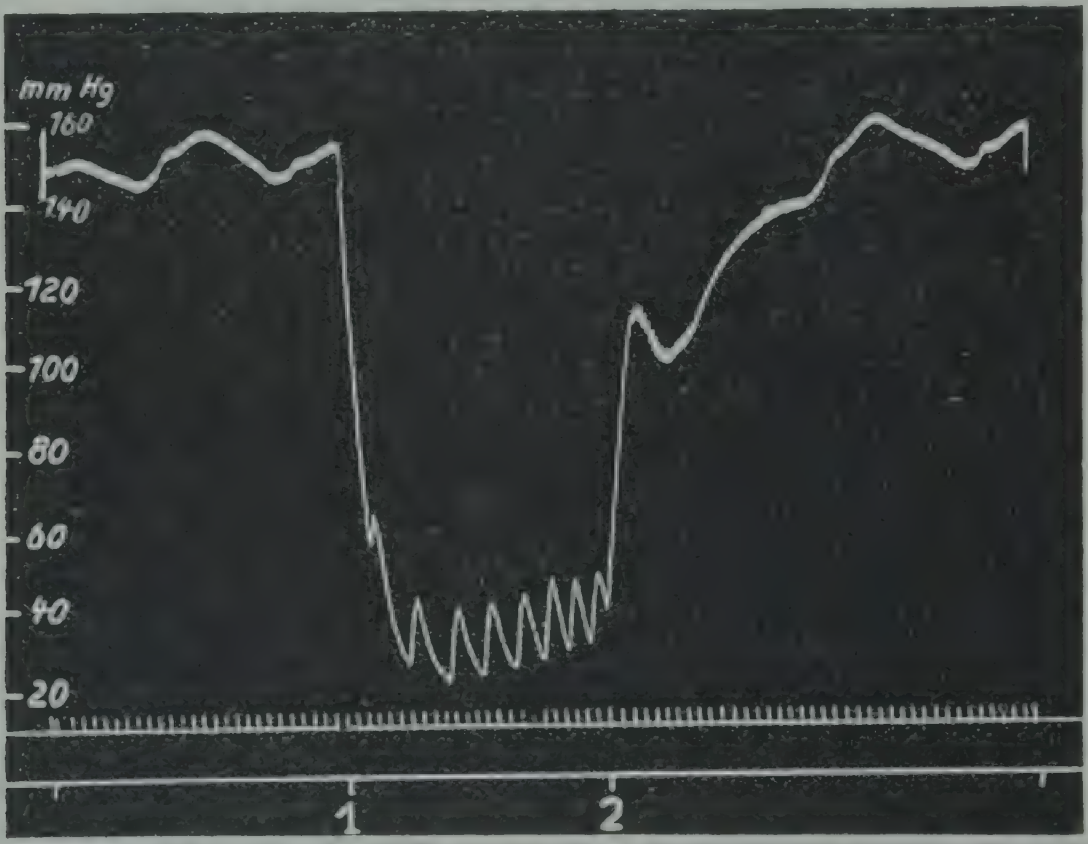

FIG. 395. Blood pressure of Dog. Stimulation of left aortic nerve between 1 and 2. Time = seconds. (SCHWEITZER. Die Irradiation autonomer Reflexe, 1937. Basel, Karger).

The nerve cells which give off the sympathetic accelerator fibres are situated in the intermedio-lateral tract of the spinal cord, near the roots of origin of these fibres. We might, therefore, speak of a *cardio-accelerator* centre in this region ; but it is most probable that the activity of these cells is subordinated to impulses arriving at them from a common site for control of visceral impulses, viz. the medulla, or even higher, as in the hypothalamic region.

Most sensory nerves of the body when stimulated give either a slowing or a quickening of the heart, *e.g.*, stimulation of the fifth nerve, as in the nasal mucous membrane, sometimes causes reflex inhibition.

In the various reflexes in which these cardiac centres are involved, this happens in a reciprocal manner, *e.g.* increase of action of the accelerator centre being accompanied by a reduced activity of the cardio-inhibitory centre.

---

* PATTERSON. *Proc. Roy. Soc.*, 1914, **88B**, 371.

† MILLER and BOWMAN. *Amer. J. Physiol.*, 1915, **39**, 149.

The most important afferent nerves which affect the heart reflexly are the cardiac afferents, from the aorta and heart itself, and the carotid sinus nerve.

Cardiac Afferents. The heart does not seem to be provided with nerves of ordinary sensibility. There is no doubt, however, that under abnormal circumstances, impulses arising in the heart can give rise to sensations of pain, which are referred not so much to the heart as to the surface of the body over the left side of the chest and left arm, in the region of the distribution of the cutaneous branches of the second and third dorsal roots. The nervous impulses responsible for these anginal pains have been said to be conveyed by sympathetic afferents.

THE AORTIC NERVE. The chief afferent nerve coming from the beginning of the aorta, is the *cardio-aortic*, or *depressor* nerve.[*] Neither name is quite satisfactory. It is usually bound up with the vagus, but many of its fibres form a separate nerve in the rabbit. This connects with the superior laryngeal branch of the vagus and with the upper vagus trunk, and runs parallel with the vagus to the cardiac plexus. In man it is represented by a twig of the external branch of the superior laryngeal nerve.

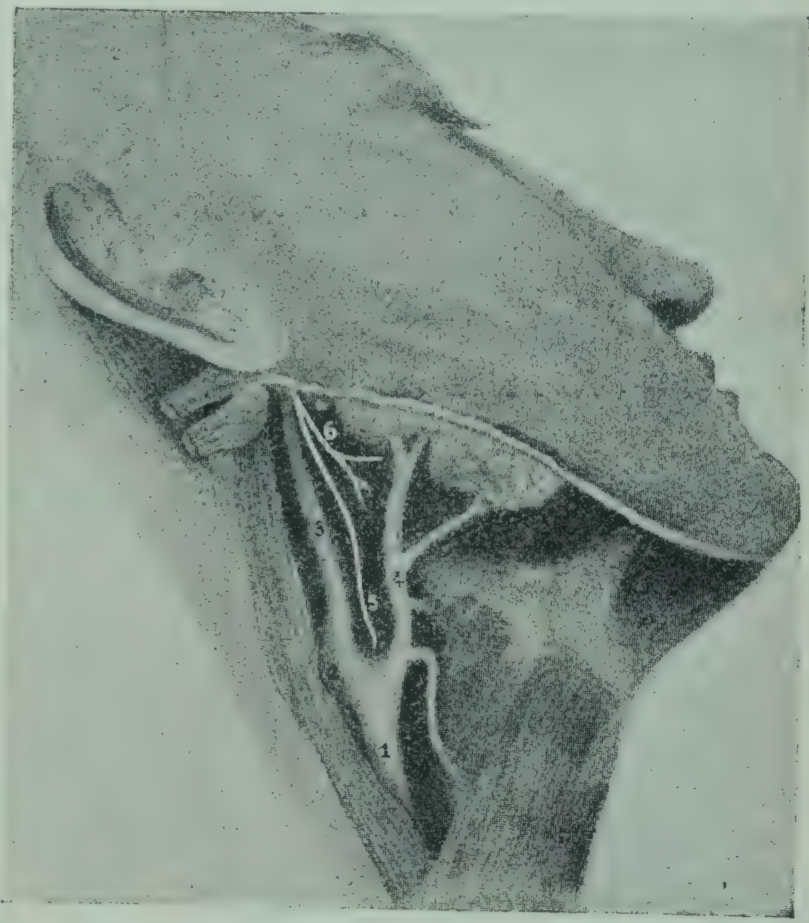

FIG. 396. Showing carotid sinus in man: (1) common carotid; (2) carotid sinus; (3) internal carotid; (4) external carotid; (5) nerve to carotid sinus; (6) glosso-pharyngeal nerve. (C. HEYMANS, "Le sinus carotidien.")

The cardio-aortic nerve arises from endings in the aortic arch and in the left ventricle. Similar afferents originate in the pulmonary artery, and have similar, but weaker, functions[†]; fibres in the pulmonary veins, also probably vagal, are more potent.[‡] These endings are sensitive to stretch.

The aortic nerve is purely afferent, stimulation of its peripheral end causing no effect. On stimulating its central end, or the central end of one vagus, preferably the left, a fall of arterial blood pressure (Fig. 395) and reflex slowing of the heart are produced, the latter effect being abolished by section of both vagi. The reflex slowing is due to impulses which ascend by the cardio-aortic fibres of the vagus and are then returned from the vagus centre *viâ* the cardio-inhibitory fibres of the vagus. The fall of blood pressure still occurs on central vagal excitation, when both vagi are divided. It was shown by Bayliss that[§] this depressor effect is due to widespread dilatation of the blood vessels of the body, chiefly in the splanchnic area.

The aortic nerve is brought into action by stretching or dilating the aorta, as happens when the blood pressure is high. At each systole a rapid shower of nerve impulses can be shown to pass up the afferent fibres of the vagus or aortic nerve; when the aortic pressure is higher these impulses are more numerous. Synchronously with these, a shower of outward impulses passes down the efferent fibres of the vagus. If the depressor nerves be cut when the aortic pressure is high, the blood pressure rises still higher. We have here a means by which the heart can be relieved of a load too great for its powers.

[§] BAYLISS. *J. Physiol.*, 1893, **14**, 303; 1908, **37**, 264; *Proc. Roy. Soc.*, 1908, **80B**, 339.

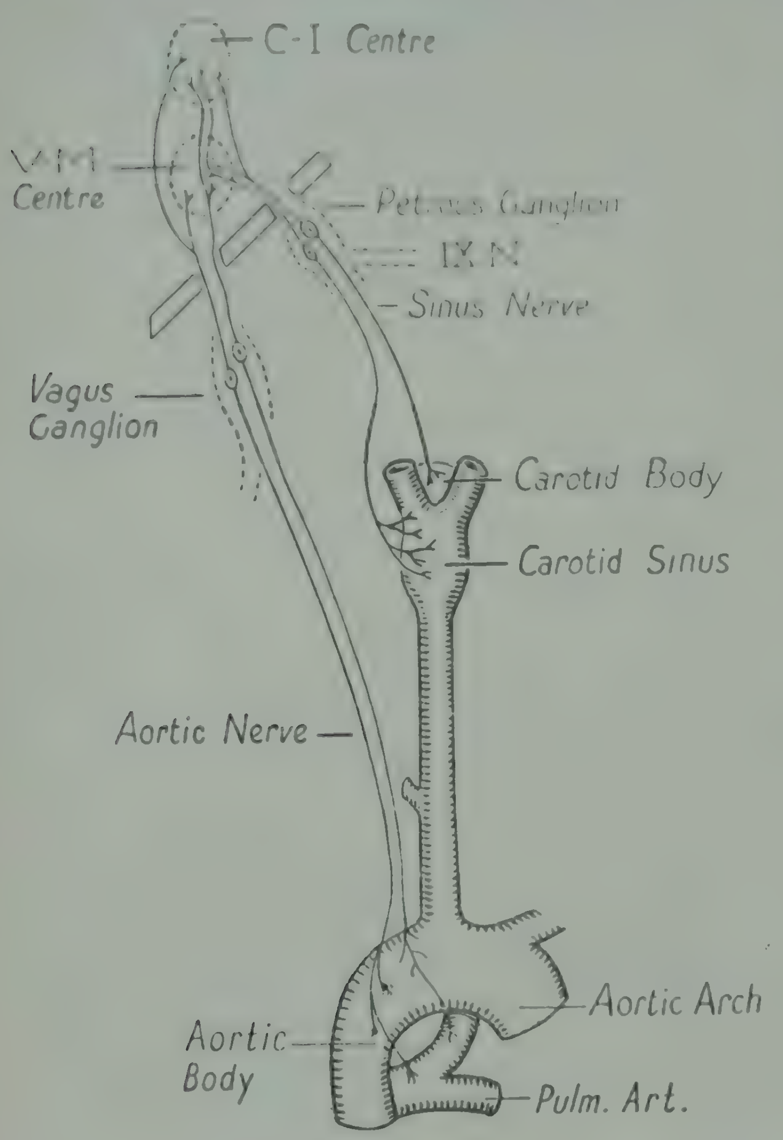

FIG. 397. Diagram of the afferent innervation of the carotid and aortic regions in relation to cardio-vascular reflexes.

The *aortic bodies*, patches of vascular tissue on the aortes, and similar in structure and function to the carotid body, also send fibres to the cardio-aortic nerve. The nerve endings from which these fibres arise are sensitive to chemical changes in the blood, but impulses along them do not affect the heart rate.

OTHER VAGAL AFFERENTS. In the mammalian heart, nerve strands can be seen running over the surface of the ventricle; these are entirely afferent, stimulation of their peripheral ends causing no effect on the heart beat. Stimulation of their central ends may cause one of five results:

(*a*) Slowing of the heart.

(*b*) Acceleration of the heart.

(*c*) Rise of blood pressure from constriction of the splanchnic area.

(*d*) Fall of blood pressure by dilatation of the arterioles of the body.

(*e*) Reflex movements.

These strands ultimately pass up in the vagus nerves.

Some strands of the cardiac plexus cause acceleration of the heart when centrally stimulated. It is probable that these strands originate in the right side of the heart; they reflexly lower vagus tone. Afferent impressions reaching the centres from the lungs *viâ* the vagi also affect the rate of the heart.* Slight inflation of the lungs or weak stimulation of the pulmonary branches of the vagi cause reflex acceleration †; great distension, or strong stimulation causes reflex slowing (*v.* also p. 600).

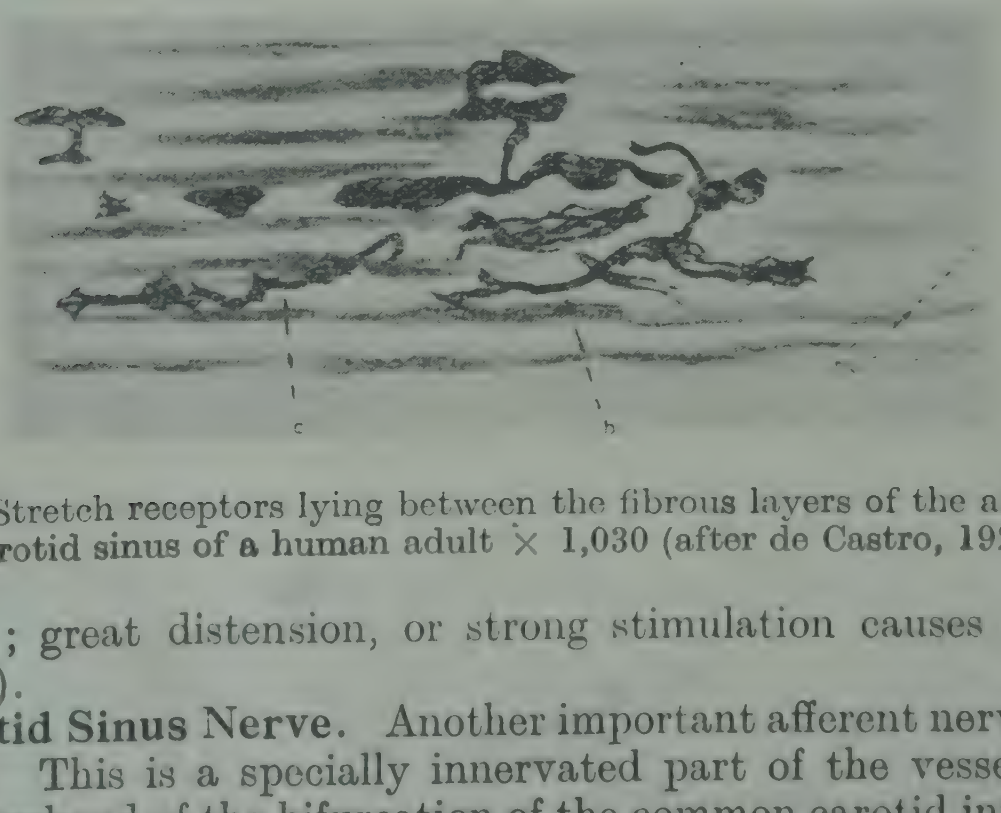

FIG. 398. Stretch receptors lying between the fibrous layers of the adventitia in the carotid sinus of a human adult × 1,030 (after de Castro, 1928).

The Carotid Sinus Nerve. Another important afferent nerve arises in the carotid sinus. This is a specially innervated part of the vessels and tissues in the neighbourhood of the bifurcation of the common carotid into its branches and includes also the carotid body. In man (see Fig. 396), and many other mammals, the common carotid artery divides into the internal and external carotids, and a bulbous thin-walled expansion, the carotid sinus or carotid bulb, is seen at the root of the internal branch. A nerve twig runs from the carotid sinus to the glossopharyngeal (Fig. 397).

---

* SAALFELD. *Pflüger's Arch.*, 1932, **231**, 33.

† ANREP *et al.* *Proc. Roy. Soc.*, 1936, **119B**, 191.

The nerves originating in the carotid sinus are stimulated by stretch, *i.e.* they originate from special stretch receptors (baroceptors) in its walls (Fig. 398).

The carotid body is richly supplied with sinusoids lined with endothelium and peculiar "glomus" cells, the latter being abundantly supplied with nerve fibres that join the carotid sinus nerve (Fig. 397). The nerve endings in the "glomus" cells are not sensitive to stretch, but respond to chemical changes in the blood flowing through the sinusoids.

Impulses set up in the carotid sinus and carotid body produce important reflex changes in heart rate, vascular tone and respiration.

Fig. 397 illustrates diagrammatically the afferent nerve supply responsible for reflex control of the circulation in response to arterial pressure changes, *i.e.* the aortic and carotid sinus innervation. The efferent paths are, of course, the vagus, for cardio-inhibition, and the sympathetic nervous system, connected with the relevant bulbar centres by way of the spinal cord, for cardio-acceleration and, as we shall see later, also for vascular tone.

Stimulation of the carotid sinus electrically, or mechanically, as by stretching its walls by pressure from within in any manner, provokes a combined reflex of cardiac inhibition and fall of blood pressure, just as does stimulation of the central end of the depressor nerve (Figs. 399 and 400). In fact, we may regard the reflexes from the carotid sinus and those from the aortic nerves as part and parcel of the same physiological arrangement for controlling the blood pressure. It is found that, after section of the vagi, stimulation of the carotid sinus in any way no longer produces the cardiac inhibition (proving that this was reflex).

Chemical Responses. Altered chemical content of the blood in the carotid body can produce alterations in heart rate by exciting the chemo-receptors, *e.g.* increase of CO_2 or deficit of oxygen causes reflex quickening of the heart. The effects are relatively weak, however.

Cardiac Reflexes. There are two very important reflex mechanisms associated with the heart itself. If, other conditions remaining the same, the arterial pressure be raised, the heart is slowed. This phenomenon, sometimes dignified with the name of "Marey's law," [*] *i.e.* that *the pulse rate varies inversely as the arterial pressure,* is not invariably seen in the intact animal or in man, because other conditions may be changed. The other reflex is an acceleration of the heart rate when, other conditions remaining the same, the pressure in the great veins and right auricle is raised, as happens when the venous return to the heart is increased. Thus we have two mechanisms, balanced, the one against the other, one causing the heart to slow down if the aorta is getting over full, the other causing it to accelerate as the right side distends.

(i) INHIBITORY REFLEXES. The first of these mechanisms is the reflex cardiac inhibition, resulting when afferent fibres of the aortic nerves (chiefly the left) are excited by the stretching of the arch of the aorta and left ventricular wall if the blood pressure rises. As a result of this the cardio-inhibitory centre is excited, with the sequel that efferent cardio-inhibitory impulses *viâ* the vagi bring about a reduction of the pulse rate.

An equally, or even more, important cause of the cardiac inhibition consequent on rise of arterial pressure is a reflex from the carotid sinus.

This is shown by the experiment called the "perfusion of the carotid sinus." For this purpose, in a dog (B), the sinus region is isolated from the circulation by ligatures, and left connected with the animal only by its nerves; this isolated segment of carotid artery with its branches can then be perfused with blood from a pump, or from a second dog (A). The blood from the carotid of A enters the cephalic end of the carotid artery of B, and, after

---

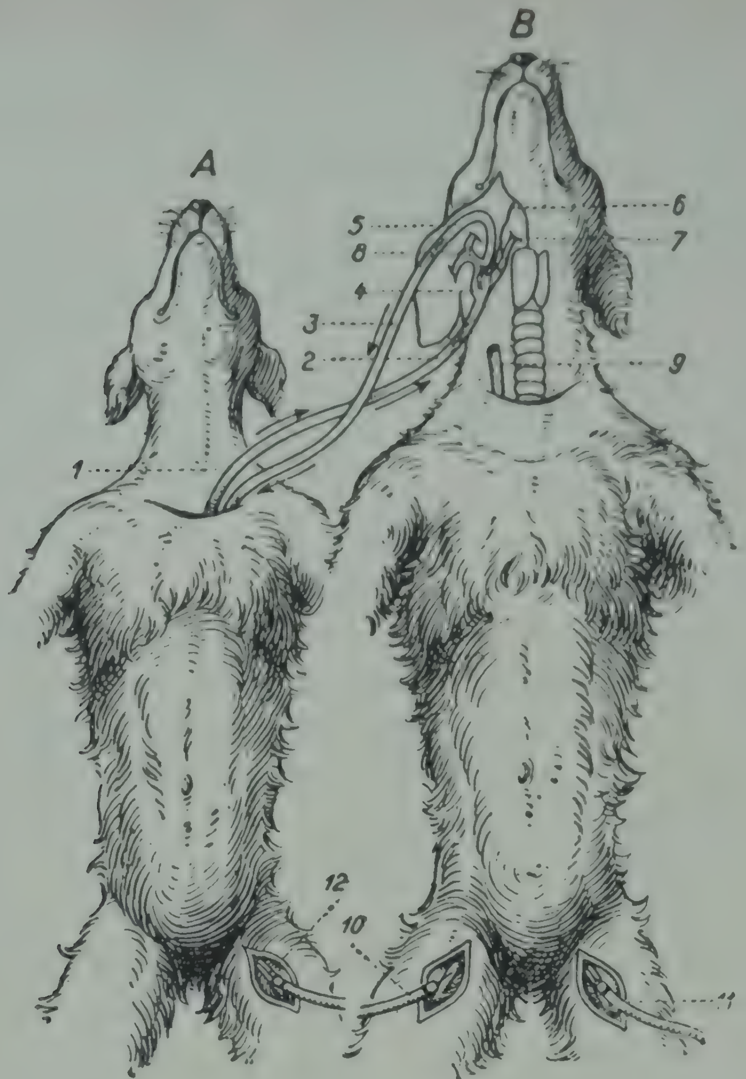

Fig. 399. Perfusion of isolated carotid sinus. A, dog supplying perfusion blood. B, dog of which the sinus is perfused. (1) Carotid artery of dog A ; (3) external jugular of dog A ; (6) nerve supply of carotid sinus of B. All other branches of the carotid sinus of B are tied off, so that the only blood entering it is that from A. (C. Heymans.)

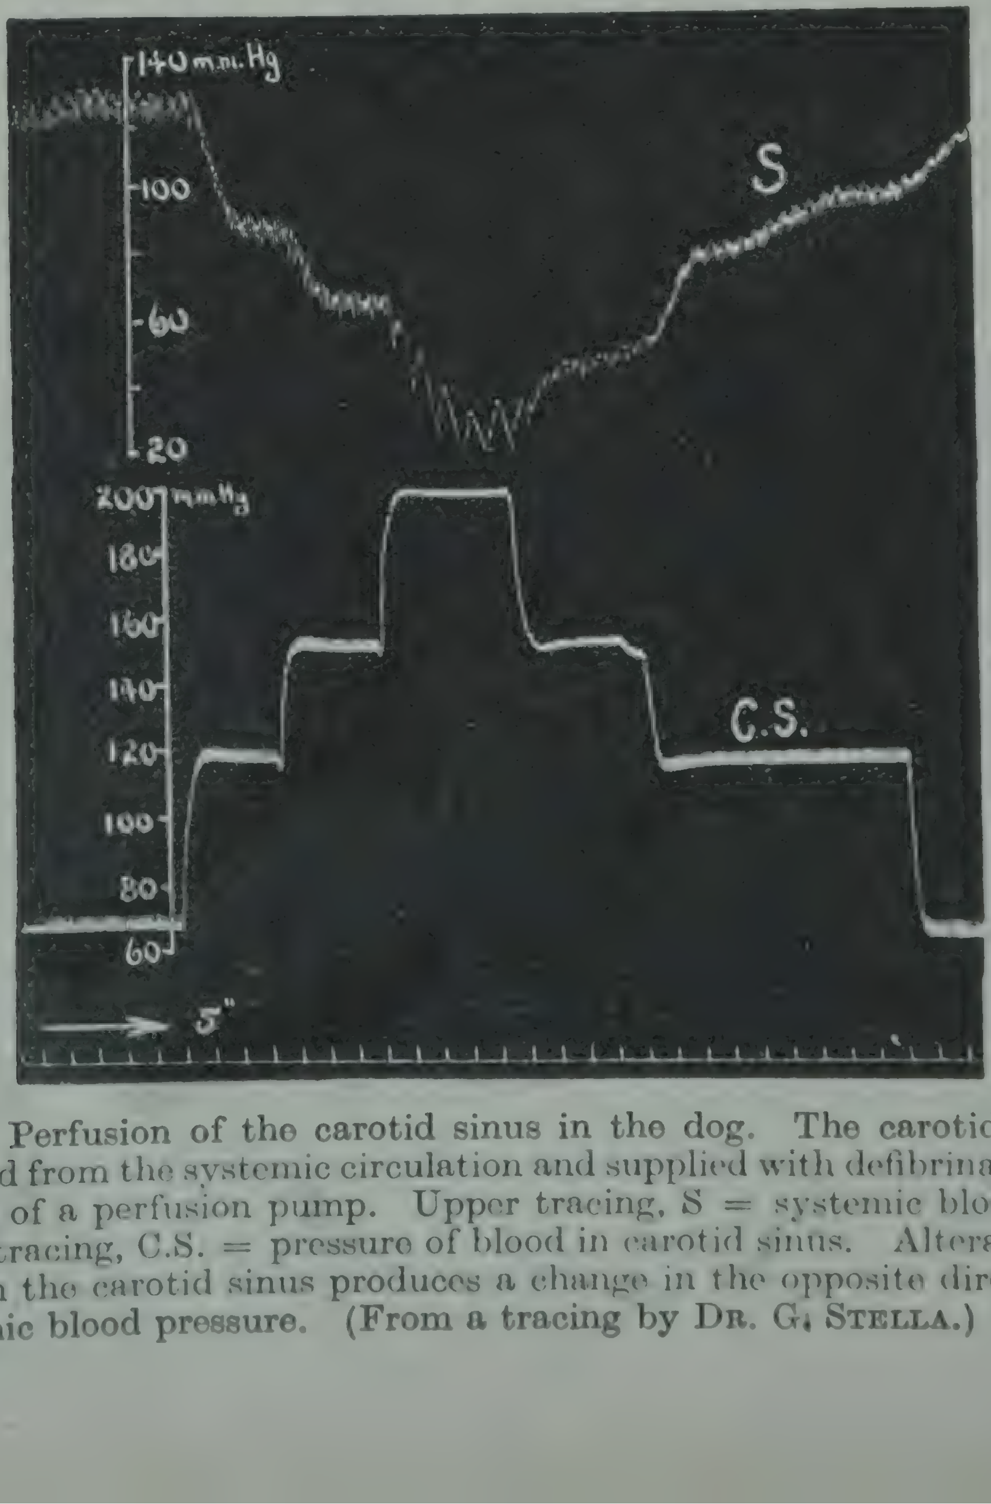

Fig. 400. Perfusion of the carotid sinus in the dog. The carotid sinuses are isolated from the systemic circulation and supplied with defibrinated blood by means of a perfusion pump. Upper tracing, S = systemic blood pressure ; lower tracing, C.S. = pressure of blood in carotid sinus. Alteration of pressure in the carotid sinus produces a change in the opposite direction in the systemic blood pressure. (From a tracing by Dr. G. Stella.)

passing along the carotid sinus segment, is returned *viâ* the external carotid artery of B to the external jugular vein of A (Fig. 399).

The pressures in the femoral artery of the recipient dog and of the perfusing supply (pump, or artery of donor) are recorded. If now the perfusing pressure is raised in any way, so that pressure is increased in the sinus of dog B, there is an immediate reduction of heart rate and fall of arterial blood pressure in the systemic circulation of the latter. If the blood pressure in the sinus of B is still further increased, there is a still further slowing of the heart and fall of pressure in dog B (Fig. 400). Conversely, by lowering the pressure in the carotid sinus of B, its systemic arterial pressure is raised, and there is at the same time cardiac acceleration. The alterations of arterial pressure in the dog B, though they accompany the alterations in heart rate, are only in part due to them, since the pressure changes still persist after elimination of the cardiac effects by section of the vagi or administration of atropine (see p. 588).

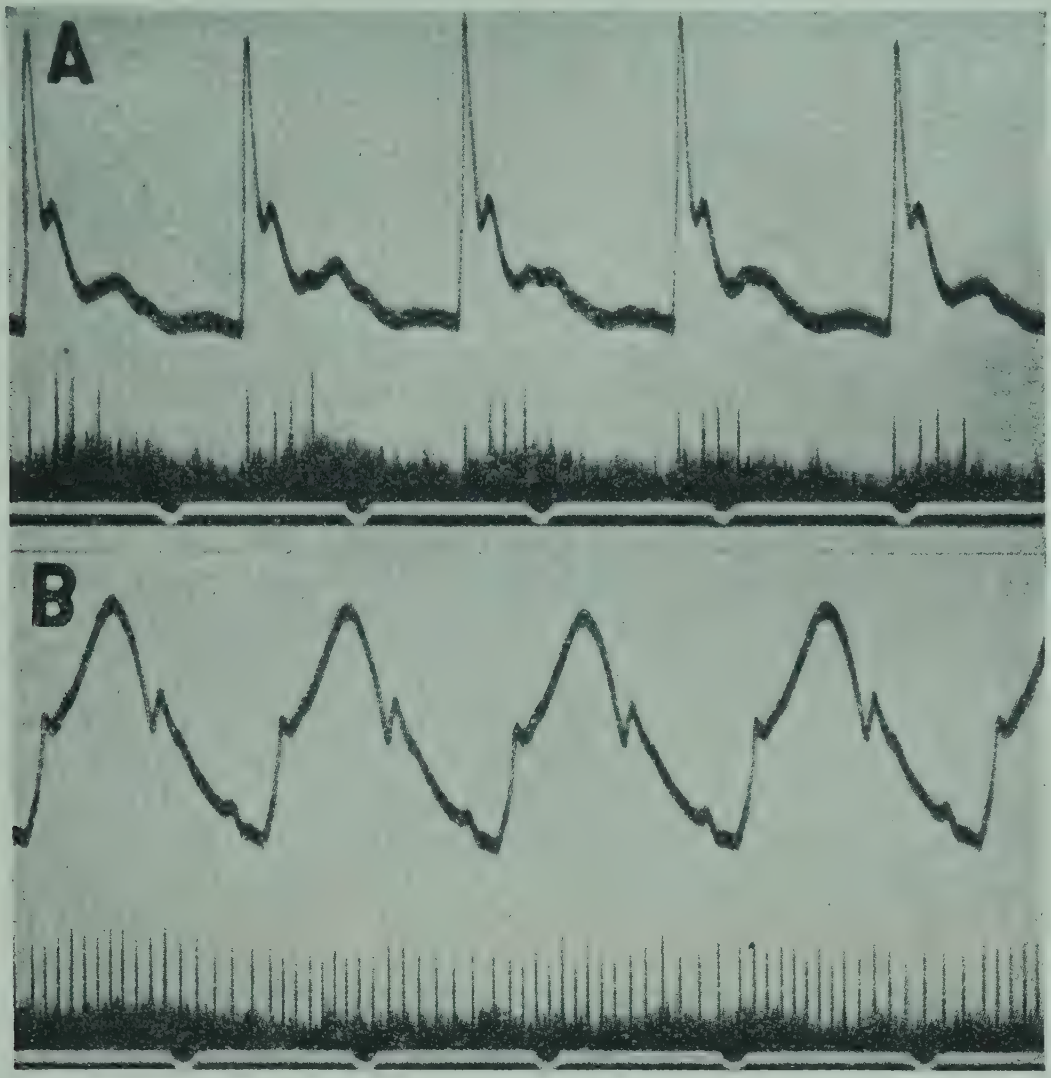

FIG. 401. Effect of increased mean blood pressure on the discharge from a single end-organ of the carotid sinus. In each tracing, the top curve is arterial pressure, middle one is electrical variations in sinus nerve, lowest one = 1/5th second. In A, B.P. = 55 mm. Hg. In B, = 135 mm. Hg. (BRONK and STELLA, *Journ. Cell. and Comp. Physiol.*, 1932, **1**, 113.)

Nerve impulses up the carotid sinus nerve are set up by rise of pressure in the carotid sinus. The electrical variations representing the nervous impulses passing along a single nerve fibre from the carotid sinus, are shown in Fig. 401. It will be seen that in tracing A, where the blood pressure was low, a burst of impulses passed along the nerve during the systolic part of each pressure-pulse curve. When the arterial pressure was raised, there was a more rapid stream of impulses, which continued also during the diastolic portion of the curve, though at a slower rate (B.).

(ii) ACCELERATOR REFLEXES. The other mechanism is a reflex, often called the Bainbridge reflex,* which is started from either auricle, and from the great veins, when these become distended by rise of venous pressure.† Afferent impulses from the auricles travel up by the vagi (perhaps chiefly by the right one) and bring about reflex cardiac acceleration by (*a*) reducing the tone of the cardio-inhibitory mechanism (the principal factor), and possibly also by (*b*) throwing the cardio-accelerator mechanism into action.

Cardiac acceleration can, of course, also result from reduction of the vagus tone. This happens when the arterial pressure falls, affecting the inhibitory zones, the carotid sinus and aortic arch.

---

* BAINBRIDGE. *J. Physiol.*, 1915, **50**, 65.

† SASSA and MIYAZAKI. *J. Physiol.*, 1920, **54**, 203.

Emotional acceleration of the heart, as, *e.g.* on hearing a loud noise, is largely due to sympathetic action, but in part to reduction of vagus tone. Then follows a fall in rate, due perhaps to intervention of the carotid sinus ; after this there may be a second rise, due to adrenaline.*

Effects of Changes in Cephalic Arterial Pressure. An important question which arises out of the discovery of the carotid sinus reflexes is that which concerns the effect on the general circulation of increased arterial pressure in the head. It has been generally agreed that an increase in the intracranial arterial pressure tends to produce, as compensatory phenomena, slowing of the heart and a fall in the somatic blood pressure.

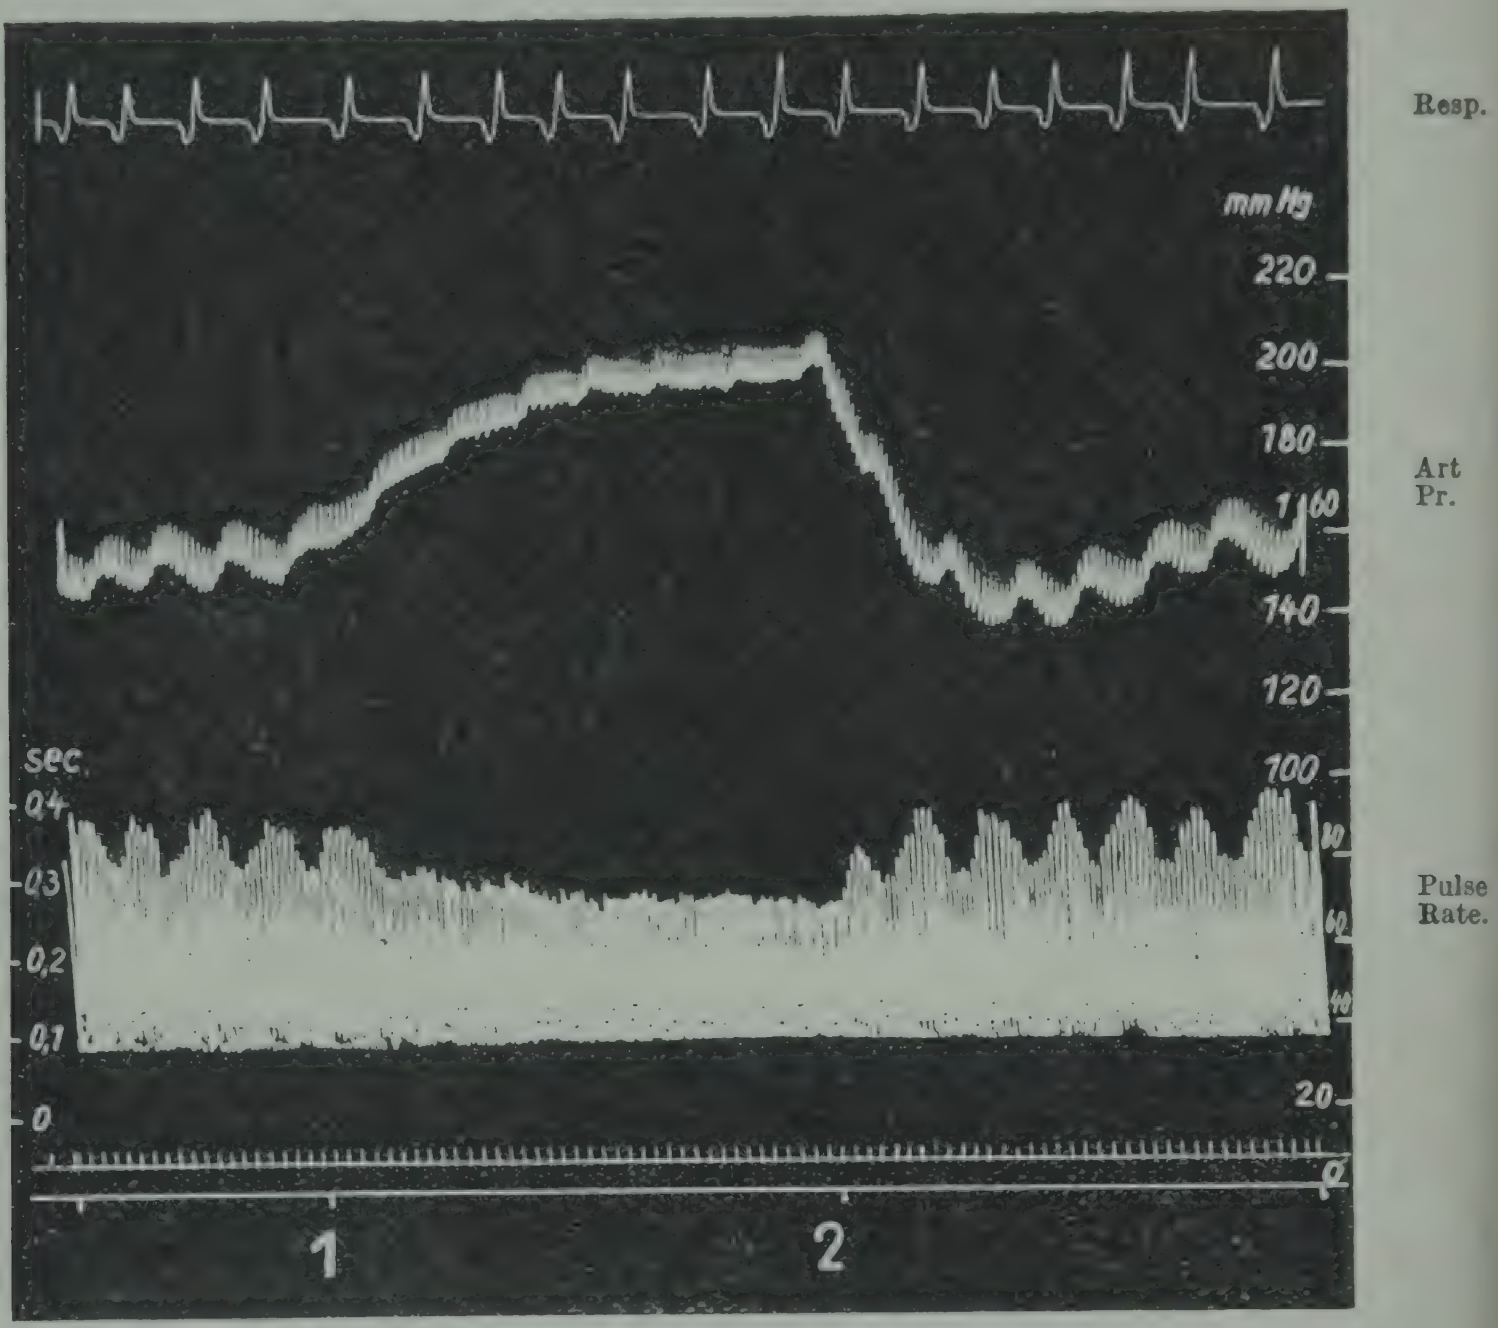

Fig. 402. Showing the effect of carotid sinus reflexes on respiration, arterial pressure, and pulse rate. In resp. trace inspiration is upwards. The right sinus and left aortic nerves have been eliminated. Between 1 and 2 the left common carotid was clipped off. Pulse rate shown by Fleisch's "time writer." Sinus arrhythmia and Traube-Hering waves are diminished during the rise of arterial pressure. Time, seconds. Ordinate on left = interval between heart beats in seconds. (Schweitzer. *Verh. dtsch. Ges. Kreislaufforsch,* 1935, **8**, 148.)

Most investigators believed that the effects were entirely due to the action of increased pressure upon the medullary centres, until it was shown by Hering that these effects disappeared when all the nerves of the carotid sinus had been destroyed. This can be illustrated by the simple experiment of lowering the cranial pressure by occluding the carotid arteries (Fig. 402). The effects disappear if the carotid sinus is denervated.

An application of the technique of the "isolated head," enables this question to be investigated. In this preparation (Fig. 403) the head of dog B is fed exclusively from dog A by anastomoses between both carotids and external jugulars of the two animals—all the tissues of the neck of B, with the exception of the two vagi, being divided. The

* Bond. *Amer. J. Physiol.*, 1943, **138**, 468.

head of B, therefore, is in vascular connection with A, and its only connection with its own body is through the two vagus nerves.

With this preparation it can be shown that a rise of pressure in A leads to a slowing of the heart in B. If the carotid sinuses of B are denervated, alterations of pressure in A no longer produce any effects upon the heart rate of B. We must conclude, therefore, that pressure changes in the head produce their effect upon the heart rate, not through any direct action on the cardio-inhibitory centre, but entirely through reflexes generated in the carotid sinus.

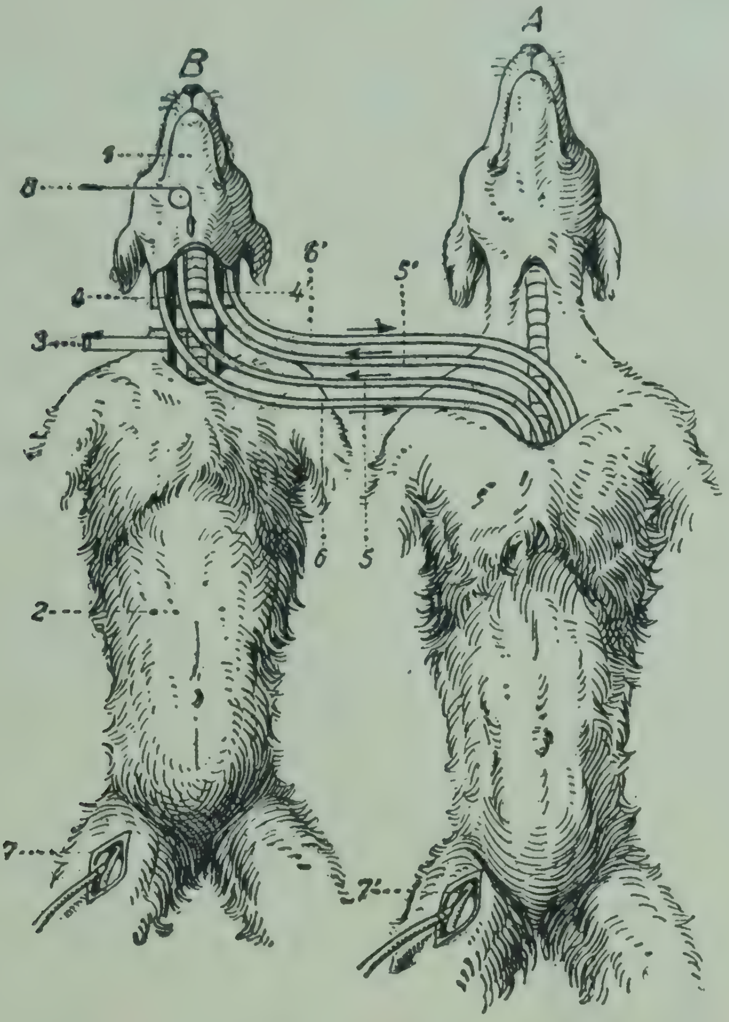

Fig. 403. Schema of the isolated head, according to J. F. Heymans. The isolated head of B is supplied with blood from dog A, and is left in connection with its own body only by the two vagus nerves. (C. Heymans.)

Schmidt and Comroe (1940). "Functions of the Carotid and Aortic Bodies." *Physiol. Rev.*, **20**, 115.

The Pulse Rate in Man. The normal pulse rate in adult men is about 70 per minute. It is largely influenced by bodily movements and varies considerably with age. The following table represents the average pulse rate in man at different ages :

Age in years.	Pulse rate per minute.
Fœtus	150
0	135
5	105
10	90
15	80
20	75
25–40	70
80	75

It must be remembered that marked differences in the pulse rate may be found in different individuals without having any pathological significance. Thus pulse rates of 30 per minute and 120 per minute have been observed in men who were otherwise perfectly healthy. It is slow in athletes. The pulse rate is raised by warmth and diminished by cold applied to the surface of the skin. It is also increased somewhat by the taking of food. The act of swallowing causes a reflex quickening of the rate by inhibition of the tonic vagus action.

The heart-beat is normally not perfectly regular, but shows fluctuations corresponding with the respiratory movements, the rate being accelerated in inspiration and retarded in expiration.

Irregularity of the pulse (or of any other movements) can be conveniently recorded by means of a special instrument,* which obviates the labour of measurement of the time intervals on an ordinary tracing. Fig. 402 shows a tracing made with this apparatus. The height of each stroke on the tracing shows the length of time elapsing between one pulsation and the next, so that a longer stroke means a slower pulse. The tracing shows that at inspiration there is acceleration (shorter stroke), and at expiration retardation (longer stroke). Perfect regularity of the pulse rate is abnormal. In most normal children, and in certain pathological states, the respiratory fluctuation is so pronounced as to be detectable on mere palpation; it is called *sinus arrhythmia*. Various explanations have been given for its occurrence, one being that it is due to a Bainbridge reflex from the right auricle, which is more rapidly filled during inspiration.

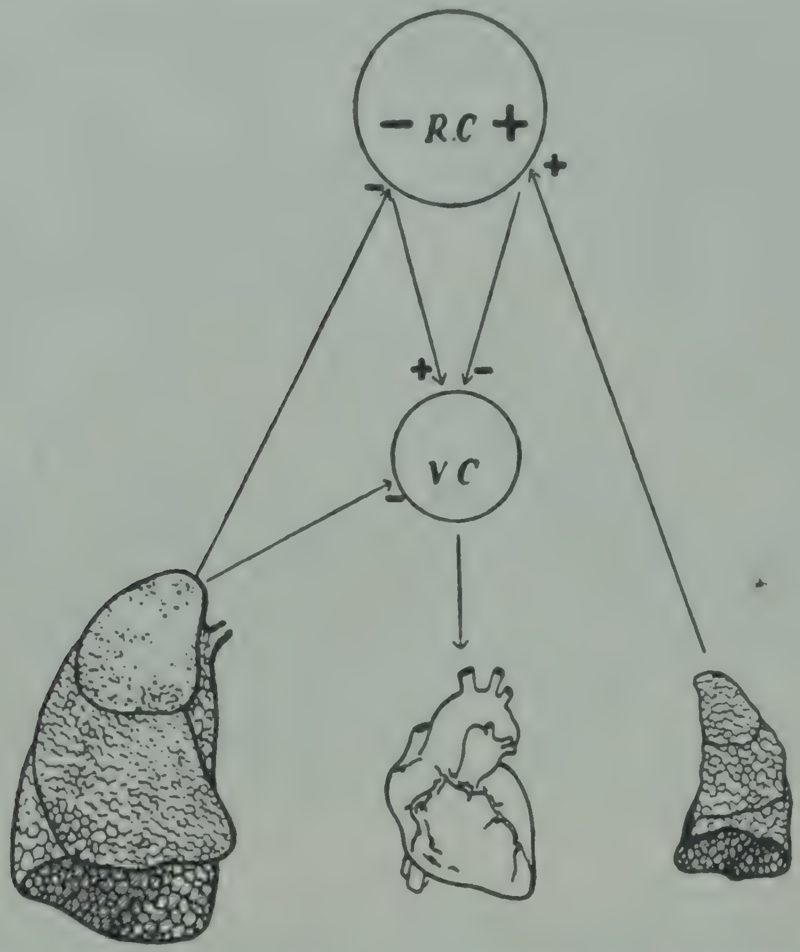

Fig. 404. Diagram showing effects of respiratory act on heart-rate. R.C., respiratory centre; V.C., vagus centre; on the right, collapse excites R.C., and indirectly inhibits V.C., so tending to produce acceleration. On left, normal inflation does the reverse, but also reflexly inhibits V.C. The effects are a resultant. (Modified from Anrep, Pascual and Rössler.)

Probably, † however, the effect is a complex one, and certainly includes some reflex effects from the lungs and some from the respiratory centre. When the lungs are inflated, the branches of the pulmonary vagus carry to the vagus centre impulses which reduce its tone; in deflation these impulses cease. Opposing these reflex effects to some extent are effects of the respiratory centre upon the vagus centre; thus inflation inhibits the respiratory centre and as a secondary result of this the vagus centre is excited. Hence the effects of the act of respiration, in addition to that due to the Bainbridge reflex, represent a resultant of excitation and inhibition at each inspiration or expiration. These effects are illustrated in Fig. 404.

NUTRITION AND METABOLISM OF THE HEART

The Coronary Circulation. The mammalian heart is nourished through the coronary arteries, the venous blood being returned to the right side of the heart. In the dog the right ventricle is mainly supplied by the right coronary artery and drained by the anterior cardiac veins, the left by the left coronary and drained by the coronary sinus.* The extent of drainage into Thebesian vessels, which open chiefly into the right ventricle, is doubtful. In the human heart the respective contributions of right and left coronary arteries varies, the most favourable (in 34 per cent.) being a balance between the two, and the least favourable (18 per cent.) one where the left artery predominates—a condition predisposing to the most serious consequences should left coronary occlusion occur,† because the larger branches of the coronary arteries show little anastomosis.‡ Hence, the occlusion of a large branch may lead to death. But anastomoses readily develop if one vessel is occluded, and are more free between veins. Capillaries are very abundant, about 11 m. of capillary per c. m.m. of heart muscle.§

---

* Fleisch, A. *Zeitschr. f. klin. Med.*, 1932, **119**, 618; Johnsen. *Acta. Physiol. Scand.*, 1945, **10**, 342.

† Anrep, Pascual and Rössler. *Proc. Roy. Soc.*, 1936, **119B**, 191, 218.

Despite its importance, we are still in doubt regarding many aspects of the coronary circulation as it operates in the normal heart in the intact chest, since nearly all available methods of experiment introduce some abnormal factor of incalculable effect.

The flow of blood through the coronary circulation may be measured by feeding an excised heart, through the coronary arteries, with blood from a pump or heart-lung preparation, and collecting the total outflow from the cut pulmonary artery. Another method is by introducing a cannula through the wall of the right auricle into the coronary sinus and collecting the blood which flows out from the latter. By a comparison of these two methods, it is found, in the dog, that the flow through the coronary sinus *usually* forms about three-fifths of the total blood passing through the coronary arteries, the remainder passing by the anterior cardiac veins and other lesser channels.|| It is therefore possible to measure the flow through the coronary sinus under varying conditions, and, by multiplying the figures so obtained by 5/3, to obtain the *approximate* total flow through the coronary circulation. In grossly abnormal conditions, *e.g.* when the heart is fibrillating, this fractionation no longer holds good.

Since the efficiency of the heart is ultimately dependent on an adequate supply of oxygen, the importance of the coronary blood flow is evident. About 5 per cent. of the cardiac output is diverted to the coronary circulation. The amount of blood passing through it per gramme of heart per minute may rise to as much as 5 c.c. In man during violent exercise the coronary flow probably amounts to about 1·5 l./min.

Factors Controlling Coronary Flow in the Denervated Heart. Other factors remaining the same, whether the work of the heart, or its rate, is varied or not, the coronary flow depends primarily on the mean pressure at which the coronary arteries are supplied. The great effect of general arterial pressure on the coronary flow is most readily demonstrated on the heart-lung preparation; this enables the mechanical factors controlling coronary blood supply to be studied alone, any influence of the nervous system being eliminated. Results of an experiment are shown in the following table :—

Heart weight, 107 grammes. Total Systemic output per minute, 1,400 c.c.

Arterial pressure mm.Hg.	Coronary circulation per minute cc.
60	50
100	90
128	124
166	208
190	500

But this circulation is also adapted to the amount of work that the heart is doing, since the oxygen usage of the heart increases with the amount of work it is given to do. When we investigate the coronary flow in the heart-lung preparation, we find, accordingly, that it is increased whenever an increase is

---

* Gregg and Shipley. *Amer. J. Physiol.*, 1947, **151,** 13.

† Schlesinger. *Blood, Heart and Circulation.* Science Press, 1940, p. 61.

|| Evans and Starling. *J. Physiol.*, 1913, **46,** 413.

demanded to supply the necessary oxygen. Hence we find that reduction in the oxygen saturation of the blood passing to the heart, or increase in the oxygen demand by it, soon gives rise to dilatation of the coronary vessels. This dilatation is almost proportional to the degree of anoxæmia, so that the accessibility of oxygen to the myocardium may remain unaltered, *i.e.* within very considerable limits, it is found that the consumption of oxygen by the heart is independent of the oxygen saturation of the arterial blood. The effect of increasing deoxygenation of the blood on the coronary flow is shown in the accompanying diagram (Fig. 405). The effect of altered arterial pressure therefore, even in the denervated heart-lung preparation, is not solely mechanical, but is in part due to increased oxygen abstraction, the result of increased cardiac work. This is probably to be explained as due to a direct effect of oxygen lack on the plain muscle of the coronary vessels; it is seen to occur at once when traces of cyanides are added to the blood, so as to suppress oxygen utilisation (Fig. 405). It has been ascribed to the action of metabolites produced in the heart muscle, and normally eliminated by oxygen.*

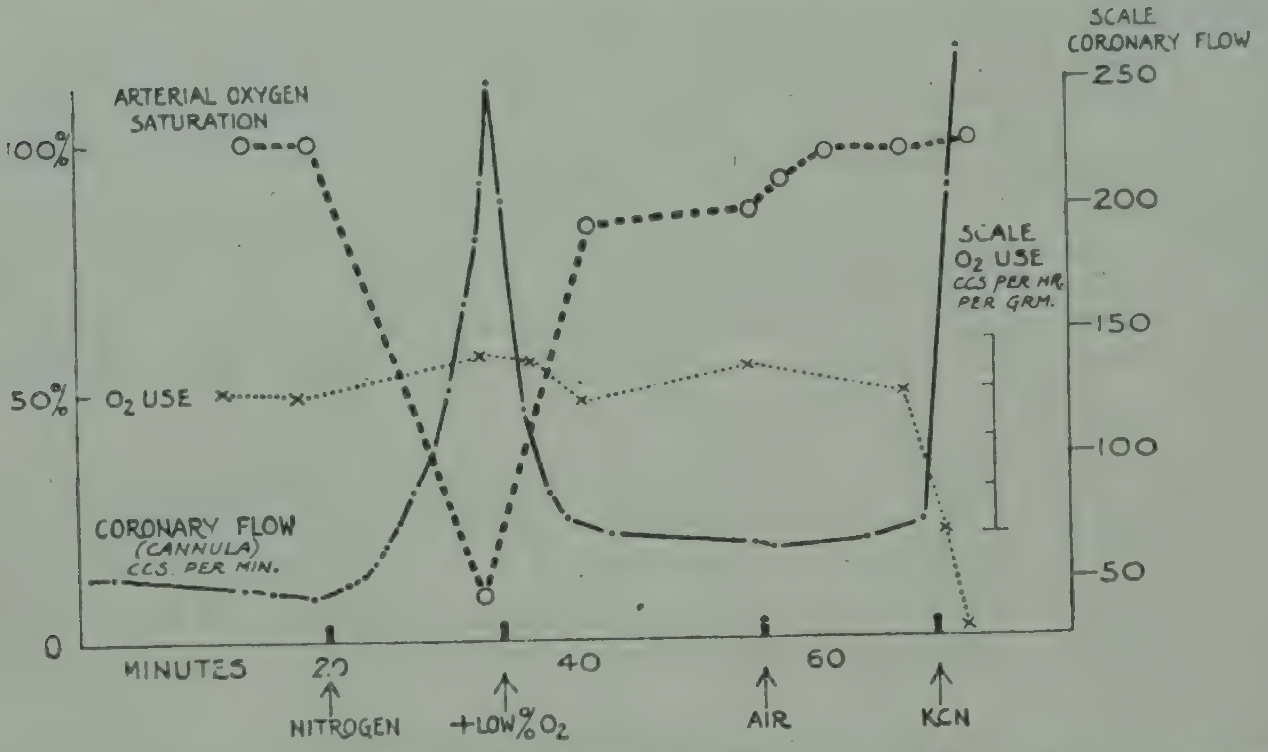

FIG. 405. Curves showing the Relation of the Coronary Blood Flow and of the Oxygen Consumption by the Heart to the Degree of Oxygen Saturation of the Blood passing through the Coronary Vessels. (HILTON and EICHHOLTZ.)

Over a moderate range, alteration in the heart-rate has little effect on the total coronary flow, but when the rate becomes very high the relative shortening of diastole results in reduction of flow.

Increase of right intraventricular pressure reduces coronary flow.

Carbon dioxide has a dilator influence on the coronary vessels, but this is slight compared with that of anoxæmia, and is probably due to the accompanying slight increase in hydrogen ion concentration.

Pitressin has powerful constrictor effects and considerably reduces coronary flow.

Control of Coronary Flow in the Innervated Heart. The coronary arteries are richly innervated from both the vagus and the sympathetic, and the vagal fibres are constrictor to the coronary vessels and normally exhibit a tonic action. Coronary vaso-constrictor and vaso-dilator reflexes probably enter into many vaso-motor reflexes, elicited from almost any part of the body.† For example, a rise of pressure in the carotid sinus probably leads to reflex coronary constriction. Section of the vagi not only quickens the heart rate but also relaxes the coronary vessels and allows an increased flow. Hence the coronary flow in the denervated heart is greater than when it is normally innervated. Further, when the output of the heart in the intact body is increased, there is, in addition to the reflex cardiac acceleration, also an independent reflex relaxation of the coronary vessels, whereby the circulation through the heart is increased : this is due chiefly to reduction of vagal tone and is not exhibited by the denervated heart-lung preparation, in which the effect of alteration of output has but little effect on the coronary flow. Experiments on unanæsthetised dogs, in which the coronary flow was measured by a thermostromuhr, have shown* that during exercise there is a large increase in coronary flow : sympathectomy did not affect this response, but double vagotomy, though it resulted in an increase of the resting flow, abolished the increase on exercise.

---

* KATZ and LINDNER. *Amer. J. Physiol.*, 1939, **126**, 283.

† GREENE. *Amer. J. Physiol.*, 1935, **113**, 399.

On stimulating the sympathetic nerve supply to the heart, or injecting adrenaline, there is an increased frequency and energy of contraction and the increased beat is always associated with greatly increased coronary blood flow. It has been inferred that the sympathetic nerves to the heart have a direct dilator effect upon the coronary arterioles,† but owing to the concurrent effect on the myocardium, with consequent increased production of metabolites, it is still uncertain whether this is so.

The above factors may be all involved in the adaptation of the blood flow to the needs of the heart when the activity of this organ is increased, either by increased arterial resistance or by increased output, in both of which the oxygen usage of the heart is increased.

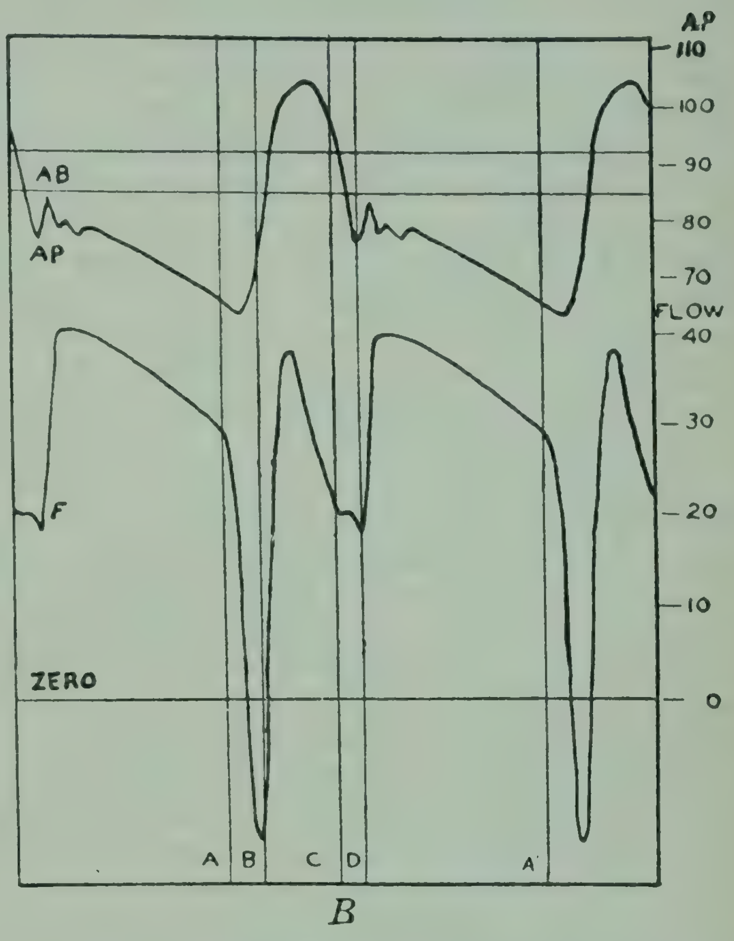

FIG. 406. Rate of inflow F into a branch of a left coronary artery, and aortic blood pressure AP, in dog. A = onset of systole. B = ejection phase begins. C = end of systole. D = closure of aortic valves. (GREGG and GREEN. *Amer. J. Physiol.*, 1940, **130**, 114.)

Phasic Changes during Cardiac Cycle. The influence of the various phases of the cardiac cycle upon the coronary flow has been the subject of much debate. *A priori* we should expect that in systole blood would be squeezed out of the cardiac veins, and prevented from entering by the arteries. Anrep studied the coronary inflow and outflow separately, and found that, in fact, these do not run parallel. The coronary outflow shows three waves, very similar to those seen in the intra-auricular pressure ; the most rapid flow is seen during ventricular systole, and is no doubt due to a massaging action of the ventricular contraction expelling blood from the coronary veins. The other waves of the outflow are probably due to the effects of auricular contraction.

Study of the rate of inflow into the coronary arteries by the most critical methods shows that the most rapid entry is during diastole. During the stage of isometric ventricular contraction the inflow is suddenly reduced, or even reversed momentarily. As soon as the ejection phase begins, the coronary flow increases again and roughly follows the rise and fall of aortic pressure until the end of systole. After the dicrotic notch, with ventricular relaxation a sudden increase of inflow occurs, and this then slowly falls off with declining aortic pressure, until onset of the next systole. (Fig. 406).

Metabolism of Cardiac Muscle. The energy for the contraction of cardiac muscle comes ultimately from oxidative processes, and we have seen that the oxygen utilisation of the heart depends on the work done, and on its diastolic volume.

When the work of the *isolated* (*i.e.* denervated) heart is increased by raising either the aortic pressure or the output, the oxygen usage rises, and usually the efficiency rises too. The two methods of raising the work in the heart-lung preparation do not, however, produce the same effects on oxygen usage and hence on efficiency; when work is raised by increase of resistance the oxygen usage shows a greater increase than it does when the work is raised to an equal extent by increase of output. Hence a greater mechanical efficiency results from a given increase of work by increase of output than by increase of resistance. These inferences need to be qualified, however, for the heart *in situ.*

When the work of the heart *in situ* in the normal body is raised, the heart rate is usually altered: *e.g.* when the work is increased by raising the arterial resistance the heart rate is slowed (Marey's reflex), while if it is raised by increase of output the rate is accelerated (Bainbridge reflex). These results are due to alterations, in the appropriate direction, of vagus and sympathetic tone. The question as to what happens to oxygen usage and efficiency when the work of the heart *in situ* is raised therefore resolves itself into two subsidiary questions, viz. (1) What is the effect of alteration of rate ? (2) What, if any, is the effect of a change of vagus and sympathetic tone, apart from that due to change of heart rate ?

It is generally admitted that increase of rate leads to an increase, though not a proportionally great one, in metabolism. When the heart is slowed by increase of vagal tone there is a greater reduction in the oxygen usage than could be accounted for by the reduction in number of beats, and conversely increase of the sympathetic tone (or the action of adrenaline) causes a disproportionately great increase in metabolism. Hence it was found that, owing to the increased vagal tone, increase of work due to rise of arterial pressure in the innervated heart was often effected without any increase of oxygen usage at all, and so the heart worked *much more efficiently at the higher load than at the lower.* This provided a marked contrast to the denervated heart, which was very well seen in some cases where for some reason slowing did not occur. The adjustment is called the "unloading reflex."

A further contrast is seen when comparison is made between increase of work by increased resistance and increased output respectively, *e.g.* in the following example (see table below) the work was doubled.

These results teach us two things. First, that it is a property of cardiac muscle *per se* to respond by a greater increase of metabolism to rise of arterial pressure than to increase

Denervated Heart. (Evans and Matsuoka, 1914.)

Method of Increasing Work.	Ao. Pressure min. Hg.	Output c.c./min.	Rate per min.	Work kg.-m./min.	O_2 used c.c./min.	Efficiency. Per cent.

of output and to reach the limits of its performance earlier in the former case than in the latter. Secondly, that when provided with its normal innervation, so that cardiac reflexes are operative, this property is so modified that rises of arterial pressure can be dealt with at least as economically as increases of output.

The cardiac metabolism also depends on the temperature, and on the influence of certain chemical agencies. Thus, if adrenaline is present there is a large increase in the oxygen usage of the heart, which is made possible by the accompanying augmentation in the coronary blood flow. The following experiment illustrates this effect :—

EFFECT OF ADRENALINE 0·2 MG. ON HEART-LUNG PREPARATION OF DOG. (EVANS and OGAWA. *J. Physiol.*, 1914, **47,** 446.)

Heart 58·5 g ; art. press. = 100 mm. Hg ; output c̄. 10·5 l./hr.

	Period of Observation mins.	Average Heart Rate p. m.	cc. p. hour. by H.-L. P.		R.Q.
			O_2.	CO_2.	
Before adrenaline .	80	145	202	164	0·81
After ,, .	30	218	597	463	0·78

A small dose of adrenaline may enable either a normal or a hypodynamic heart to perform tasks previously too great for it. The heart volume is reduced and much greater pressures and volumes of blood can be dealt with. But as the oxygen usage shows, the effect, at least on the *denervated heart,* is not economical but profligate. The heart has been flogged to inordinate activity, and although the work has been done the cost has been high and the efficiency correspondingly low. In fact, by prolonging the administration, the heart works apparently well for a time, and then, with scarcely any warning, passes into acute failure.

When adrenaline is given to an *innervated heart* connected by its nerves to a separately perfused head, the " unloading reflex " already mentioned is brought into play, the increased vagus tone opposing the stimulating effect of adrenaline on the cardiac metabolism, which shows a sharp peak followed by a fall ; the coronary flow is increased greatly so that the venous blood is never very deoxygenated.

Adrenaline also exerts an effect owing to its action on centres in the brain. To study the central effect of adrenaline, the drug is given to the perfused head of an innervated heart-lung preparation, but not to the heart itself. The result is great reduction of metabolism, slowing and transitory coronary constriction.

Finally, when adrenaline is given to the whole animal we have both types of action—the unloading reflex from the heart itself and the central unloading reflex, both of which antagonise the direct effect of adrenaline on the heart. As the outcome of the competition between them there usually results an actual *diminution* of oxygen usage and of rate, while the work done may even increase. Coronary flow is greatly augmented, and the coefficient of oxygen utilisation is much reduced, because the direct effect of adrenaline on the coronary vessels is greater than the reflex constrictor effect. The efficiency is greatly increased, as contrasted with the lowered efficiency in the isolated heart.

In chemical composition the heart muscle somewhat resembles striated muscle ; it contains glycogen, adenosine triphosphate, and creatine phosphate, though the latter is in smaller amount than in striated muscle. It would be expected, therefore, that it might resemble striated muscle in the nature of the chemical reactions associated with contraction, but, in fact, there are certain clear differences.

The metabolic changes in the heart can conveniently be studied by analysis at intervals of the blood in the heart-lung preparation, and this has often been done. But it has the drawback that the metabolism of the lungs cause changes in the blood which are by no means negligible ; the most conspicuous change introduced by the lungs is a great acceleration of glycolysis, by which the blood glucose is converted into lactic acid in passing through the lungs.*

---

* EVANS, HSU and KOSAKA. *J. Physiol.*, 1934, **82,** 41

In order to eliminate the lungs, and so obtain a clearer picture of the sugar usage and metabolism of the blood-fed heart doing work, the lungs can be replaced by an artificial oxygenator. Such a heart-oxygenator preparation, * which has other applications also, is shown in Fig. 407.

The two auricles are supplied with blood through the adjustable taps R and L, and cannulæ 1 and 2, from a narrow common reservoir V.R. This reservoir is kept full to overflowing with blood from a stock reservoir, S.R. by the pump P, the blood passing on its way through a warming tube W and a filter F. The unwanted overflow from V.R. passes by the siphon S along the overflow tube O.T., back again to the stock reservoir. Blood expelled from the aorta passes by cannula 4 through an adjustable pneumatic resistance A.R. (as used for a heart-lung) back into V.R.; the rate of output can be measured when required in the graduated vessel A.O. (Not all the blood expelled by the left ventricle passes out by cannula 4, because the coronary supply has been deducted from it.) Blood from the right ventricle (which consists of that entering from cannula 1 plus that returning from cardiac veins) passes through the variable resistance P.R. (which can be omitted), through the graduated vessel P.O., and on to the spinning plate of a Drinker oxygenator, D.O. This is filled with suitable gas, generally oxygen containing 5 per cent. CO_2, and the blood flowing down its sides becomes arterialised and enters the stock reservoir S.R. again. Auricular and arterial pressures are given by the four manometers shown in the figure.

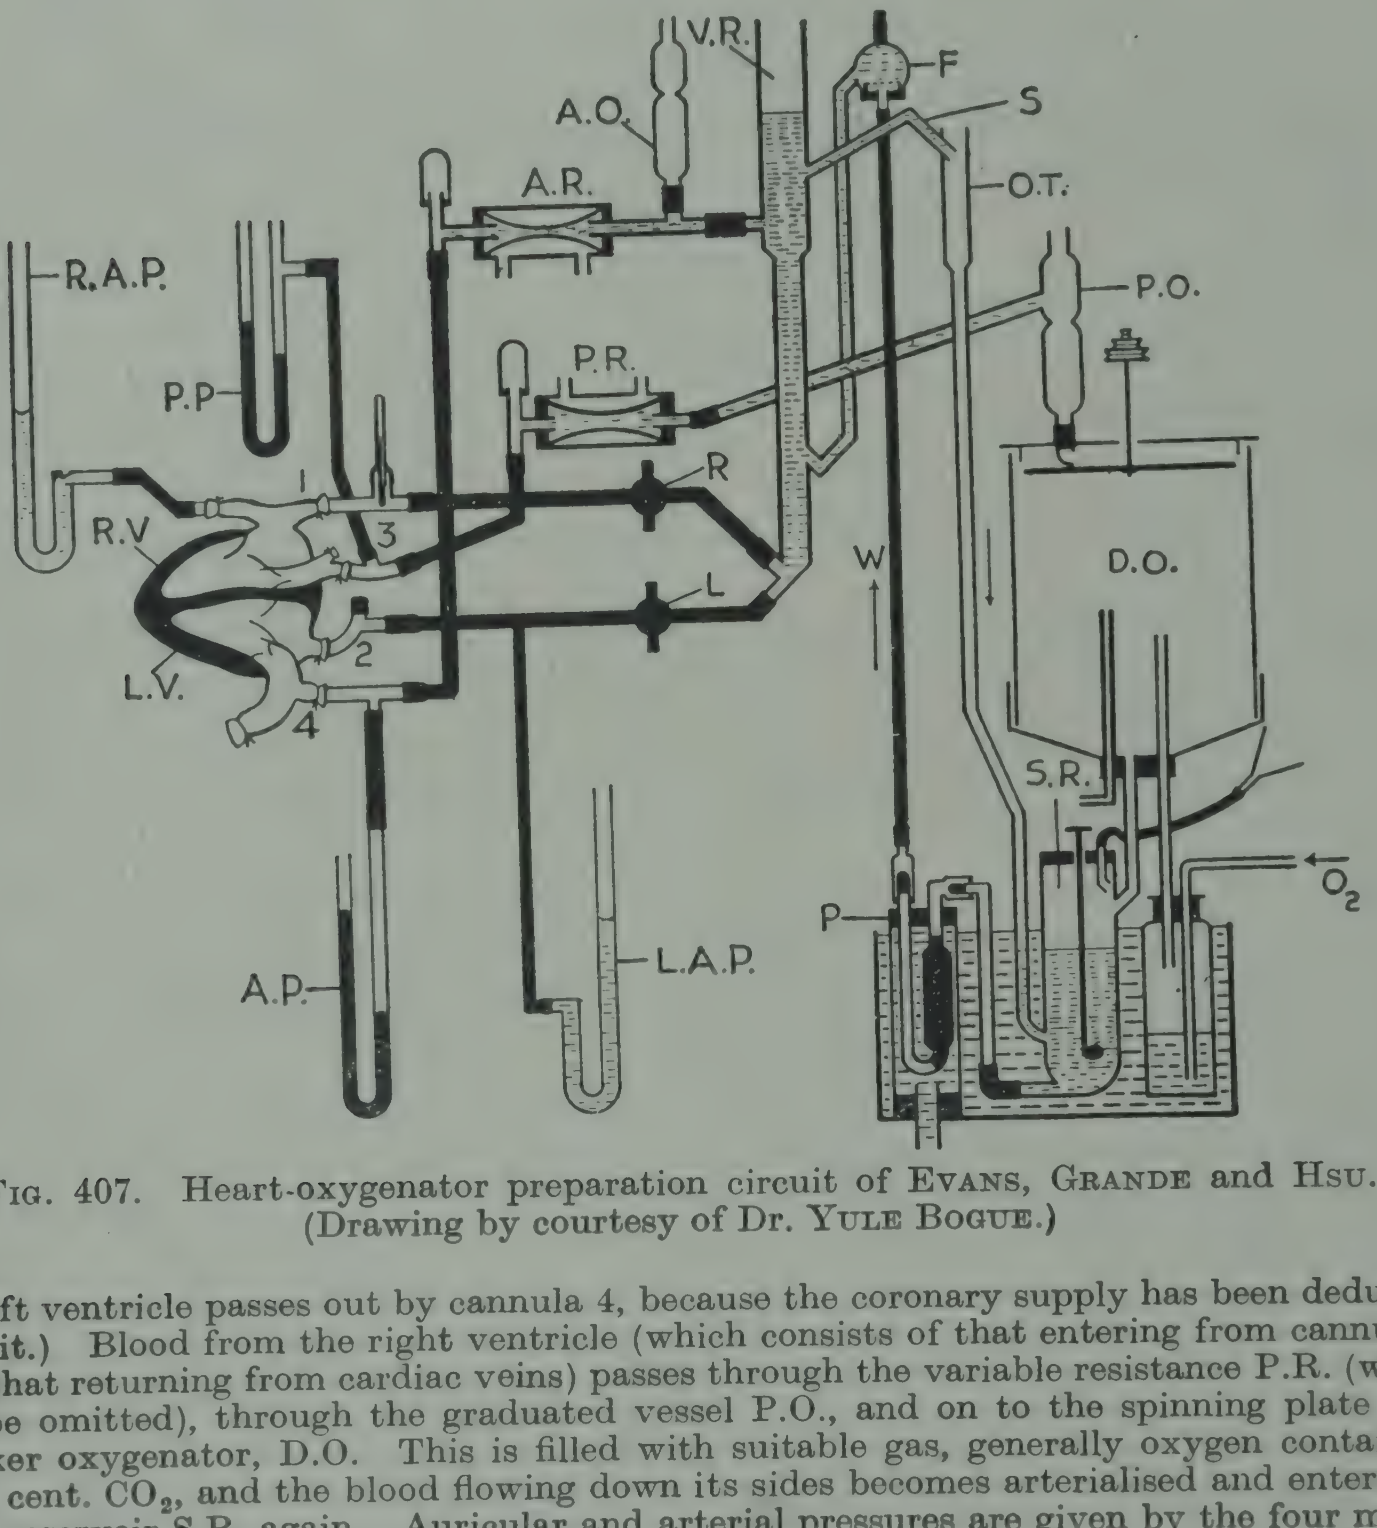

FIG. 407. Heart-oxygenator preparation circuit of EVANS, GRANDE and HSU. (Drawing by courtesy of Dr. YULE BOGUE.)

With this preparation the isolated heart can perform work at reasonable rates for several hours, the conditions of pressure and output on the two sides being independently adjustable. It will also be evident that by closing tap R, the only blood entering and leaving the right side will be the coronary venous blood, the rate of flow or chemical composition of which can thus easily be determined.

It can be calculated that if the heart were only oxidising its own glycogen as a source of energy and not replacing it, a dog's heart containing about 0·7 per cent. glycogen should only be able to work for at most two hours, before exhausting all its glycogen. Since the isolated heart easily works for four or five hours, at the end of which time it often contains an amount of glycogen normal for a fresh heart, it is evident that it either does not normally use glycogen, or else that the glycogen is replaced as used. Now it has long been

---

* EVANS, GRANDE and HSU. *Q. J. Exp. Physiol.*, 1934, **24**, 283.

known that the heart can remove sugar from the blood, but it has also been shown that the amount used under ordinary conditions is too small to supply the energy requirements.* It does, however, quite unlike skeletal muscle, readily use lactic acid from the blood.*† It also easily consumes pyruvic acid.‡ The amounts of glucose and lactate used vary reciprocally, so that if lactate is absent, glucose is used in greater amount, and *vice versâ*. The ordinary dog heart, in a heart-oxygenator circuit uses about 70 mg. glucose and 200 mg. lactic acid per 100 g./hour,† but if the work is increased the amounts of both are greater. §

The lactic acid used by the heart is normally formed from blood glucose by glycolysis in the blood stream, this process being accelerated in passage of the blood through the lungs. If, in a heart-oxygenator circuit, the heart is allowed to use up all the glucose and lactate, or if it is subjected to intense work, it then draws upon its own glycogen. It should be noted that in the absence of lactate from the blood, the heart becomes weak, but is restored to a better condition by the addition of lactate, which is more effective for the purpose than is glucose. The glycogen of heart muscle is formed from blood glucose, but not from lactate.‖

In addition to carbohydrate and lactic acid, the heart muscle probably utilises fat¶ ; its respiratory quotient is about 0·8 to 0·85. It is uncertain at present whether the heart draws on its glycogen normally, and continually replaces it from glucose, or whether it normally burns glucose and lactate direct, keeping the glycogen in reserve for emergencies. In oxygen lack, lactic acid is formed by the heart, and glycogen is lost.

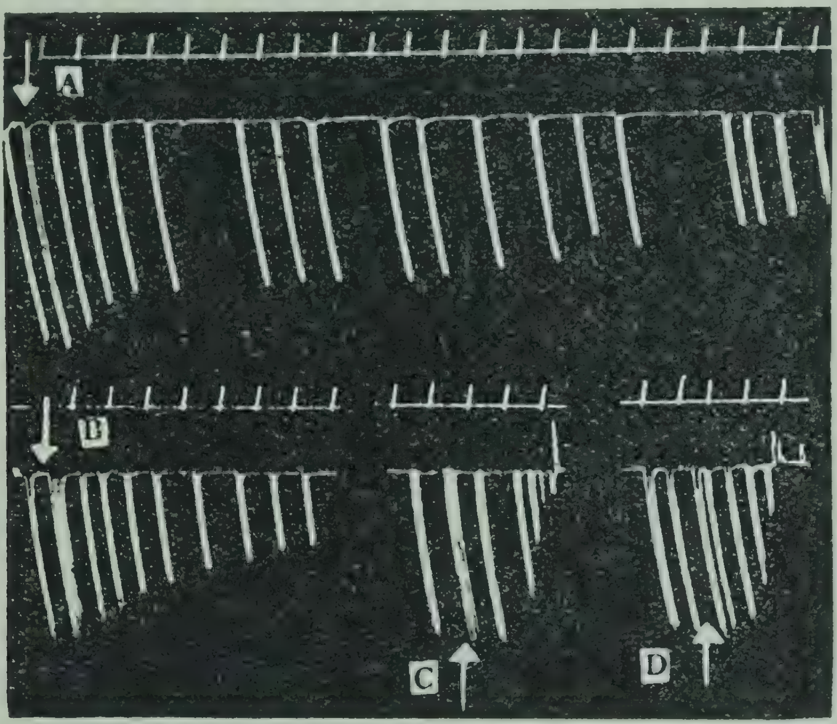

FIG. 408. Illustrating the effect of asphyxia on the frog's heart. Isometric contractions were taken for short periods at irregular intervals—downstroke = systole, time = minutes. The arrow shows commencement of full anaerobiosis.
A. Normal ventricle filled 0·3 c.c. of equal parts plasma and Ringer's fluid.
B. Normal ventricle filled 0·3 c.c. unbuffered Ringer's fluid.
C. Ventricle after poisoning with iodoacetic acid, 1 part in 20,000. Filling as in B.
D. Ventricle poisoned iodoacetic acid filled with 2 c.c. equal parts plasma and Ringer's fluid. (CLARK, *Quart. J. Exp. Physiol.*, 1935, **25**, 167.)

Further light is thrown on the chemistry of cardiac muscle by the study of the effect of oxygen lack and of iodoacetic acid. It will be recalled that when a skeletal muscle is poisoned with iodoacetic acid, no lactic acid is formed on contraction, but that contractions can be repeated in the presence or absence of oxygen until all the creatine phosphate has been broken down.

¶ CRUICKSHANK and KOSTERLITZ. *J. Physiol.*, 1941, **99**, 208.

The heart, poisoned with iodoacetic acid, can contract for an indefinitely long time if oxygen is available * ; its usage of lactate is unaltered and its phosphagen content not reduced. When oxygen is withdrawn from it, however, it fails after a very few beats † (Fig. 408). We may provisionally interpret these results as follows : The energy for contraction is given immediately or mediately by the breakdown of A.T.P. and phosphagen ; the energy for resynthesising these is provided normally by the *oxidation* of pyruvic or lactic acid. If oxygen is lacking, however, glycogen is broken down instead (as is normal in all cases for skeletal muscle), with formation of lactic acid, and this change now provides the necessary energy. When poisoned with iodoacetic acid, formation of lactic acid from glycogen is no longer possible ; hence, withdrawal of oxygen leads to rapid failure of the heart.

It seems that this oxidation of pyruvic and lactic acid represents an essential aspect of the metabolism of the heart. If the lactate is present in abundance in the blood it is that which is burned. When adrenaline is given the lactate demand of the heart is greatly increased. If lactate is lacking from the blood, then it must be obtained by breakdown of the heart's own glycogen. This, however, is either at once, or later on, replaced from blood sugar if any is available ; but if not, the glycogen will continue to fall until, when it is all, or nearly all, exhausted, the heart fails.

This theory, that oxidation of lactic acid is the central point of cardiac metabolism, explains why lactate cannot form glycogen, but why when abundant in the blood it can prevent glycogen loss.

It may well be that the fundamental difference between cardiac and skeletal muscle is to be sought in two structural differences. First the blood supply of cardiac muscle is relatively greater, and secondly the cardiac muscle cells have no sarcolemma. The first provides for a much more abundant oxygen supply, thereby facilitating all oxidative arrangements ; the second enables lactate to pass readily into or out of the muscle cell and so, if present in the blood, to be readily available for the latter. The ability of the heart to utilize lactate places it in a favourable position in severe muscular exercise.

CHAPTER XXXIII

DYNAMICS OF THE CIRCULATION

BLOOD PRESSURE

Since the blood travels from the arteries to the veins, it is evident that the pressure which drives it onwards must get less and less as it passes along.

On cutting through an artery, blood escapes from the end nearest the heart, with great force and in a series of spurts, each of which corresponds to a contraction of the ventricles. This shows that in the arteries the blood is at a high pressure, and that the flow from the heart is a pulsatory one.

The same lesson was learnt by an experiment, which was first performed in 1732 by the Rev. Stephen Hales,* and may be described in his own words :

> " In December I caused a mare to be tied down alive on her back. Having laid open the left crural Artery about three inches from her belly, I inserted into it a brass Pipe, whose bore was one sixth of an inch in diameter ; and to that, by means of another brass Pipe which was fitly adapted to it, I fixed a glass Tube, of nearly the same diameter, which was nine feet in length : Then untying the Ligature on the Artery, the blood rose in the Tube eight feet three inches perpendicular above the level of the left Ventricle of the heart : But it did not attain to its full height at once ; it rushed up about half way in an instant, and afterwards gradually at each Pulse twelve, eight, six, four, two, and sometimes one inch : When it was at its full height, it would rise and fall at and after each Pulse two, three, or four inches."

Arterial and venous blood pressures are now measured by special manometers, arterial pressures being recorded in terms of the pressure of a column of mercury.

If a vein be ligatured, it swells up on the distal side of the ligature. If the vein be cut across, blood escapes chiefly from the peripheral end, and instead of spurting out with each heart beat, it flows steadily and with very little force, so that light pressure by a bandage is sufficient to restrain the hæmorrhage. Since venous pressure amounts to only a few millimetres Hg., it is customary to use manometers filled with an aqueous solution, *e.g.*, sodium citrate, for venous pressure experiments.

By taking the pressure at different parts of the circulation, we obtain a distribution which is represented roughly in Fig. 339, p. 538. The blood pressure, which is about 100 to 120 mm. Hg in the large arteries near the heart, falls only slowly in these arteries, so that in the radial artery it is not very much below that in the aorta. Between the medium-sized arteries and capillaries there is a very extensive fall of pressure as the blood passes through the arterioles, so that in the capillaries the pressure on an average may be taken as 10 to 20 mm. Hg ; from the capillaries to the veins the blood pressure falls steadily until in the big veins near the heart it may be " negative," *i.e.* below atmospheric pressure.

The following table may serve to give an idea of the average height of the *mean* (not systolic) blood pressure at different parts of the vascular system in a young adult man, in the horizontal position. The pressures are all subject to considerable variations according to the activity of the individual and of the various parts and organs of the body :

Large arteries (*e.g.* carotid)		90 mm. mercury (65–110).
Medium arteries (*e.g.* radial)		85 mm. ,,
Capillaries	about	10 to 30 mm. mercury.
Small veins of arm		9 mm. mercury.
Portal vein (estimated)		10 mm. ,,
Inferior vena cava (estimated)		3 mm. ,,
Large veins of neck	from	0 to − 8 mm. mercury.

---

* Hales. " Statical Essays ; Hæmastatics, etc.," 1769, (London), **2**, p. 1.

The Arterial Pressure. The *mercurial manometer*, used for measuring and recording arterial pressure, consists of a U-tube with two vertical limbs about a foot in height, which is half-filled with mercury (Fig. 409). On the surface of the mercury of one limb is a float of vulcanite from which a stiff fine rod rises, bearing on its upper end the writing-point which writes on the travelling paper surface. Since the mercury is displaced equally, up in one limb and down in the other, it is obvious that any displacement as recorded must be multiplied by two to obtain the actual pressure in terms of a mercury column. The other limb of the manometer is connected by a side-branch and a flexible inextensible tube with a cannula, which is tied into the central end of an artery, a clip being previously placed on the artery so as to prevent the escape of blood. This limb is also connected, through a tap, with a reservoir bottle placed several feet above it, and filled with sodium citrate (4 per cent.) First, the tap is opened and the manometer, connecting-tube and cannula filled with this solution. The tap is then closed so that the manometer remains in connection only with the cannula, the mercury in that limb being now, say, about 150 mm. above that in the other. The clip is then taken off the artery. The pressure in the cannula being greater than that in the artery, a small amount of the fluid used to fill the tubes runs into the circulation. The mercury in the manometer drops to a height, usually of 100 to 120 mm. Hg., and stays about that level, rising and falling slightly with each heart beat (Fig. 410). Any blood which enters the cannula does not clot for a considerable time, owing to its admixture with the citrate.

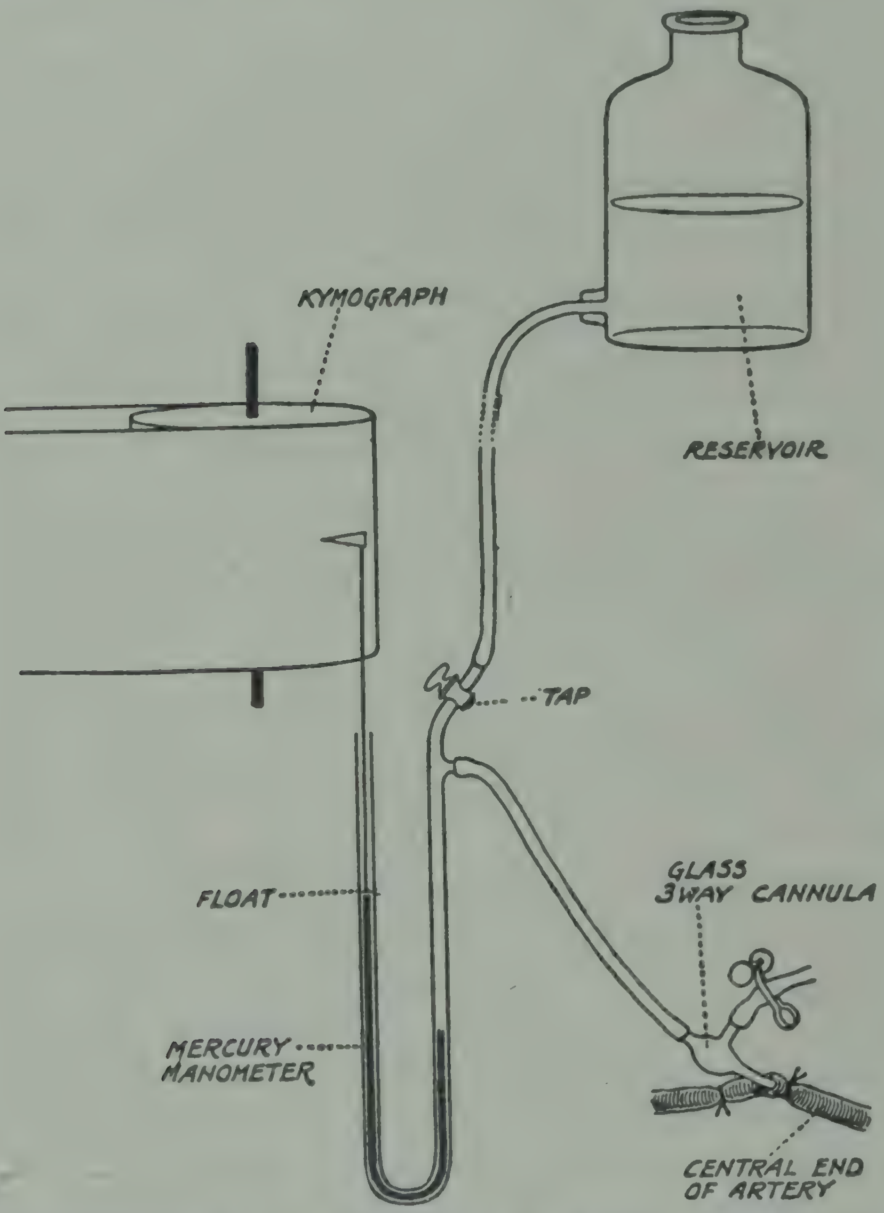

FIG. 409. Arrangement of an Apparatus for taking Blood Pressure Tracing.

The arterial blood pressure as recorded by a mercurial manometer exhibits a series of pulsations, each corresponding to a heart beat (Fig. 410). These pulsations are due to the fact that at each systole, blood is pumped out through the aortic valve, so that the artery becomes distended. During diastole, the aortic valves are closed, and blood passes on from the distended arteries into the capillaries and veins, so that the blood pressure falls. The mercurial manometer, however, owing to the inertia of the column of mercury, does not register accurately these rapid changes of pressure in the artery. With a wide-bore manometer, in fact, the oscillations may be almost imperceptible. But it gives a true and valuable record of the *mean arterial pressure*.

In order to determine the true course of the pressure changes in the arteries it is necessary to diminish to the utmost extent the inertia of the moving parts of the recording instrument, as in one of the forms of manometer already described, (p. 557) in which the pressure changes are registered photographically.

Examination of records obtained by these superior methods (Fig. 410) shows that the variation in the arterial pressure at each heart beat is much greater than would be anticipated from the tracing given by the mercurial manometer. The highest pressure, which occurs while blood is passing from the heart into the aorta, is called the *systolic arterial pressure :* the pressure at the end of diastole is the *diastolic pressure :* and the range between these two extremes is known as the *pulse pressure.* In many animals the systolic pressure as measured in the carotid artery, is under normal conditions about 120 mm., while the diastolic pressure is only about 75 mm., so that the pulse pressure is about 45 mm. Hg. As we pass outwards towards the periphery the pulse pressure becomes less and less, until finally, in the capillaries and veins, there are usually no pulse waves perceptible.

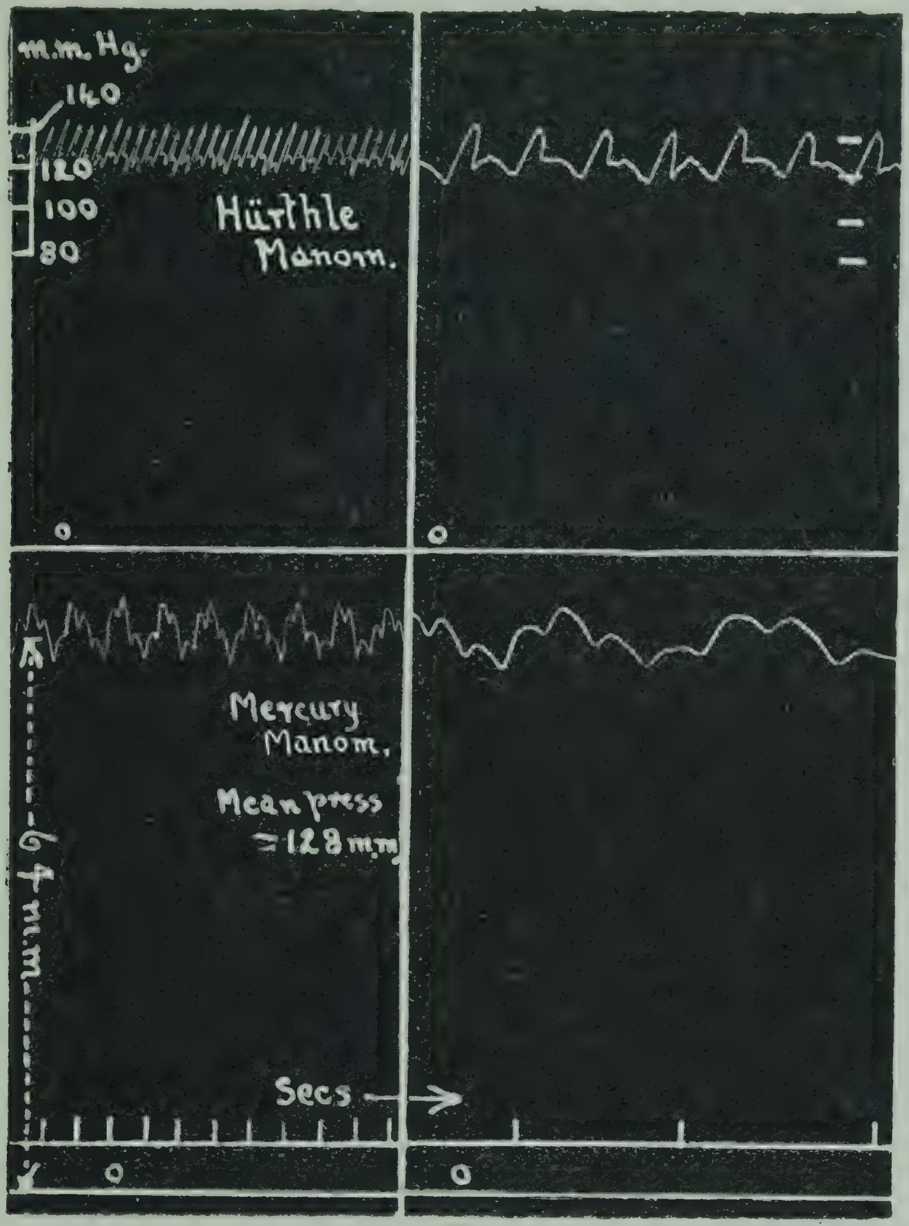

FIG. 410. Arterial Blood Pressure from carotids of Dog, recorded simultaneously with Hürthle Manometer (upper tracing) and Mercury Manometer (lower tracing), on slowly and rapidly moving surfaces. The form and extent of each pulse is much more correctly shown by the Hürthle Manometer, but the slower changes due to respiration are more evident with the Mercury Manometer. 0 = line of zero pressure. The left-hand half is on a slowly moving, and right hand on rapidly moving surface. (C. L. E.)

The Venous Pressure. In experimental animals the venous pressure may be recorded by connecting a branch of the required vein with a manometer filled with $NaHCO_3$ solution or 4 per cent. citrate, and provided with a light recording float. It is important that there should be no valve in or near the branch selected ; consequently the choice of veins is restricted, and the significance of results often in doubt. Venous pressures near the periphery are not definitely pulsatile, but in the great veins there are considerable pulsations, the venous pulse (p. 640), and these need special methods of recording.

ARTERIAL AND VENOUS BLOOD PRESSURE IN MAN

Arterial Pressure. The determination of the systolic pressure in the arteries is easily carried out by the use of the sphygmomanometer,* of which there are many modifications. This apparatus (Fig. 411) consists of a leather or canvas cuff about 10 cm. wide, which can be buckled closely round the upper arm. Inside this band is a rubber bag of the same shape, which communicates by a rubber tube with a mercurial manometer or other pressure gauge, and by a side tube with an air pump, and with an outlet valve. The band is buckled round the upper arm and the fingers of the observer are placed on the radial pulse. The bag is then distended with air so that it exercises a pressure on the arm, the pressure being indicated on the mercurial manometer. Air is forced in until the radial pulse disappears. By means of the outlet valve the air is then let slowly out of the bag until the radial pulse is just perceptible. The height of the mercurial manometer at this moment is equal to the systolic pressure in the main arterial trunk from which the brachial artery takes origin.

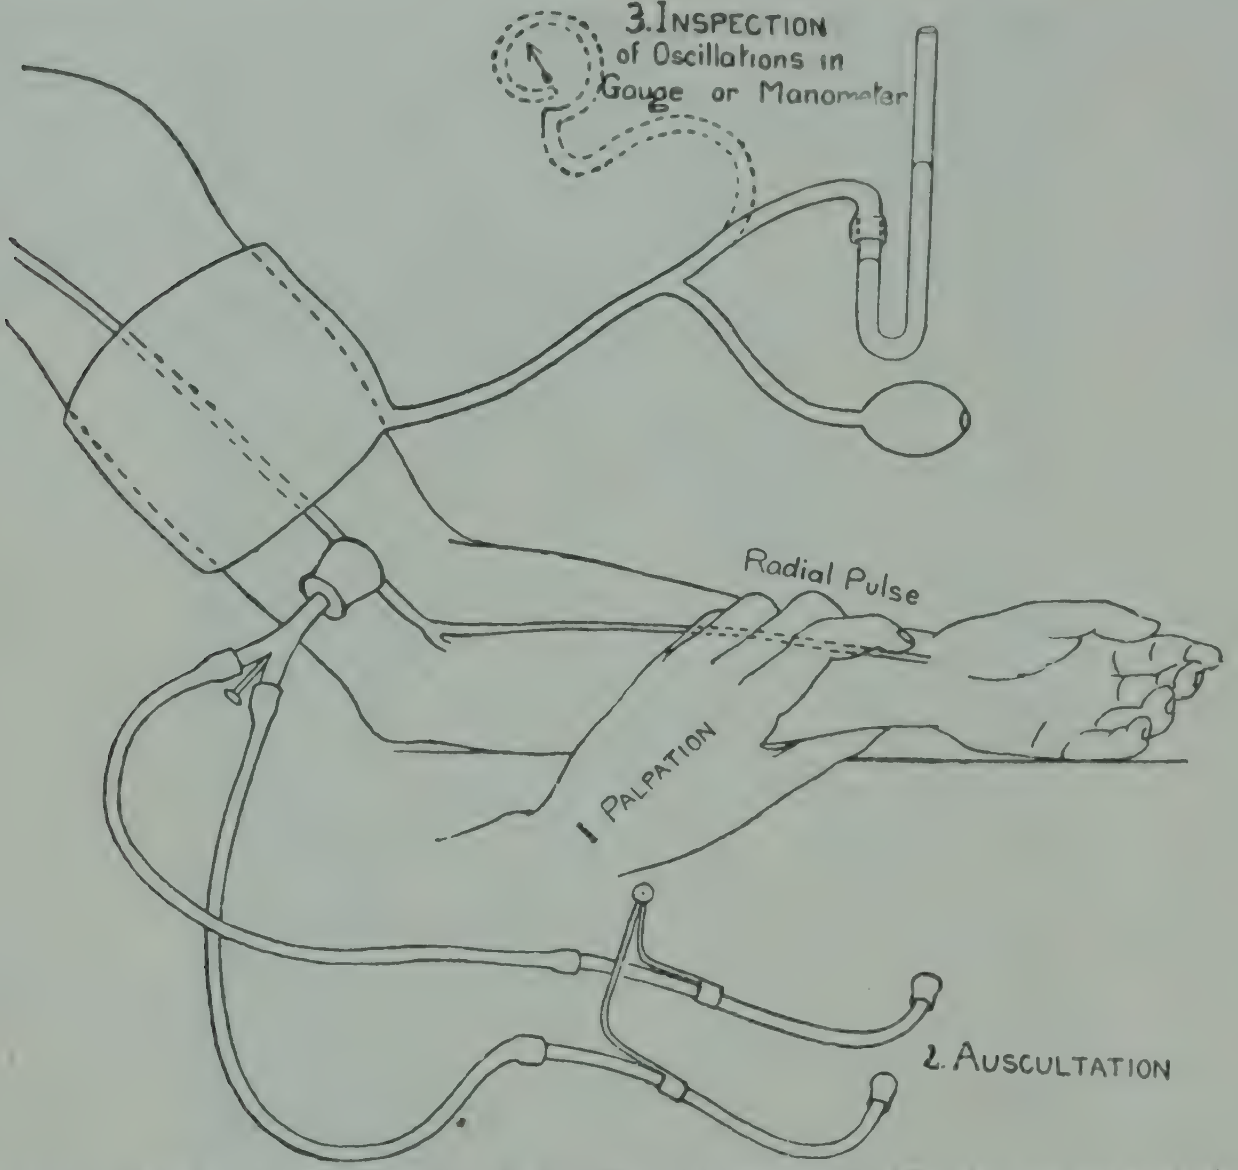

Fig. 411. Methods of using the Sphygmomanometer. (Outlet valve not shown.) (Harris, "Experimental Physiology.")

The principle of this method will be made clear by reference to the diagram (Fig. 412). If we imagine A as a segment of the brachial artery passing through the tissues which are surrounded by the rubber bag, we see that so long as the pressure in the interior of the artery is greater than that exerted by the tissues on the exterior, the artery will be patent and the pulse can pass through. If, however, the pressure in the tissues becomes greater than the maximum pressure inside the artery, the segment of artery will collapse (as in B), thus stopping the transmission of the pulse wave. If we exclude the elasticity of the tissues themselves, we may take the pressure in the bag as representing the pressure in the tissue fluids surrounding the artery, so that the pulse-obliterating pressure in the bag will correspond to the systolic pressure in the artery.†

By a slight modification of the apparatus it is also possible to determine the diastolic pressure. For this purpose the rubber bag is connected with a gauge of small inertia, giving a true representation of the actual changes of pressure. When the pressure in the bag just exceeds the diastolic pressure, the artery will be collapsed in diastole, and will then dilate almost to the utmost with the systolic rise of pressure. If we are taking a record of the pressure changes in the bag in this way, the pulse waves as recorded by the manometer will slowly increase in size as the pressure in the bag is gradually raised from zero. At one point the waves rapidly reach a maximum, and the pressure in the bag at this point is taken as the diastolic pressure. As the pressure is still further raised, the excursions of the manometer diminish again, first slowly and then rapidly, and the point of rapid diminution corresponds to the systolic pressure. Above this point the manometer still shows small oscillations, due to the impact of the stump of the occluded artery on the upper border of the bag.

† Mummery. *J. Physiol.*, 1905, **32**, Pr. xxiii.

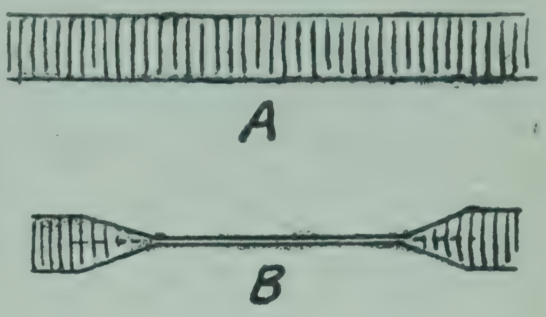

FIG. 412.

THE AUSCULTATORY METHOD. The most convenient method of finding systolic and diastolic pressures in the artery is to apply the bell of a stethoscope over the brachial artery a little distance below the cuff of the sphygmomanometer. When the cuff is rapidly inflated to a point beyond the extinction of the pulse, and then gradually deflated, a series of sounds ("Korotkov sounds") are heard, divided by Wiggers into five periods:

(1) As the pressure falls there is a sudden appearance of a clear sound, as the first flow of blood occurs through the compressed artery. This corresponds to the *systolic pressure.*
(2) The sound becomes more continuous, like a murmur.
(3) The sound becomes progressively louder.
(4) The sounds suddenly become muffled; this is the *diastolic pressure.*
(5) The sounds disappear.

The arterial pressure varies over a wide range in normal subjects, and over a narrower range from time to time in any given healthy subject. Values often quoted for adults are 120 mm. Hg systolic and 75 mm. Hg diastolic, usually written 120/75, but the errors of estimation are considerable, and it would be incorrect to accept these values as fixed standards of normality.* Apart from the incidence of disease, there is a tendency for arterial pressure to increase with age, *e.g.* at six months about 90/60, at four years about 100/65, at sixteen about 120/62, but different observers usually get different actual figures. A survey of systolic blood pressures in 7,216 apparently normal persons between sixteen and forty years gave the following results (Alvarez †):—

	Age.	
	18 years.	16–40 years.
Number of cases	1,216	6,000
Mean systolic pressure . . .	130 mm. Hg.	128·9 mm. Hg.
Standard deviation	13·4 mm.	13·5 mm.

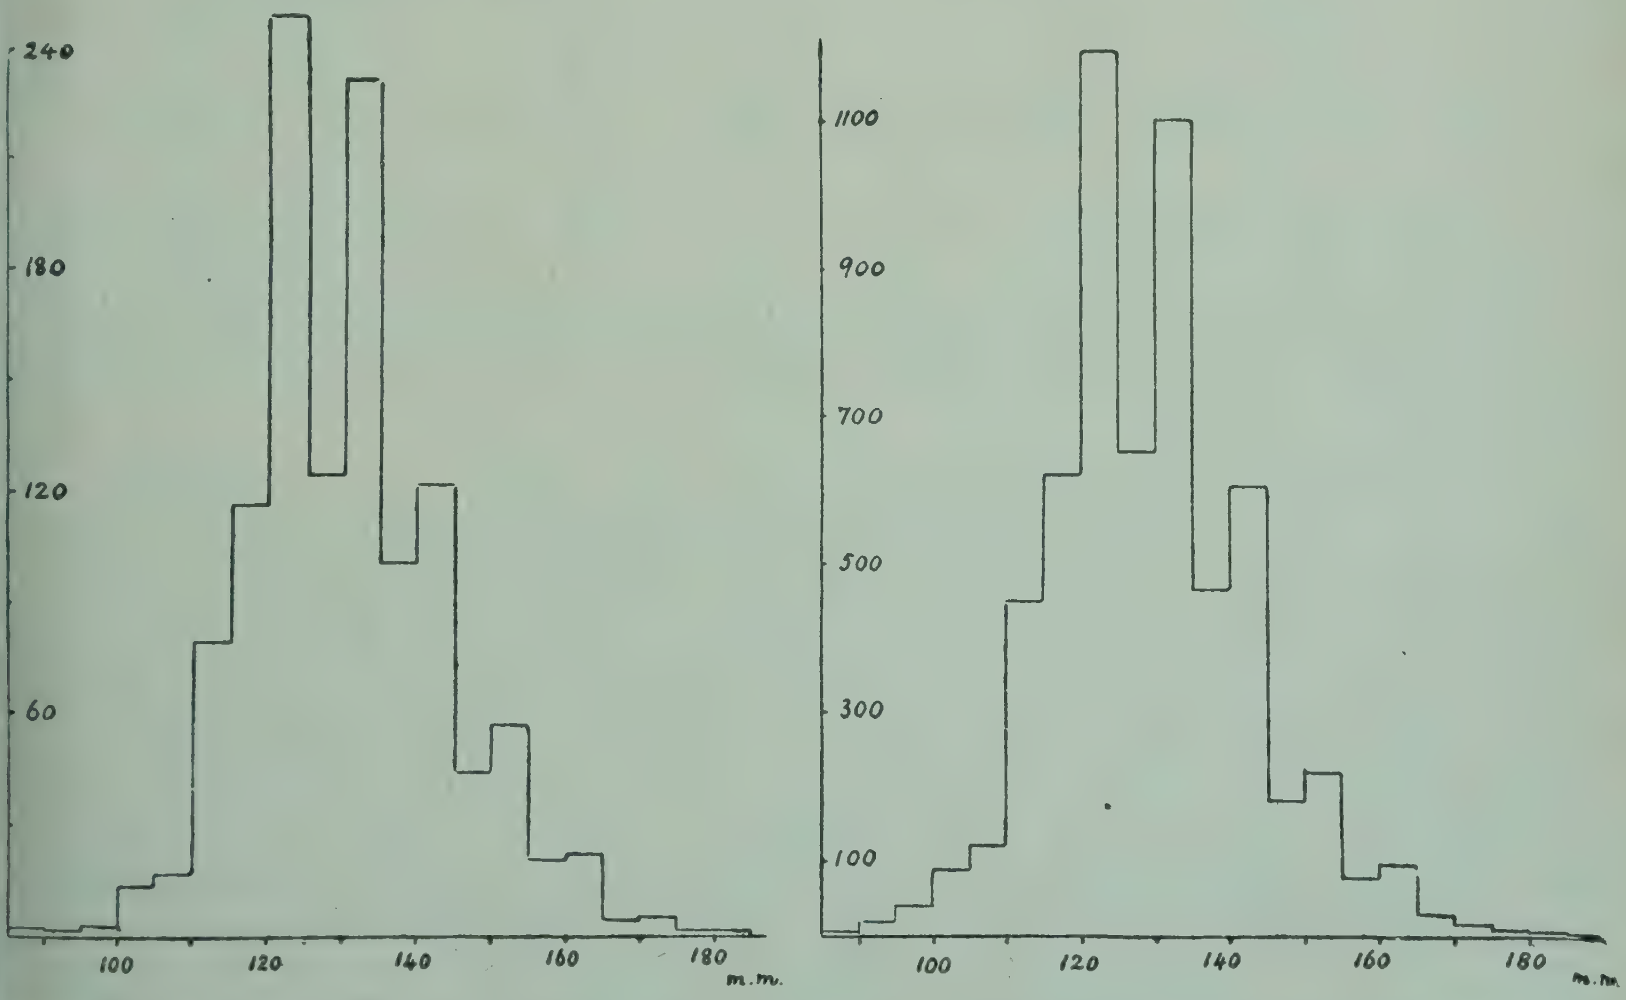

FIG. 413. Showing Frequency-distribution of the Normal Systolic Blood Pressure. (From Alvarez's tables.) Blood pressure as abscissa, number of persons as ordinate. On the left is shown the distribution of figures for 1,216 persons of 18 years of age. On the right figures for 6,000 persons from 16 to 40 years of age. (BURN. *Proc. Roy. Soc. Med.*, 1934, **28**, 15.)

* BURN. *Proc. Roy. Soc. Med.*, 1934, **28**, 5. TREADGOLD. *Lancet*, 8th April, 1933.
† ALVAREZ. *Arch. Int. Med.*, 1923, **32**, 17.

Unless we are to suppose that a proportion of these people were in an early stage of disease which at the time had produced no other effects, the figures mean that one-third of all males between the ages of sixteen and forty years of age have normal systolic pressures less than 116·5 mm. Hg or greater than 143·5 mm. Hg, *i.e.* one-sixth will have pressures normally over 143·5 mm. Hg. One man in about every forty will have a normal pressure greater than 157 mm. Hg, or less than 103 mm. Hg. The figures actually ranged from 85 mm. to 180 mm., in a distribution shown in the form of a frequency diagram in Fig. 413.

Venous Pressure. The pressure may be approximately estimated in the superficial veins in man by altering the elevation of the part containing the vein so that the vein just collapses: the horizontal distance of this level from the heart, or from some agreed surface marking, such as the manubrio-sternal junction, is then measured. This method of course only gives minimal pressures, the pressure in the feet when standing, for instance, being greater than when lying with the leg in such a position that the veins just collapse.

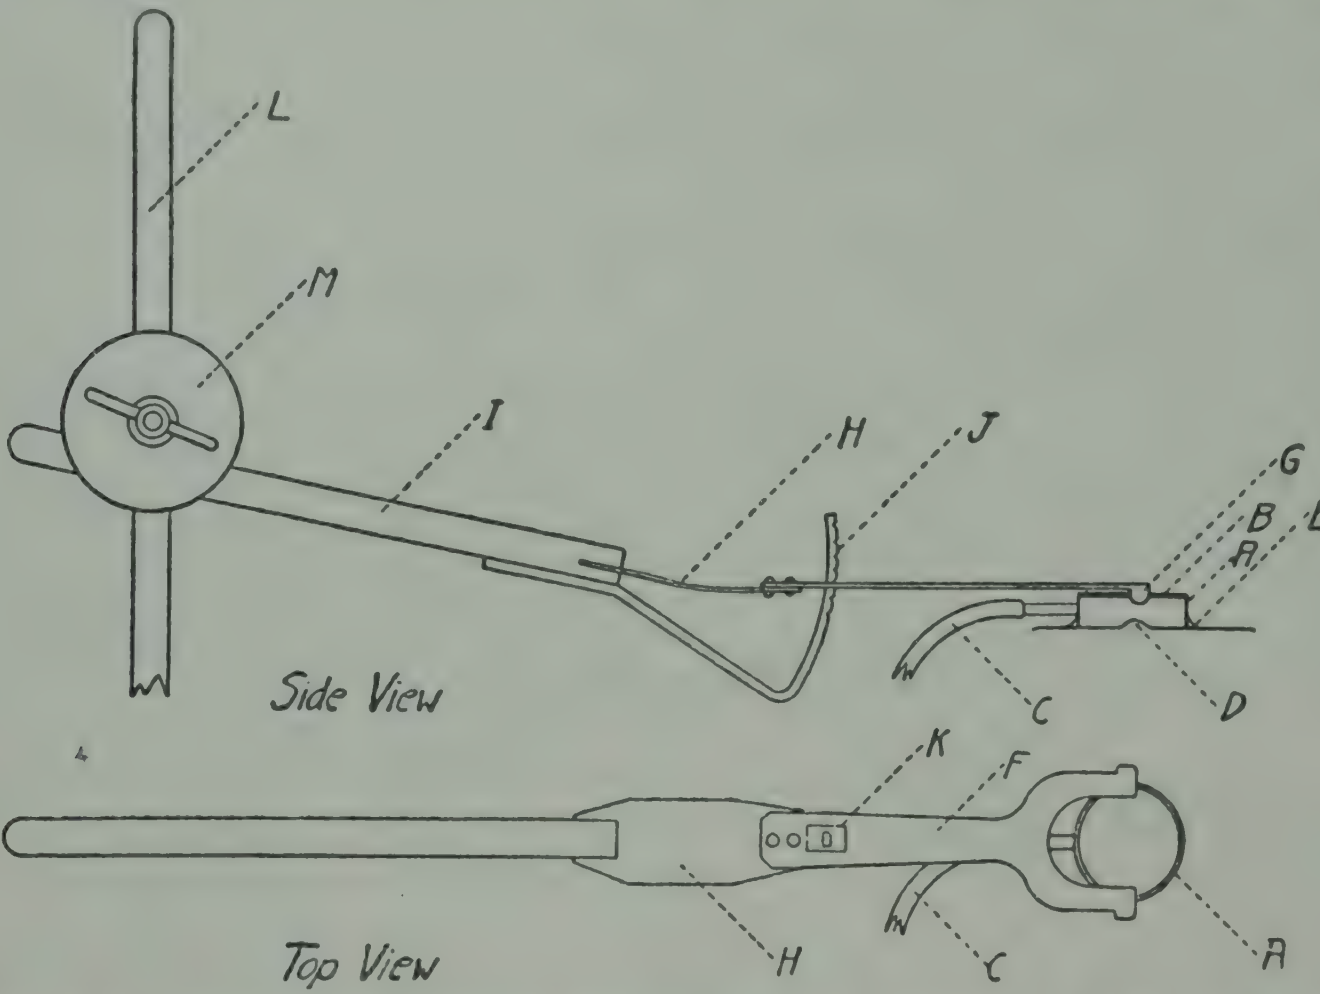

FIG. 414. Capsule for Measurement of Venous Pressures in Man. (KROGH TURNER and LANDIS. *J. Clin. Inv.*, 1932, **11**, 357.)

In order to determine the venous pressure directly the simplest way is to pass a hollow needle into the vein, and connect it with a citrate manometer by a connecting tube entirely filled with fluid. The level of the citrate solution is then referred to that of the manubrio-sternal junction; records of variations can be taken by connecting the open limb of the manometer to a tambour.*

Another method depends on the use of a principle introduced by v. Recklinghausen.† One of the modifications of this method is by Krogh, Turner and Landis ‡ (Fig. 414). A celluloid capsule A, with a celluloid top B, and a notch D on each side for the vein, is cemented to the skin over the desired vein, and held in position by a clamp having a steel spring H by which suitable pressure can be put on the capsule. A side tube C leads to a pressure bulb and water manometer, by which the air pressure inside the capsule can be altered to a known extent. The air pressure necessary to just collapse the vein is found, and is taken as equal to the venous pressure.

In the measurement of venous pressures it is customary to refer the hydrostatic level to that of the heart, but this is a purely arbitrary point and necessarily vague. It has in fact been shown that in the dead animal the reference point is caudal to the heart and is the same whether in the head-up or in the head-down position: in the living animal there are two reference points owing to the fact that the column of venous blood is interrupted by the heart; one point for the head section is above the heart and one for the tail section is below the heart.§ Owing to the uncertainty of the position of these reference points it is a common practice to measure the venous pressure levels from some definite anatomical point, *e.g.* the manubrio-sternal junction.

ELEMENTARY HYDRODYNAMICS OF THE CIRCULATION

The blood flows through a branched closed system of tubes of elastic properties and of extremely variable diameters; moreover it is not a homogeneous liquid. Also, it is pumped intermittently into the arteries. The physical principles involved are consequently of great complexity and are for the most part as yet incapable of strict mathematical treatment. Nevertheless, certain elementary principles of hydrodynamics help towards a partial elucidation of the problems involved.

The cause of the pressure gradients in the different parts of the vascular system will be rendered clearer by a study of the flow of fluid through a tube of uniform bore (Fig. 415) from a reservoir, the level in which is maintained constant, and which therefore exerts a constant hydrostatic pressure. It really amounts to the statement that water flows downhill. If the tube AG be connected with the reservoir R, fluid will flow out from G under the influence of hydrostatic pressure. The pressure on the fluid at each part of the tube can be measured by attaching at a series of points, *e.g.* at B, C, D, E, F—vertical tubes in which the fluid will rise to a height corresponding to the lateral pressure existing at these several points. If AG is of uniform bore, it will be found that the heights of the fluid in the tubes show a continuous descent, so that the line joining the tops of the fluid in the various tubes is a straight one. The movement of the fluid from D to E can be regarded as due to the difference of the pressure between D and E, *i.e.* P_4—P_5. It will be noticed in the diagram that the straight line joining the tops of the fluid does not strike the surface of the fluid in R, but falls a little below it. Of the total potential energy represented by the pressure H in R, the large portion h' is employed in overcoming the resistance to the flow in the tube AG, while the remainder h represents the force which gives to the fluid as it leaves the reservoir at A a certain velocity. The potential energy of the flowing liquid diminishes as it moves along, as is shown by the fall of lateral pressure, but the kinetic energy is constant throughout in such a uniform tube. If the flow of fluid be diminished by partially clamping the end at G, or by increasing the length of FG, the rate of fall of the pressures will be diminished. This is because in such a type of flow the velocity varies inversely as the frictional resistance, and *vice versâ*. A smaller portion (h) of the hydrostatic pressure is now used to impart velocity to the fluid, and a larger portion, h', to overcome resistance. The same effect will be produced either by raising the level of G or by lowering the level of the reservoir and so the pressure at A. This is because the velocity, and hence the frictional resistance, depends on the pressure difference.

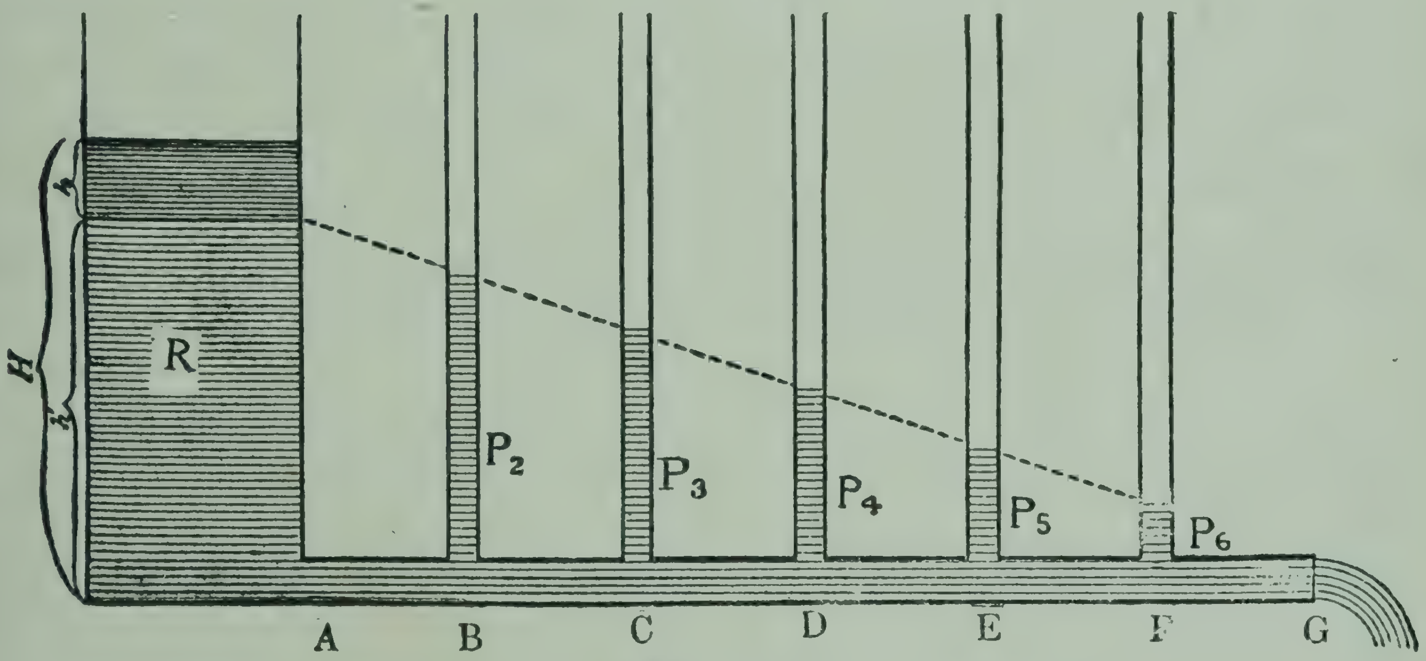

Fig. 415.

The difference of pressure between any two points, *e.g.* between D and E, may be regarded as that pressure which is necessary to maintain a certain volume-flow of the fluid against the resistance offered by the friction of the fluid in contact with the walls of the tube. This friction, and therefore the resistance to the flow, can be increased by diminishing the diameter of the tube, when a larger difference of pressure will be necessary in order to maintain the same flow. This can be shown by introducing a resistance between D and E by partially clamping the tube at this point (Fig. 416). The uniform fall of pressures in the vertical tubes is at once abolished. Between A and D there is a continuous, but slower, fall,

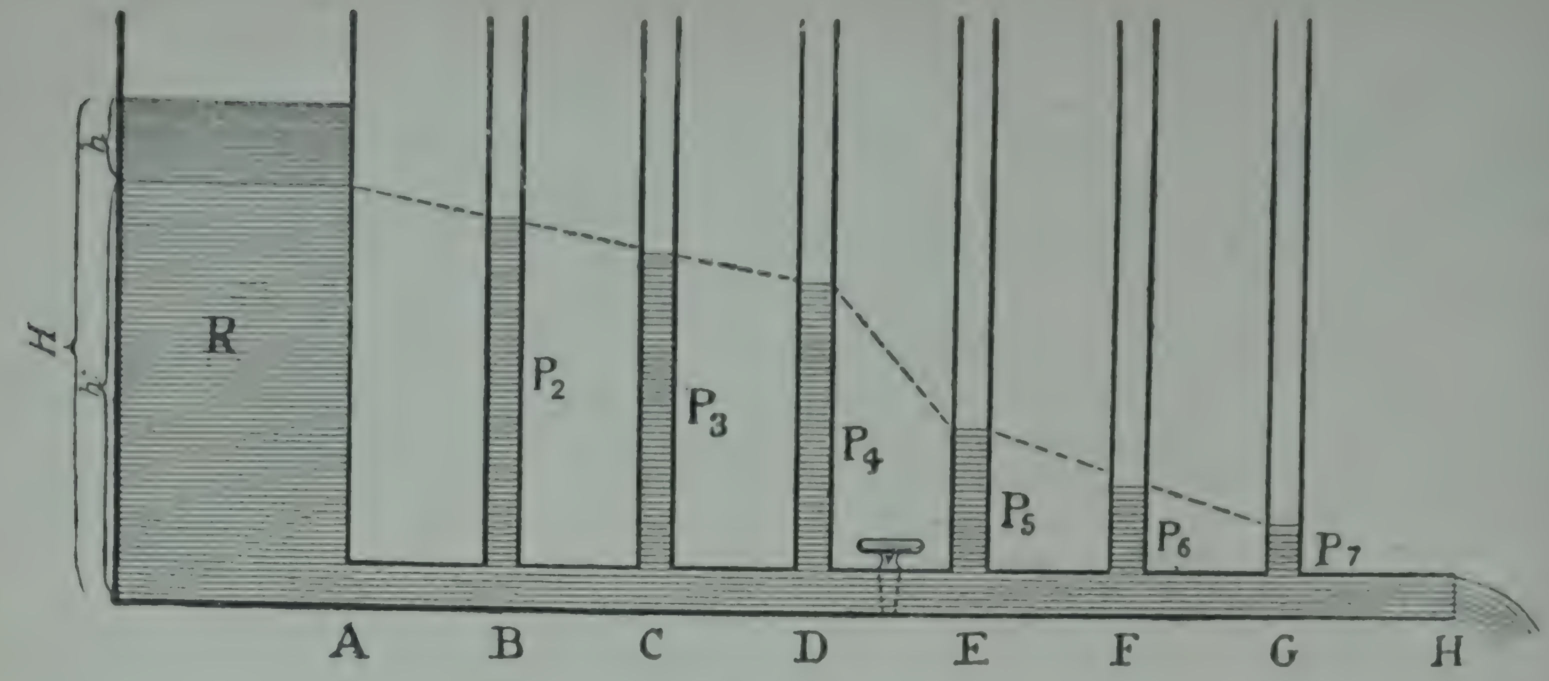

FIG. 416.

which is succeeded by a steep fall (P_4—P_5) between D and E, and this again by a gradual fall between E and G. Actually the volume of fluid flowing in unit time from a constant pressure source steadily along a straight tube varies as the fourth power of the radius of the tube and as the pressure difference between its ends, and inversely as the length of the tube and the viscosity of the liquid (η). This is Poiseuille's formula : Vol. $= \frac{\pi P r^4}{8 \eta l}$.

or resistance to the volume flow, $R = \frac{8 \eta l}{\pi r^4}$.

In the scheme shown, the reduction of the diameter of the tube at one point necessitates a greater difference in pressure between D and E than between the other points, in order to drive equal volumes of fluid through each section of the tube ; the total flow is also reduced for the reasons given above. The mean velocity of movement of the liquid is $\frac{\text{volume flow}}{\pi r^2}$ and hence, from Poiseuille's formula Vel. $= \frac{P r^2}{8 \eta l}$. In any such system of tubes, therefore, through which fluid is flowing, the fall of pressure between any two points will be $= \frac{\text{Vel} \times 8 \eta l}{r^2}$, *i.e.*, will be proportional to the product of the velocity and the resistance to the flow $\left(= \frac{8 \eta l}{r^2}\right)$ between these two points. The velocity on the other hand, $\left(= \frac{P r^2}{8 \eta l}\right)$, like the volume flow, will vary directly as the difference of pressures, and inversely as the resistance between the two points. These relations may be expressed by the simple formulæ

$$P \propto VR,\ R = \frac{P}{V} \text{ and } V \propto \frac{P}{R}.$$

The scheme we have just considered is only capable of limited applications to the problems of the circulation. A nearer approximation could be got by studying the problem, not of a flow from a constant pressure source, but that of a constant *volume* of fluid in unit time, as from a rotary pump, along the tube of uniform bore (Fig. 417). This would more nearly represent the conditions in the circulation, except for the fact that in the latter the flow is intermittent. Again we have a gradient of pressure, as shown by the vertical tubes A to F ; the gradient will be steeper the narrower the horizontal tube and the greater the volume of fluid delivered in unit time by the pump ; *i.e.* its steepness will depend on the energy needed to overcome the frictional resistance in the tube. At the free opening G, the fluid will have no lateral pressure, but will have a certain kinetic energy, dependent on its velocity, *i.e.* on the difference between the potential energy at the source and the frictional loss in the tube. If now an increase of resistance be put in at X, as by partly closing a tap, the effect will be of the same nature, but much more marked than with the former scheme, because now there can be no question of the resistance causing a diminution of the flow, which by definition, is constant. The effect will be a considerable rise of pressure in the near side and an equally pronounced fall on the far side of the resistance (Fig. 417).

Next, let us consider the effect, on the same scheme, of altering the volume of fluid flowing through the horizontal tube. It will be found that the greater the volume delivered in unit time the higher the lateral pressure near its entry will be, and the steeper the gradient (Fig. 417).

We have supposed in all these examples that the movement of the fluid is "stream-lined." In this, the simplest type of fluid motion, the liquid moves in a straight line as concentric fluid tubes ; the layer in contact with the walls of the tube is stationary, the next layer glides over it slowly, the next one over that, and so on until, at the axis of the tube, we have the maximal velocity. In such a case the resistance, which is due to the friction of the layers over one another, varies directly as the mean velocity. In normal conditions the flow of blood in the arterial system is stream-lined. When, instead of being stream-lined the flow is whirling or turbulent, which happens above a certain critical velocity, even in straight tubes, the resistance varies approximately as the square of the mean velocity.* A formula used by engineers for such cases is $R = kSv^2$ where R is resistance, S is the surface area of the wall, and v the velocity. The lower the viscosity of the fluid, and the narrower the tube, the more readily does turbulent motion ensue, and hence the greater becomes the resistance. Murmurs are produced when the flow in large vessels is turbulent.

We may now apply some of these principles to the vascular system. In the living vascular system, the largest difference of pressure exists between the arteries on the one side and the small veins on the other, a great fall occurring between the small arteries and the capillaries themselves. This distribution of pressure points to the chief gradient in the vascular system as being situated in the arterioles. The resistance presented by these vessels is due to their small calibre, since they are maintained in a state of tonic contraction.

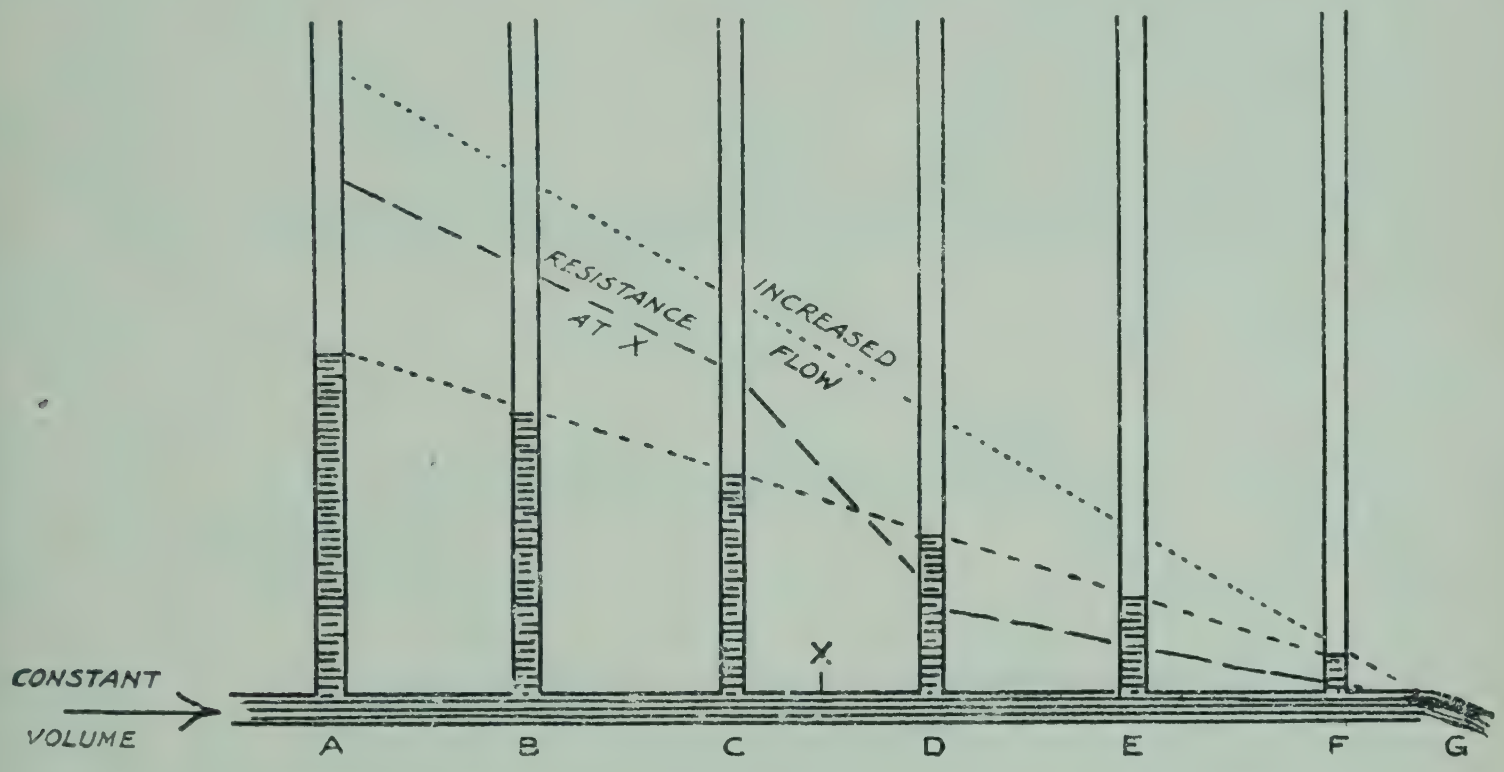

FIG. 417.

The total bed of the stream in the region of the arterioles, while greater than that of the arteries, is considerably less than that of the rich meshwork of capillaries, while the difference between the diameters of arterioles and dilated capillaries is not very great. On this account the velocity of the blood in the arterioles is very much greater than that obtaining in the capillaries, and since friction, and therefore the resistance, probably varies as the square of the velocity, the resistance to the flow of blood through the arterioles must often be greater than that presented by the capillaries. When the capillaries constrict, however, they also add largely to the peripheral resistance. The large part taken by the arterioles in determining the difference of pressure between the arteries and veins is shown by the fact that this difference can be diminished to one-half by any means which causes a general dilatation of the arterioles, as for example, destruction of the vasomotor centre.

As regards the occurrence of turbulent motion, Muller † found that in an elastic tube only 7·5 mm. in diameter the flow began to be turbulent at a velocity of about 50 cm. per second. Hence, quite apart from turbulence due to branching, the flow in the larger arteries could be a turbulent one.

The mean arterial pressure, *i.e.* the average pressure within the arteries at any given time, is thus dependent on :

(1) The resistance to the outflow of blood from the arterial system, *i.e.* on the state of constriction of the arterioles and, to a smaller extent, of the capillaries.

(2) The output of the heart per unit of time.

If one factor is known, the other can be computed, *e.g.* the total peripheral resistance $= \frac{P}{V} = \frac{\text{mean pressure}}{\text{cardiac output}}$.

The Effect of Branching. When a tube gives off a branch, the pressure exerted in the branch by a fluid *flowing along* the tube will depend upon the angle at which the branch leaves the main vessel. If, as at A, Fig. 418, the branch leaves at right angles, then the hydrostatic pressure in the branch is equal to the lateral pressure on the walls of the main vessel. If the branch inclines at an acute angle to the direction of flow, as at B, then owing to the kinetic energy of the moving column of fluid, the pressure in B will be greater than the lateral pressure in the main stem, while if at an obtuse angle, as at C, it will be less. This is the principle of what is known as the *piezometer*, and it follows that if B and C are connected together, as shown in the lower diagram of Fig. 418, there will be a subsidiary (so-called piezometric) circulation of fluid along the side system in the direction indicated by the arrows. This is in fact what happens very extensively in many parts of the circulatory system, particularly in the smaller arterial anastomotic circulations, *e.g.* from arch of aorta to internal mammary artery, then *viâ* ascending aortic intercostal arteries to the descending aorta.*

† *Ztschr. f. d. ges. Exp. Med.*, 1924, **39**, 210.

Most of the arteries give off their branches at an acute angle, so that the end-on pressure in the branch is greater than it would otherwise be.

The Effect of Viscosity. For reasons already explained (p. 501), the apparent viscosity of blood, as measured by the rate at which it flows along a capillary tube under given conditions, is variable. Direct experiment shows that in passing through the capillaries of the vascular system, blood behaves as though it had about twice the viscosity of water, although glass capillary viscosimeters usually give a viscosity at least double this. The reason for the low viscosity in the circulation is due to the small diameter of the vessels in which the main resistance is met. In such narrow vessels the corpuscles tend to move like a rod in the middle of the stream, leaving the plasma at the periphery to encounter the frictional resistance of the wall.†

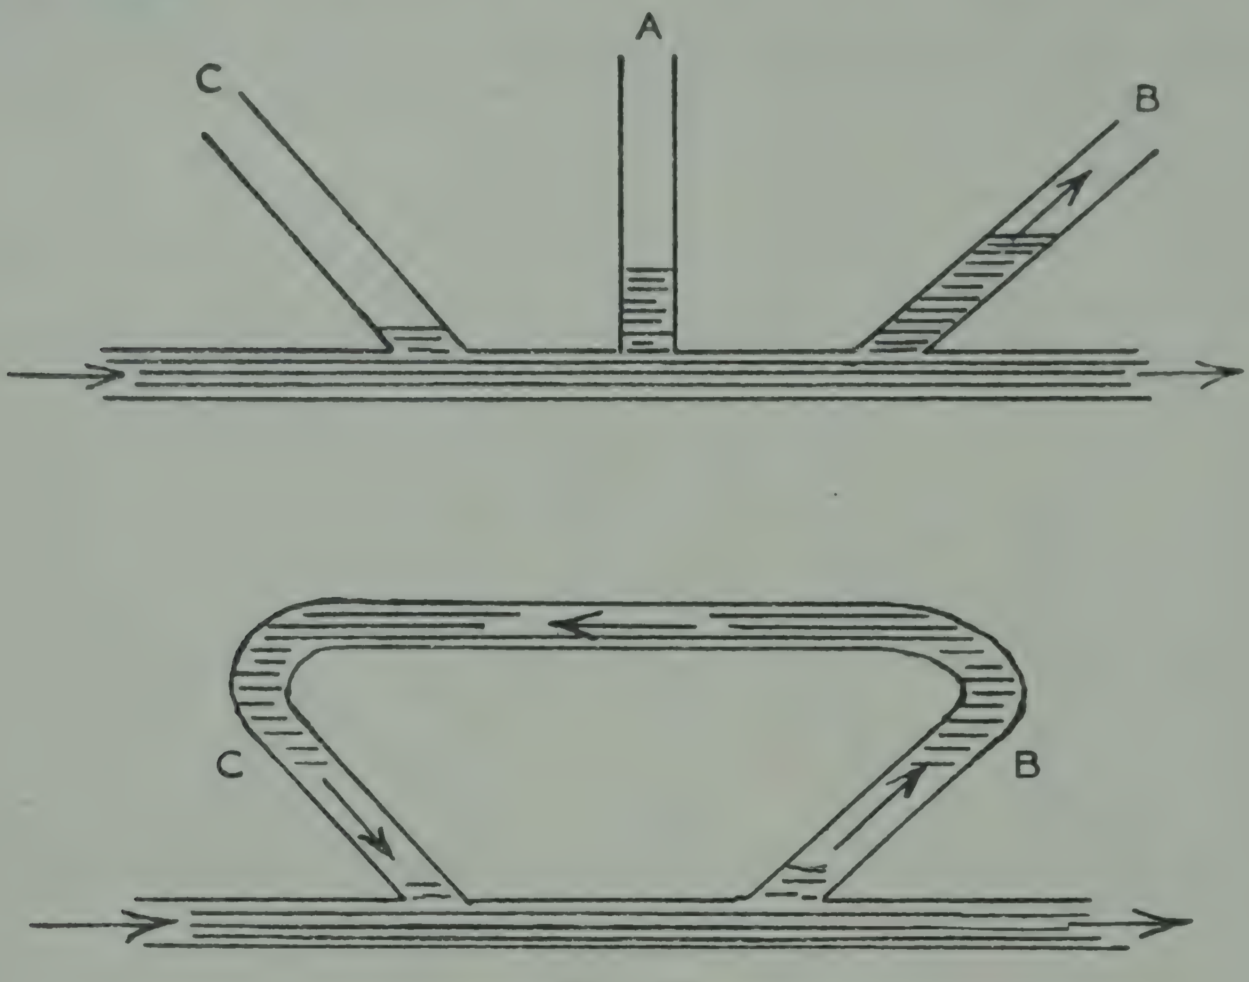

Fig. 418.

Increase in the corpuscular content increases the viscosity, *i.e.* more pressure is required to maintain a given flow along a given capillary ; in other words, if the corpuscular content is increased, a given capillary tube will offer a greater resistance to the flow (Fig. 419).

THE EFFECT OF CAPACITY. So far, we have considered only the influence of changes of flow, pressure and resistance in a simple tube with a head of pressure at one end and a free outflow at the other. In the body, however, the vascular system is a closed circuit of branched elastic tubes presenting varying resistances to the flow of blood, and of varying diameters and distensibilities at different parts of their course. In this closed system is inserted a pump which drives the blood through the system. Since all the blood vessels are elastic and distensible, the capacity of the system must vary with the internal pressure to which the vessels are subjected. Moreover, the position of the different parts of the body must have an influence on the capacity of the system, since the dependent vessels will be distended, not only by the average pressure of the fluid throughout the system, but also by the hydrostatic pressure due to the weight of the column of fluid above them. The elasticity of the tubes is also a varying factor, and can be considerably altered by the contraction of the muscular coats of the vessels, or by pressure exerted on the vessels by the surrounding muscular and elastic structures.

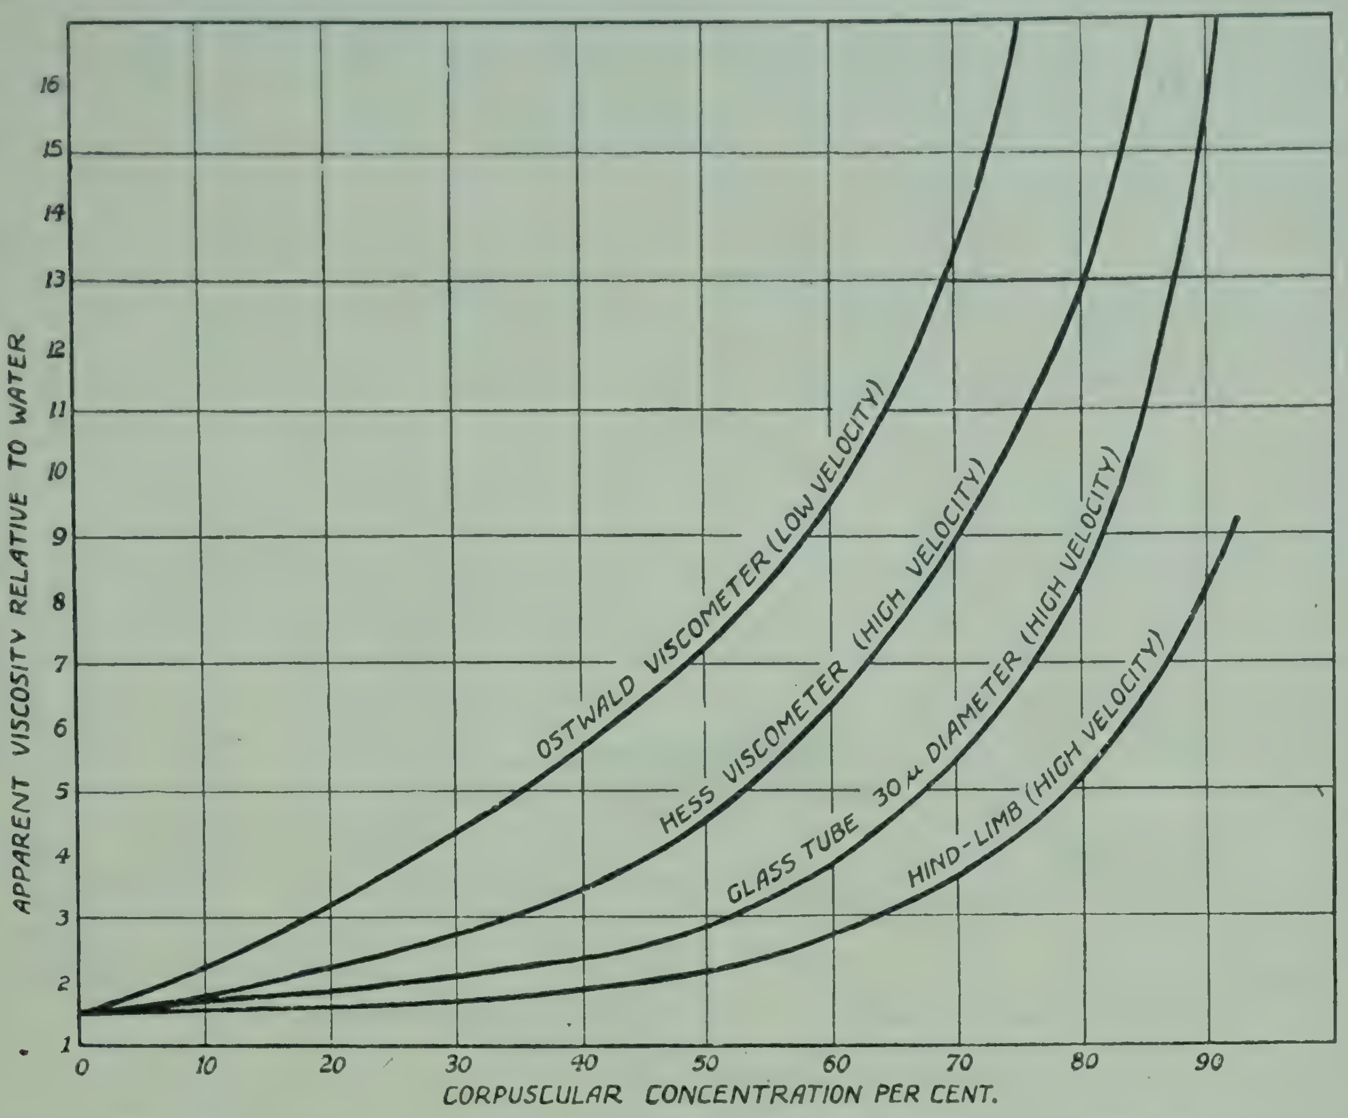

FIG. 419. The Influence of the Corpuscular Concentration (measured with a hæmatocrit) on the Apparent Viscosity of Blood.

Measurements were made on dog's blood, defibrinated, with four different types of viscometer: (1) the Ostwald (low velocity), (2) the Hess (high velocity), (3) a glass tube of very small diameter, and (4) the dog's hind limb. If the glass tube used had had an even smaller diameter, the apparent viscosities would have been still lower. (After WHITTAKER and WINTON and L. E. BAYLISS.)

Circulation Schema. It will simplify the discussion of the main factors of the circulation if, for the present, we neglect the variable factors and see what would take place in such a closed system of elastic tubes all situated on one horizontal plane. Such a system is represented in the diagram (Fig. 420), and a working model of it in Fig. 421.

The heart H is interpolated at one part of the circuit, while the free flow of the fluid from B to D is impeded by the presence of a peripheral resistance at C. Such a system would have a definite capacity at zero internal pressure, but a greater one under a positive pressure. We will assume that the pressure throughout the system when at rest is 10 mm. Hg., *i.e.* the elastic tubes are all slightly distended. If the heart H now begins to contract, it will pump fluid from E into A. The pressure in E will fall, while that in A will rise, the resistance at C preventing the free escape of fluid from B to D, and so causing the fluid to pile up in A.

If the properties of the tubes were uniform throughout the system, the rise of pressure in A would approximate very nearly to the fall of pressure in E. In the vascular system the veins are, however, much more easily distended or collapsed than the arteries

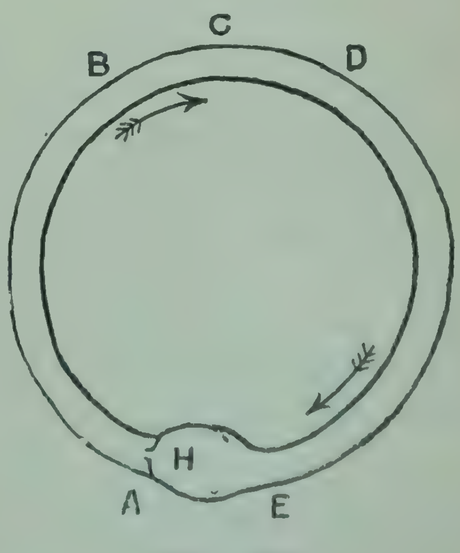

FIG. 420.

(Figs. 421 and 422). The vein collapses when there is no distending force in its interior. The slightest rise of pressure causes a considerable increase in its capacity, which rises rapidly with increasing pressure up to about 20 mm. Hg. Whereas the artery needs a pressure of about 100 mm. Hg to distend it, and continues to stretch, but more slowly, at higher pressures, the vein is distended almost to its maximum at about 10 mm. Hg. Therefore, the tubes at E are made of thin-walled rubber, which will be considerably distended under a pressure of 10 mm. Hg, that has practically no influence on the thicker-walled arterial tube A.

A small amount of fluid taken from E would thus cause very little fall of pressure on this side. A considerable force will be necessary to send this fluid into the more resistant arterial tube, so that on pumping enough fluid from E to A to lower the pressure in E, say 5 mm., the pressure in A has to be raised to say, 100 mm. Hg in order to distend the arteries to such an extent that they will accommodate the extra fluid.

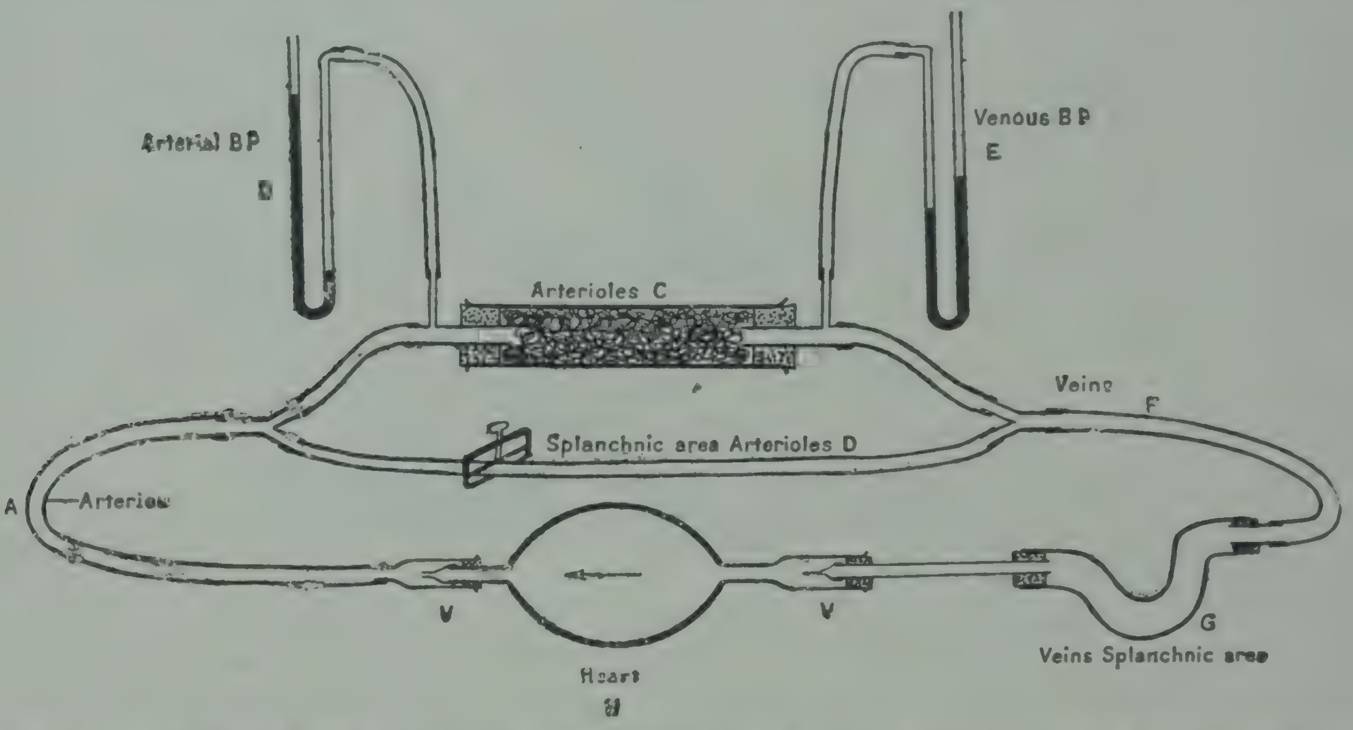

FIG. 421. Artificial Schema to Demonstrate the Main Features of the Circulation.

The heart is an enema syringe with valves at V and V. The artery is a thick-walled rubber tube. On the venous side is placed a length of wide thin-walled tubing, to represent the large thin-walled distensible veins. The arterioles and capillaries (peripheral resistance) are represented by wide glass tubes packed with sponges. By opening the clamp on the tube D ("splanchnic area arterioles") the peripheral resistance can be removed, and a free passage of fluid allowed from arterial to venous side.

In such a system, when the heart contracts, it takes fluid from the veins to the arteries, and piles up the pressure on the arterial side until it is sufficient to cause fluid to flow through the peripheral resistance into the veins at the same rate as it is taken by the heart from the veins. This rise of pressure in the arteries may be many times greater than the fall of pressure in the veins. If more fluid is injected into the system, the whole system will be more distended and the *mean systemic pressure will rise.* Then, according to the rate of output by the heart, the arterial pressure may be less than, equal to, or greater than the pressure attained before the introduction of fluid. Supposing it to be the same as before, the increased amount of fluid must be accommodated somewhere, so that the venous side must be fuller. In the same way, the withdrawal of a certain amount of fluid may lower the mean systemic pressure, and it would still be possible for the pump to maintain an arterial pressure equal to that produced when the mean systemic pressure was 10 mm. Hg, but to obtain this effect the rate of its output would have to be increased, and the veins would be more empty than they were previously. The maintenance of a constant arterial pressure with varying amount of fluid in the system can therefore be accomplished either by alterations in the output of the heart or by alterations in the peripheral resistance, and therefore in the ease with which the blood is allowed to pass from the arterial to the venous side.

Alterations of the capacity of the system will have the opposite effect to alterations of its contents. Thus diminution in the volume of veins, such as might be caused in the living body by pressure on the veins from without, will drive the fluid into other parts of the system and therefore raise the mean systemic pressure. This rise of pressure may be confined to the arteries by increased action of the heart, or it may be confined to the veins by diminished action of the heart or decreased constriction of the arterioles forming the peripheral resistance.

Similar change in capacity may be brought about by alterations in the hydrostatic pressure in the vessels. If, in the model illustrated (Fig. 421), we allow the thin-walled vein to hang over the edge of the table, the pressure of the column of fluid within it causes it to distend and to accommodate more fluid, and this increased capacity might be so great that the pressure in the section of the vein near the heart might fall so low that the heart would receive no blood. The whole arterial system might in this way drain under the influence of gravity into the large veins.

All the conditions in our artificial schema have their exact analogue in the living body. The determination of the mean systemic pressure in the living body is difficult to carry out with accuracy. Direct measurement shows that it is not more than 10 mm. Hg. Under the influence of gravity, the pressure would be easily reduced to zero, or, in the upper parts of the body, even to a pressure below that of the air, but for the nervous reactive mechanism which we shall consider later on, and the whole of the blood would accumulate in the abdomen and lower parts of the body, and the circulation would come to a standstill.

Widespread or universal dilatation of the capillaries, as may occur under the influence of histamine, or in some forms of "shock", may so increase the total capacity of the vascular system that the blood remains in the capillaries, and an ever decreasing amount of blood is available to pass on into the heart. The heart thus has a diminished output, and is unable to maintain the normal arterial pressure in the arterial system.

The *mean pressure* may be altered in the vascular system in the following ways:

(1) Alteration of capacity of the total system, either by contraction of the walls of the vessels or by pressure on them from without.

(2) Alteration of the total volume of the circulating fluid.

The *distribution of pressure*, *i.e.* the relative pressure in the arteries and veins, will be determined by

(3) Alteration in the output of the heart. This may be augmented by greater amplitude of ventricular contraction increasing the output per beat, or by greater frequency of beat. Generally both means are employed.

(4) Alteration in the peripheral resistance and therefore in the ease with which the blood can pass from arterial to venous side.

In any change, either in arterial or venous pressure, at least two of these factors are involved. Nearly always such a change will involve as its immediate consequence some corresponding alteration in the heart beat, so that at least three factors will usually co-operate in the production of the rise or fall of blood pressure.

The Dependence of Arterial Pressure on Output of Heart. Arterial pressure is a resultant of the two effects:

(*a*) The rate at which blood enters the arterial system from the heart;

(*b*) The rate at which blood leaves the arterial system through the peripheral resistance.*

---

* For hydrodynamical treatment *v.* BROEMSER and RANKE. *Z. f. Biol.*, 1930, **90**, 467; WEZLER. *Ibid.*, 1938, **98**, 438.

It is evident that the arterial pressure will be altered by varying either of the two factors—output of the heart or peripheral resistance. The cardiac output will depend on the stroke volume of the heart and on the pulse rate. The filling of the heart at the beginning of each beat is in its turn dependent on the pressure in the great veins. If the heart is beating with optimum rate and force, it will reduce the distension of the veins nearest the heart, and it is not possible for it to obtain more blood to put into the arterial side, however frequently it may beat. Increased frequency of heart beat would not, therefore, necessarily increase the total output of the heart. There will be an optimum frequency of the heart beat which will depend on the state of filling of the great veins. The fuller these are, the more the total output can be augmented by an increase of the heart rate. On the other hand, slowing the heart from its optimum rate will increase its stroke output, but diminish the minute output.

BLOOD FLOW

The Conversion of an Intermittent into a Constant Flow. By the time it has arrived in the veins, the flow of blood has been converted from a pulsatory into a continuous flow. This change is connected with the elastic nature of the arterial walls and will be more easily understood by a simple illustration. If a pump be connected with a rigid tube, every time that a certain amount is forced into the beginning of the tube an exactly equal quantity will be forced out at the other end. Increasing the peripheral resistance by partial closure of the end of the tube will not affect the intermittent character of the flow, but will merely increase the force necessary to expel the fluid. If, instead of a rigid tube, we employ a wide elastic tube, and the end be left open so that no resistance is offered to the outflow, the outflow will, as with a rigid tube, be intermittent. But now, if the end of the elastic tube be narrowed so as to increase the resistance to the outflow, there will be a marked difference. Each stroke of the pump forces the same amount of fluid into the tube as before, but owing to the peripheral resistance this does not now all escape at once ; instead, part of the force of the pump is spent in distending the walls of the tube, and part of the fluid that was forced in remains for a time in the tube. The distended tube tends to empty itself and force out the fluid which over-distends it before the next stroke of the pump occurs. So now the outflow may be divided into two parts, one part which is forced out by the immediate effect of the stroke of the pump, and another part which is forced out by the elastic recoil of the tube between the strokes. If the strokes be rapidly repeated before the tube has time to empty itself thoroughly, it will get more and more distended. Greater distension means stronger elastic reaction, and therefore a larger outflow of the fluid between the beats. This distension goes on increasing till the fluid forced out between the strokes by the elastic reaction of the wall of the tube is exactly equal to that entering at each stroke, and the flow thus becomes continuous.

The same thing occurs in the living body. A man's heart at each beat forces about 60 c.c. of blood into the already distended aorta. The largest arteries, such as the aortic arch, innominate, and subclavian arteries are highly distensible, and so the expelled blood is readily accommodated in them ; this wave of distension is transmitted with gradually decreasing force along the arteries and is what we feel as the pulse. After each heart beat the arteries tend to return to their original size, and drive the blood onwards. By the time the blood has reached the veins, all trace of the heart beat has disappeared.

VELOCITY OF THE BLOOD

The velocity of the blood as a whole will vary directly as the rate of the cardiac output, but, apart from changes in this, the speed of movement of the blood in different parts of the circulation will always vary greatly, for reasons already explained.

We may consider (1) the circulation time, *i.e.* the time taken for blood to traverse a part or the whole of the circulation; (2) the linear velocity of the blood as it passes a particular spot, and such velocity may be considered either as a mean velocity or as a velocity fluctuating from moment to moment; (3) the volume of blood flowing through a particular part of the circulatory system.

(1) **Circulation Time.** Measurements of the circulation time are made by introducing into the blood stream some easily recognised substance at a given point, and finding how long it takes for that substance to appear at any other given point in the circulatory system. If the tell-tale substance is injected into a vein, and the time taken for it to appear in the blood of the same vein distal to the point of injection, or in the corresponding vein on the opposite side, then we get the *total circulation time;* if the transit is from vein to lungs we get a measure of the time for the pulmonary circuit; if from vein to capillaries we get the time for flow from vein through pulmonary circuit, left heart and arteries to capillaries, *i.e.* total circulation time less the time for venous, return, etc.

Substances which can be used for injection are: (1) Potassium ferrocyanide, in animals; (2) radioactive material, detected at various points, without drawing blood, by the use of an ionisation chamber; (3) the dye fluorescin, for total time; (4) acetone or ether, detectable in the breath, for pulmonary circuit time; (5) histamine (0·001 mg. phosphate per kg.), which causes flushing of capillaries of the face, or saccharin, which gives a sweet taste when it reaches the tongue, for the vein-heart-capillary time. (6) A small dose of NaCN, which causes hyperpnœa when it reaches the carotid body.

Typical times found are:

Total circulation time (vein to vein)	12 to 28 secs. (av. 25)
Arm vein to face (histamine)	24 secs. (saccharin 11 secs.)
Arm to artery (radio-active method)	14 to 24 secs.
Vein to lungs (ether or acetone)	6 secs. (radio, 11 secs.)
Arm to heart (radio-active method)	2 to 14 secs.
Arm vein to carotid body (NaCN)	12 to 15 secs.

It will be evident that the time measured in all these methods is the shortest time taken by any of the blood to traverse the given part of the circulation, and hence the figures are variable unless exactly the same method is used. For different animals the circulation times are shorter the smaller the animal, as would be expected. The number of heart beats per circulation time, is, however, about the same for all species, viz. about thirty beats per total circulation time.

Factors which increase the cardiac output will tend to shorten the circulation time. Hence it is reduced in exercise, after adrenaline and in such diseases as hyperthyroidism, where the total metabolism is raised, or anæmia, in which the blood volume and viscosity are diminished. It is increased in myxœdema, because the basal metabolism is reduced, in polycythæmia, because the viscosity of the blood is increased, and in uncompensated disorders of the heart.

(2) **The Velocity of Flow at Different Points.** It is evident that an increased output of the heart in unit time will speed up the rate of flow of blood in all parts of the circulation. At any given rate of output, however, the velocity of the blood varies as it passes along the vessels. If a liquid be flowing steadily along a tube of unequal bore, as represented in Fig. 422, since the amount of fluid passing *a* during a given interval of time must be equal to the amount passing *b*—where the bed of the stream is wider—the velocity of the flow must be smaller at *b* than at *a*.

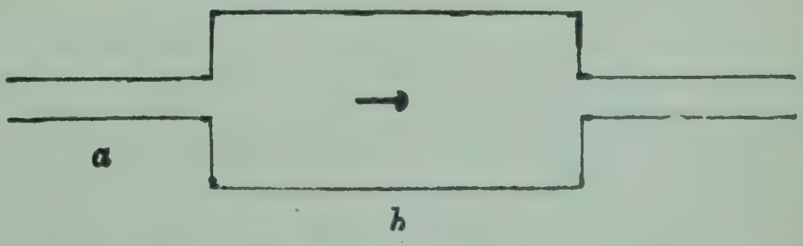

Fig. 422.

It is obvious that the velocity of flow at any two points in the same system will vary inversely as the cross-sectional areas of the whole bed at those points. Thus in a closed circuit (Fig. 420) with a steady flow from the arterial to the venous side, the amount of fluid passing A during a minute must be exactly equal to the amount passing through the peripheral resistance C. The total area at C is, under average conditions in the body, probably one thousand times that of the aorta at A, and we should expect therefore a proportionate slowing of the blood stream. As a matter of fact, while the mean velocity of the blood in the aorta of a large animal may be taken as about half a metre per second (varying at different parts of the cardiac cycle from 0·1 to 1·0 metre per second), the velocity of the blood in the capillaries is about half a millimetre per second. Moreover, since the total cross section of the big veins near the heart under a normal distending pressure is about twice that of the first part of the aorta, the velocity of the blood in the great veins is only about half of that found in the aorta.

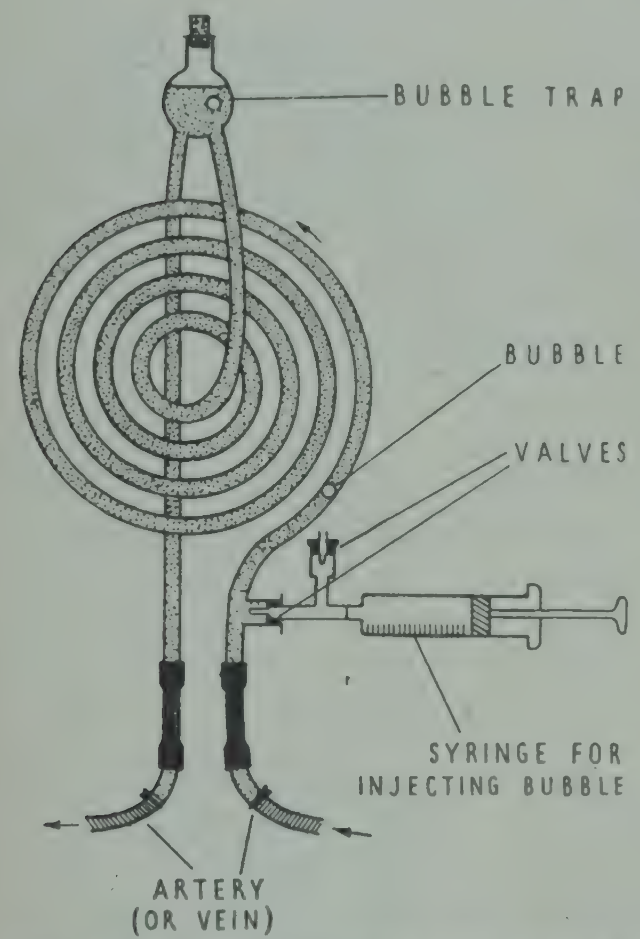

FIG. 423. Diagram of the bubble *Stromuhr*, as described by DUMKE and SCHMIDT. (*Amer. J. Physiol.*, 1943, **138**, 421).

The foregoing discussion must not be applied directly to the changes in the velocity in any part following on *local* alterations in the resistance. In this case the local changes are insufficient to affect the general arterial blood pressure, and the result of diminution of perpiheral resistance is to furnish a short cut from the arterial to the venous side for a portion only of the total output of the heart. Thus, dilatation of the vessels of the submaxillary gland, while not altering the general blood pressure, causes the blood flow through the gland to be increased six to eight times. The pressures and velocities in the *local* arterioles, capillaries and veins are all increased by this local vaso-dilatation. Conversely, constriction of the arterioles of any given part will diminish the velocity of the blood through this part and also the pressure in its capillaries.

The larger the area affected by the change in the peripheral resistance, the more difficult it is to predict *a priori* what will be the result on the velocity of the blood and on the circulation as a whole, or in the parts specially affected. In the living body a widespread dilatation of the arterioles increases the total capacity of the system. The arterial relaxation, therefore, not only gives rise to an easier outflow from arteries to veins, but may also cause a diminished filling of the veins, and therefore of the heart during diastole. The heart output is therefore also lessened, so that a final result of a dilatation of the arterioles may be a diminished, instead of an increased, velocity throughout the system.

METHODS OF MEASURING THE FLOW AND VELOCITY OF THE BLOOD. If we can measure the average volume of blood passing along a given vessel per minute, we can calculate the mean speed of its movement. In experimental animals, the mean flow can be measured by a *Stromuhr*, of which there are many types. A modern form is shown in Fig. 423. Its principle should be obvious. The passage of the heparinised blood along the spiral, which is inserted in the course of a blood vessel, is timed by measuring the time taken for a bubble of air injected by the syringe to pass from a mark near the syringe to a second mark beyond the spiral. The capacity of the tube between these two marks being known, a simple calculation will show the amount of blood passing along the vessel per minute.

Another form of stromuhr is the *thermostromuhr*.* The principle is that a spot

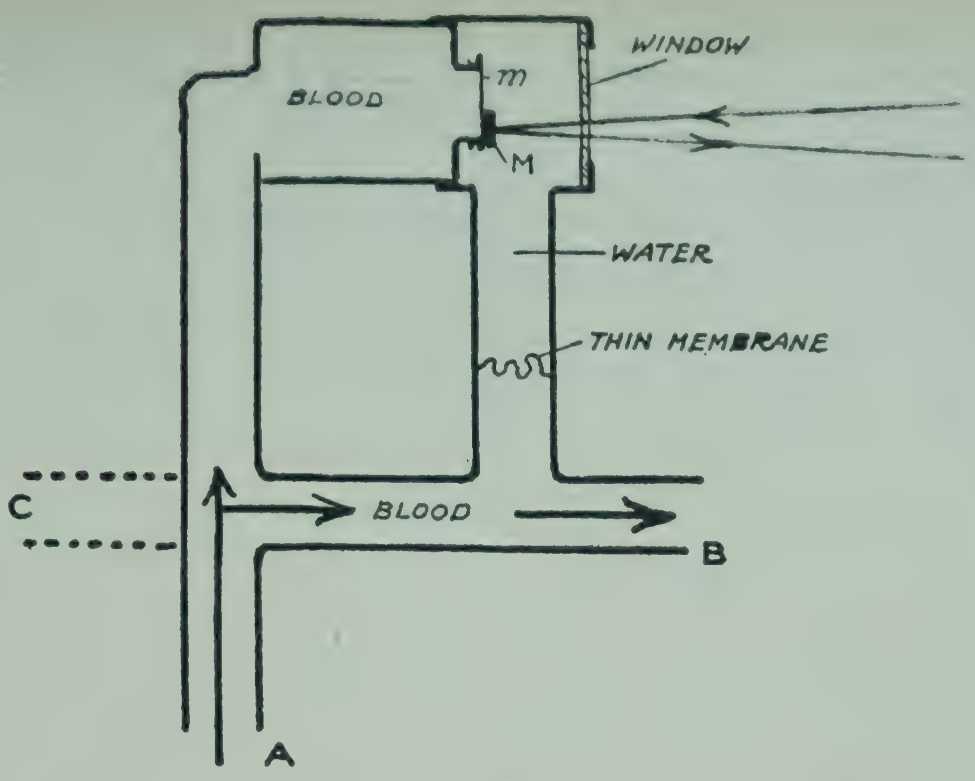

FIG. 424. Principle of the Fleisch Differential Stromuhr. The difference in pressure in the two branches is communicated to the thin membrane manometer, *m*, bearing a mirror M. The outer chamber is filled with water, so that light passing through the window can be reflected from the mirror, and on to a photographic surface, whereby the pressure differences can be graphically recorded. The thin *lax* membrane separates the water from the blood, but does not interfere with the pressure transmission.

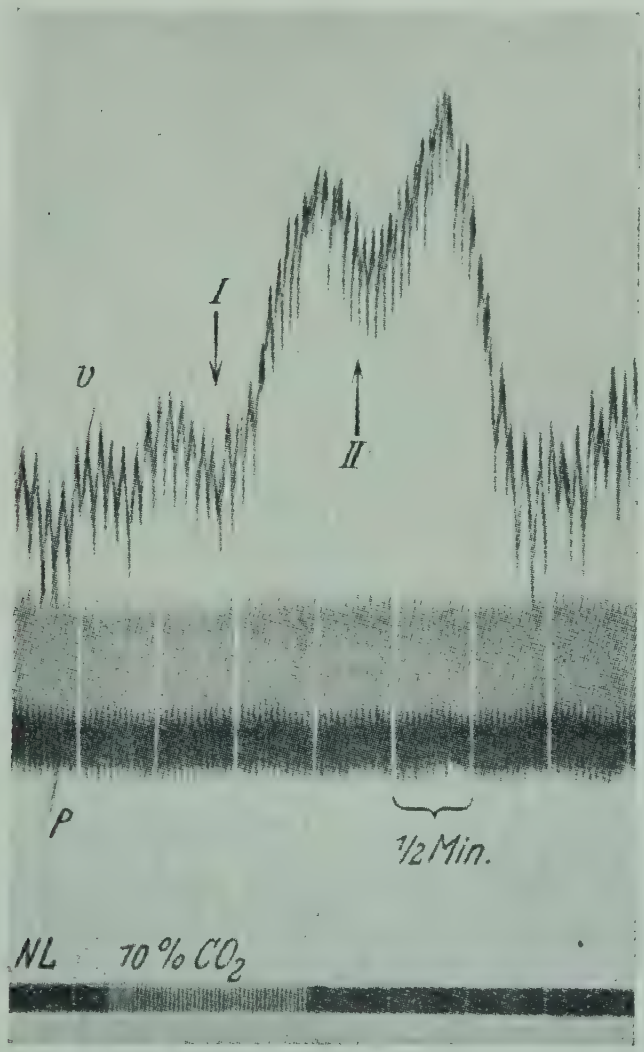

FIG. 425. Record of Velocity of Blood flowing along the Superior Mesenteric Artery of a Cat. The artery was perfused with blood from a pump, the perfusing pressure being kept constant, and the blood being arterialised in a separate pair of lungs. Upper tracing = blood velocity : the sudden downward strokes, about fourteen per minute at the commencement, are produced by a device which shows when each 1 c.c. of blood has passed through. They get closer together at the arrow II., and the whole tracing is moved upwards, both of which events show that the blood is flowing more rapidly. Second tracing : P = perfusion pressure, and time tracing in half minutes. Lower tracing shows the time during which the lungs of the perfusion circuit were supplied with a mixture containing 10 per cent. CO_2. (FLEISCH *et al.*, *Pflüger's Arch.*, 1932, **230**, 814.)

on the vessel is heated at a known rate (by a high-frequency current) and the rise of temperature is then recorded a short way downstream by a thermoelectric couple. The rise varies inversely as the velocity of flow. A method based on an electromagnetic principle has also been described.*

The velocity of the blood in the capillaries can be measured by direct observation of the capillaries under the microscope, and noting the time it takes for a blood corpuscle to move a measured distance.

These methods give mean velocities and give no information of the rapid changes occurring in the velocity of the blood at each heart beat. For this purpose we must have recourse to some such instrument as the *differential Stromuhr* used by Fleisch.† This is based on an application of Venturi tubes. If a current of blood, rendered incoagulable by a suitable method, be directed along the tube AB (or CB) possessing two vertical side tubes (Fig. 424), the pressure in the first branch will be greater than that in the second, since when the flow is from A to B, the momentum of the moving mass of blood is added to the lateral pressure of the fluid; if from C to B, there is still a difference, though a smaller one, due to the lateral pressure gradient along the tube. In recording the variations in blood flow, *e.g.* in an artery, the apparatus is inserted in the artery, so that blood enters it at A and leaves it at B to continue on its course along the vessel.

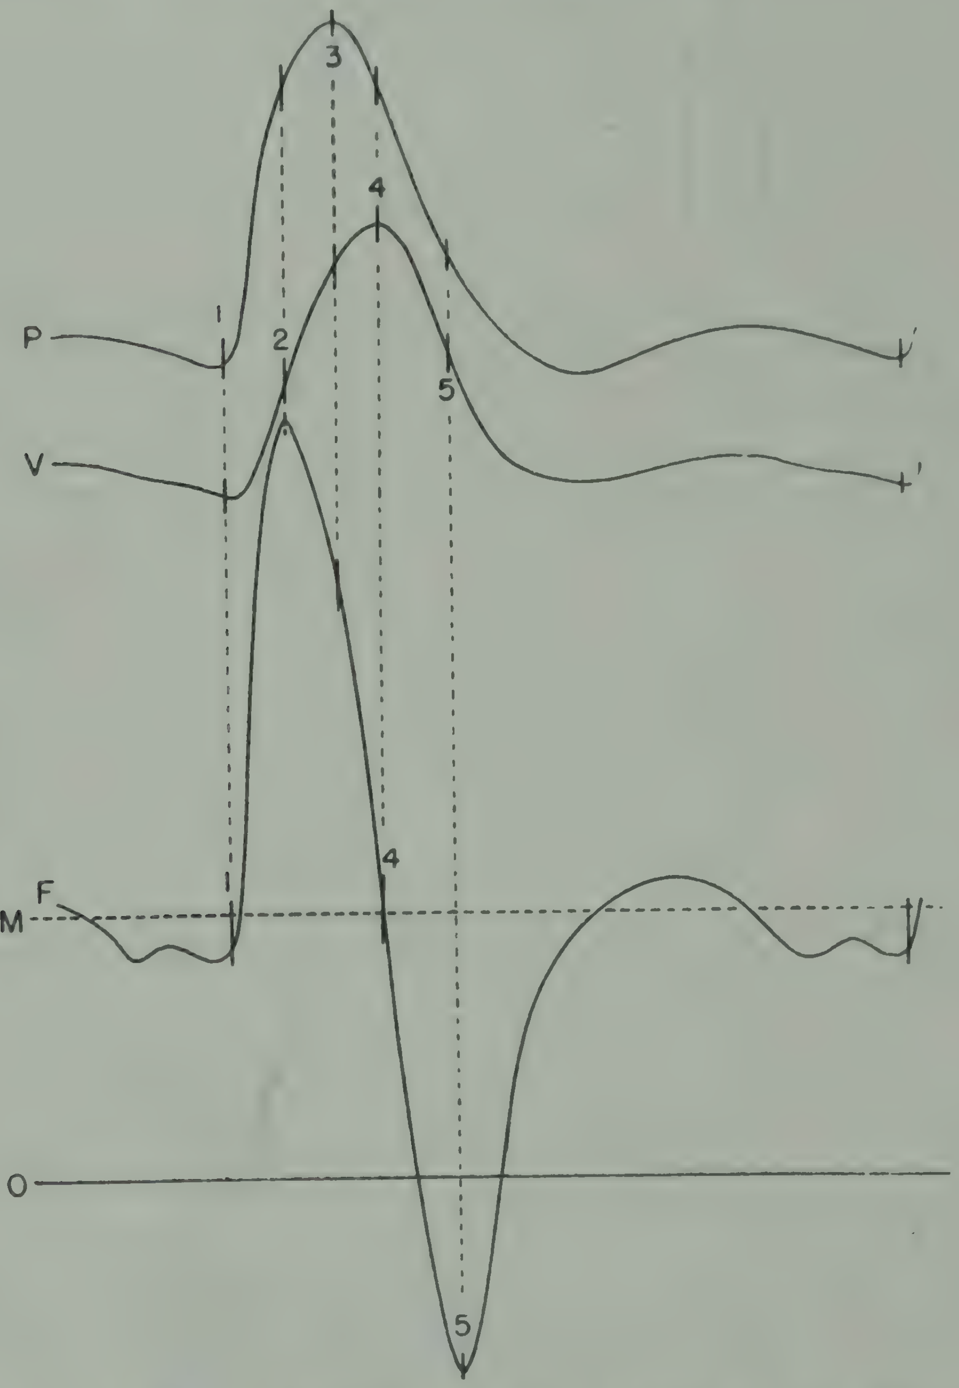

FIG. 426. Femoral artery pulsations in dog. Curve P, the pressure changes; curve V, the intravascular volume curve; curve F, the flow pattern. Line M, mean flow level; line O, zero flow level. Line 1, onset of flow and pressure rise: 2, maximal rate of forward flow and volume increase; 3, peak of applied pressure; 4, point of maximal intravascular volume; 5, maximal rates of back flow and volume decrease. (SHIPLEY, GREGG and SCHROEDER. *Amer. J. Physiol.*, 1943, **138**, 718.)

The difference of pressure will be greater if the flow accelerates, and will disappear if it ceases. It can be recorded by means of a membrane manometer, one surface of which is in connection with one branch and the other with the other branch, as shown in Fig. 424. The instrument must, of course, be calibrated empirically if the actual velocities are required. Fig. 425 gives a tracing taken with such an instrument, and illustrates the increase of blood flow which results when the splanchnic area is perfused, at constant pressure from a pump, with blood containing an increased amount of carbon dioxide. The velocity in the artery shows regular fluctuations with each stroke of the pump, as it would with the heart beat, an increase with each systole, and a decrease with each diastole (the tracing is on too slow a surface to show these clearly); there are also slower fluctuations in the form of waves (six are seen in the tracing) which are due to rhythmic changes in the vascular tone.

† FLEISCH. *Pflüger's Arch.*, 1920, **178**, 31.

The Arterial Velocity Pulse. During systole the velocity of the blood in any part of the arterial system is greater than during diastole; thus in the carotid artery the velocity during systole may be as great as 500 mm./sec., and during diastole only at the most two-thirds as great. The fluctuations in velocity attending each heart beat are only approximately parallel to the fluctuations of pressure which we know as the pulse. By the use of accurate recording flow meters capable of following rapid changes in the velocity of the blood, it has been shown that in the large arteries, such as the axillary, femoral and carotid arteries, the peak velocity corresponding with the period of expulsion from the left ventricle is followed by a rapid decline in speed, culminating in a brief back-flow.* The smaller arteries, *e.g.* renal, hepatic and superior mesenteric, do not show this back flow, and in the smallest arteries, capillaries and veins of small size, there is little in the way of flow pulsations. The relations between pressure, velocity and volume, shown in Fig. 426 are complex, and cannot be discussed here: it will be seen, for instance, that the volume change does not follow the rapid pressure changes, and this is ascribed to the effect of viscous damping. What these valuable tracings do show, however, is that great care needs to be taken in the construction of apparatus for hæmo-dynamical research, and in the interpretation of the results obtained.

(3) **The Mean Volume Flow.** The volume of blood which flows through any portion of the circulatory system in a given time bears no simple relation to the actual speed of movement of the blood along the vessels concerned. For whereas the volume of blood transmitted at constant arterial pressure varies directly as the fourth power of the diameter of the small arteries that supply the part, and inversely as the resistance of the total circuit, the speed of movement at any given point under a constant head of pressure will vary directly as the volume transmitted, and inversely as the total sectional area of the local bed, at that point. It usually follows, therefore, that any dilatation of the arterioles supplying an organ leads to an increase in the velocity of movement of the blood, as well as to an increased input of blood to the organ.

The flow may be measured directly by actual collection of the blood, rendered incoagulable by heparin, as it emerges from a vein; the time required to collect a given volume is measured and the blood re-injected into the circulation. Or we may measure the blood entering by an artery, by inserting a stromuhr of some pattern on its course.

Another method is by the use of the plethysmograph (p. 643), by which the volume of an organ is recorded. If an organ is placed in a plethysmograph, and the outlet of blood by the veins be then obstructed for a definite *short* time, the organ will swell by an amount that can be read off from the record, so giving the amount of blood that entered it during the period of occlusion.† The flow of blood through the hand or arm in man can be arrived at by this method, which has been widely employed.

The method for the forearm is illustrated in Fig. 427. The forearm is placed in a plethysmograph P, connected with a suitable volume recorder R, and filled with water at an appropriate temperature. Above and below the plethysmograph are placed sphygmomanometer cuffs: the upper one V, for compressing the venous return, the lower one A, for shutting off the hand. In making a measurement, first A is inflated to a pressure, say 200 mm. Hg. well above the arterial; then V is suddenly inflated to a pressure, say 70 mm., which is above venous, but below arterial pressure. The forearm swells with inflowing blood. After 10 to 15 secs. both cuffs are deflated, and the recorded expansion measured against a calibration of the volume recorder. By a slight modification, the flow into the hand can be measured. Flow into forearm mainly represents muscle flow, that into the hand flow through skin.

† Brodie and Russell. *J. Physiol.*, 1905, **32**,, Proc. xlvii; Lewis and Grant. *Heart*, 1925, **12**, 73.

With a cardiac output of 5·5 l./min. and body weight of 70 kg., the mean

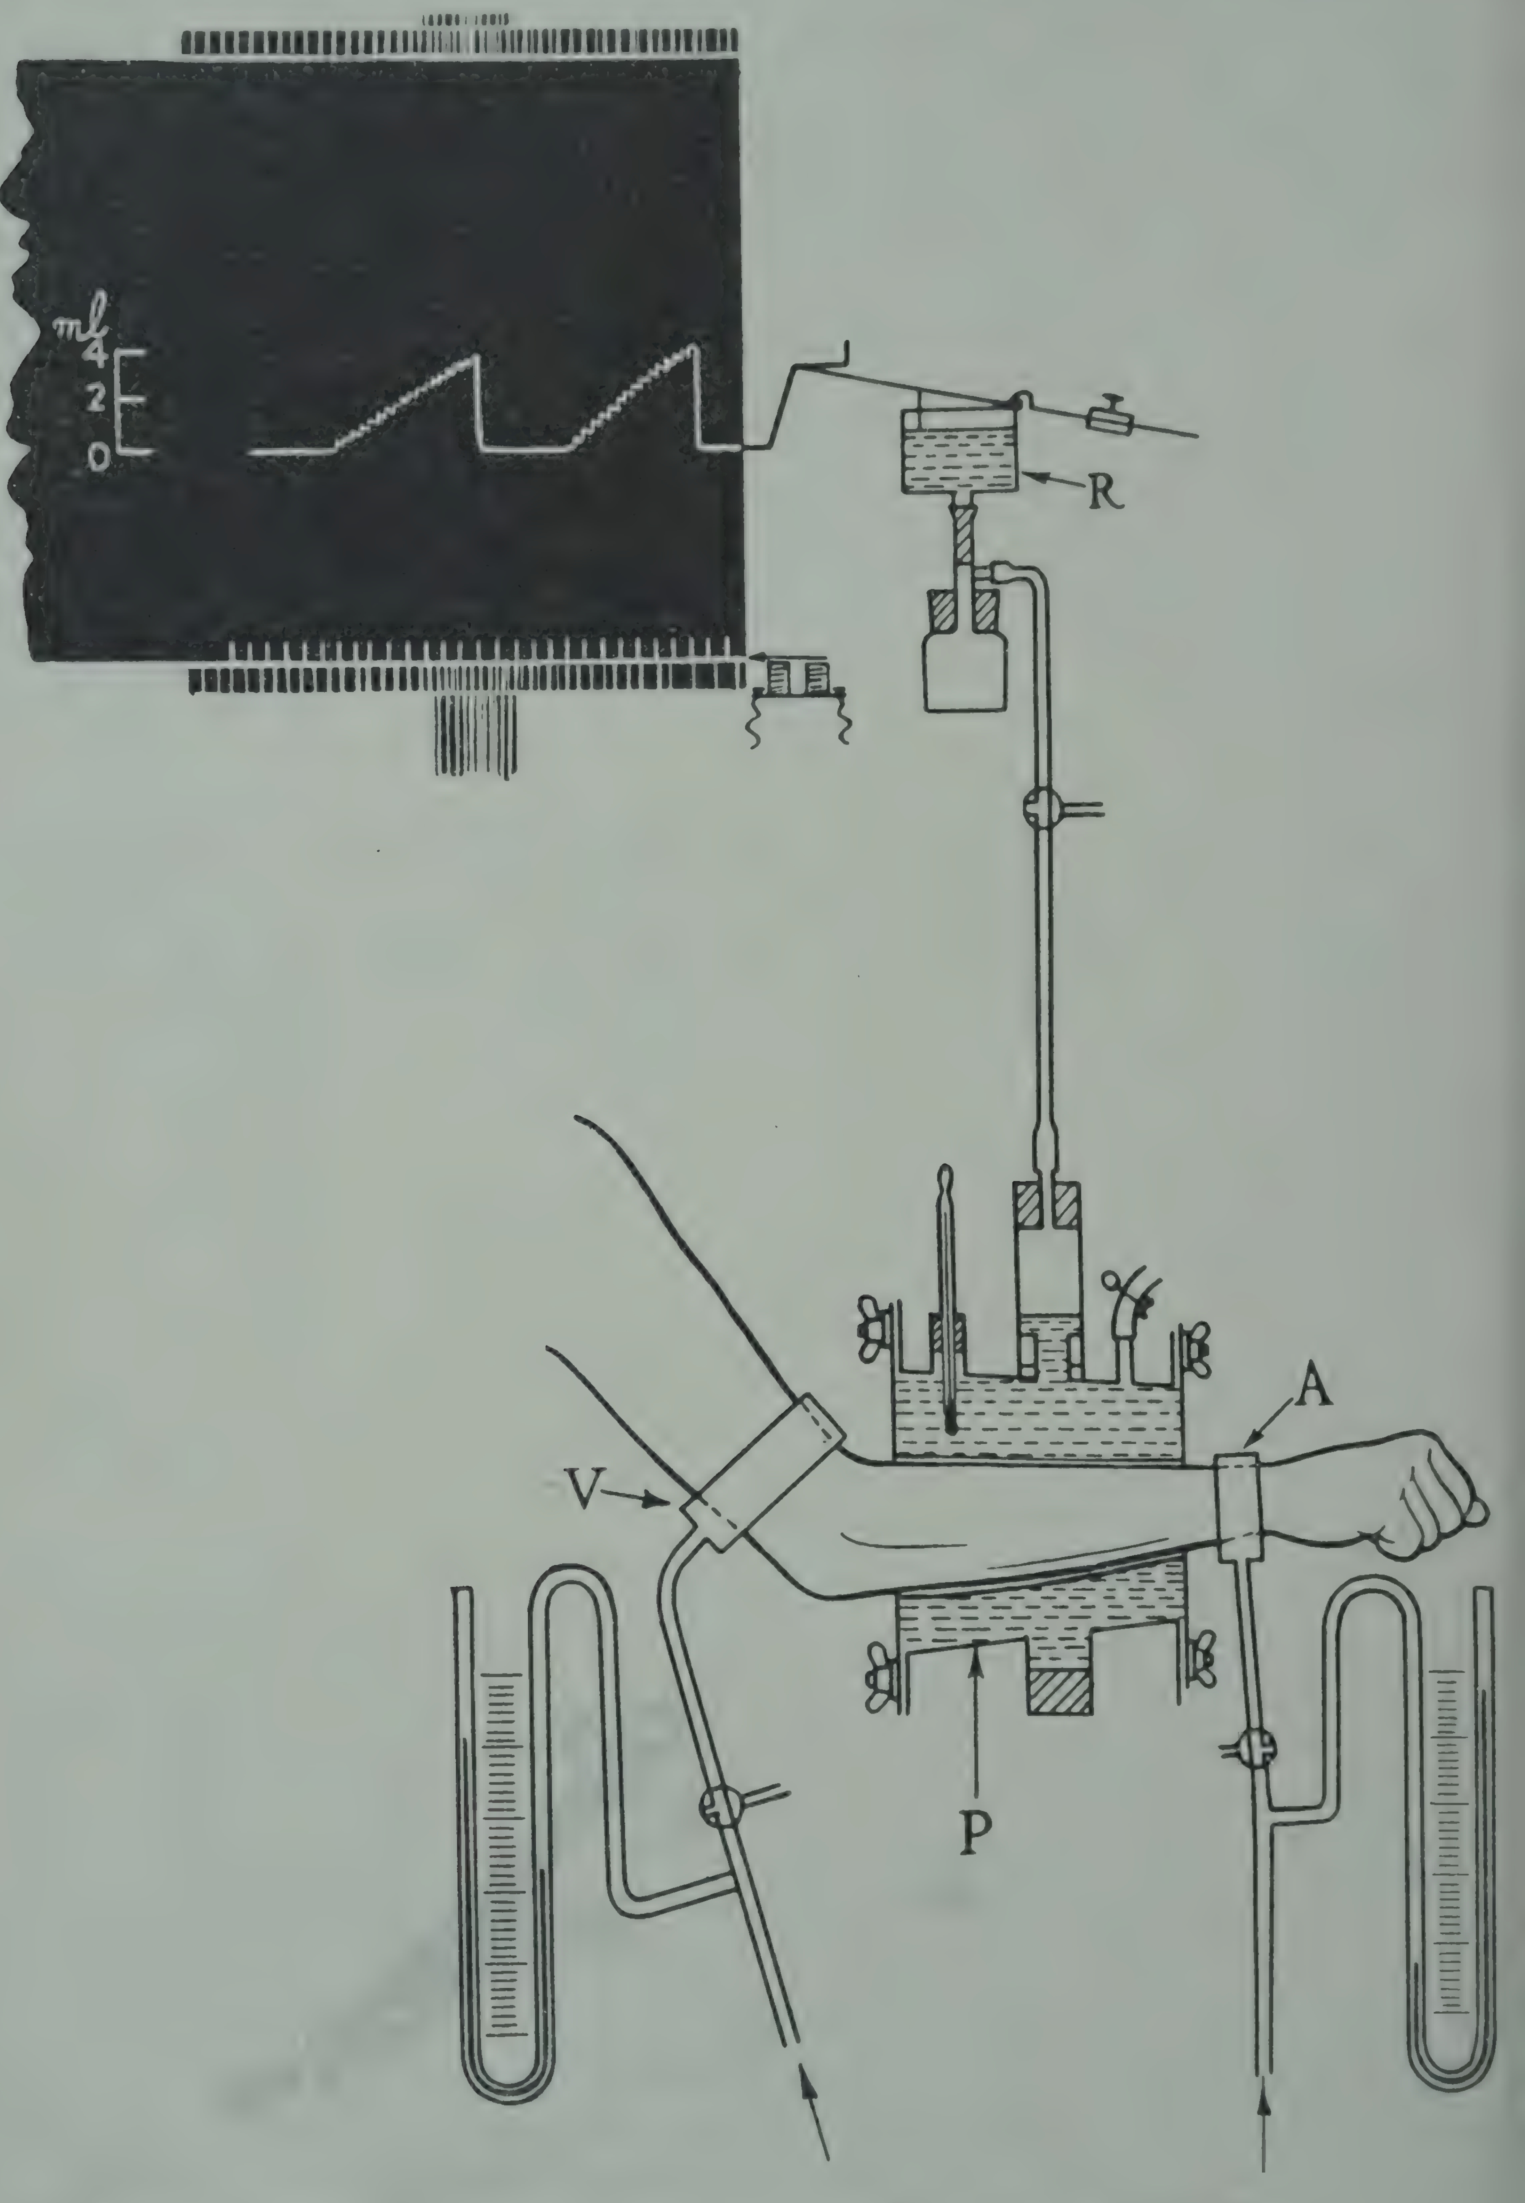

Fig. 427. Illustrating method of measuring forearm blood flow.

flow for the whole body would only be 8 c.c./100 g./min. The volume of bloo flowing through the various organs shows wide variation, depending chiefly o the intensity of metabolism of the organ, and so on its oxygen requirement If the organ becomes more active the blood supply to it is increased by dilatatio of the arterioles, or capillaries, or both.

The following figures give approximate rates of flow per 100 g. organ per minute :

Thyroid	560 c.c.
Kidney	400 c.c.
Liver (1/3 arterial, 2/3 portal)	150 c.c.
Heart (coronary circulation)	100 c.c.
Brain	55 c.c.
Intestine	70 c.c.
Resting muscle	3 c.c.
Tissues of hand (mainly skin)	4 to 30 c.c.

Of the total output of the left side of the heart it is probable that in states of muscular rest about half goes to supply the head, upper extremities and liver [*] : about one-quarter goes to the kidneys, and a quarter to musculature and other regions.

THE ARTERIAL PULSE

The systolic rise of pressure at each heart beat causes an expansion, spoken of as the pulse, which can be felt in any superficially situated artery, such as the radial. As we have seen, the amplitude of the pulse decreases as we go farther away from the heart.

From time immemorial the physician has sought, by feeling the pulse, to come to some idea as to the condition of the heart. A number of different qualities have therefore been distinguished, *e.g.* the *rate* may be rapid or slow, the size or *amplitude* large or small, while the *hardness* of the pulse is determined chiefly by the blood pressure.

If the pulse is compressible it is spoken of as *soft ;* if it can only be obliterated with difficulty it is *hard.* Certain combinations of these qualities are also described. Thus a large and hard pulse is spoken of as *strong*, a *weak* pulse being both small and soft. If the rhythm of the heart beat is irregular the pulse is also *irregular.* An *intermittent* pulse is one in which one heart beat is dropped occasionally, *e.g.* once in every four or eight beats, and may be due either to the interposition of a ventricular contraction which is too weak to propel the pulse so far as the radial artery, or to the occurrence of a premature contraction, followed by a compensatory pause.

A distinctive pulse is that known as the " *water-hammer* " *pulse,* which is observed in cases where the aortic valves are diseased and allow of regurgitation. The systolic rise of pressure in the arterial system is followed by an extremely rapid fall. Under such conditions, if the arm be held above the head, the pulse in the arteries of the wrist is felt as a smart blow.

Cause of the Pulse Wave. If the arterial system were perfectly rigid, the increased pressure at each ventricular systole would occur practically simultaneously at every point. The arteries are, however, elastic and distensible, so that the first effect of the flow of blood into the aorta is to distend the section of the aorta nearest to the heart. The shock due to this suddenly increased tension is transmitted from segment to segment of the arteries in the form of a wave, at the velocity of about seven metres per second.

It is important not to confuse the velocity of the pulse wave with that of the blood flow ; the latter is never greater than 0·5 metre per second, and is very much less than this in the smaller arteries. Perhaps the difference between the two quantities may be made clearer by analogy. When a railway engine shunts a row of slowly moving trucks, a jolt is very quickly passed on from truck to truck until the end van is reached, though in that short time the train as a whole has moved a very short fraction of its length, by the constant push of the engine. In the arteries, the continuous pressure is furnished by the elastic reaction of the arterial wall, and we see how the impact of the blood may travel quickly as a wave of increased pressure, while the blood itself is moving slowly along, impelled by the reaction of the arterial wall.

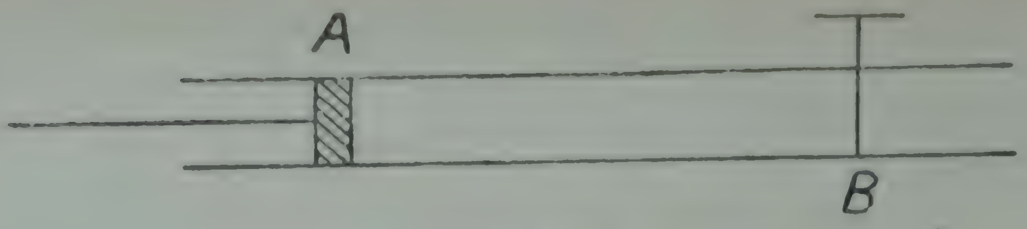

FIG. 428

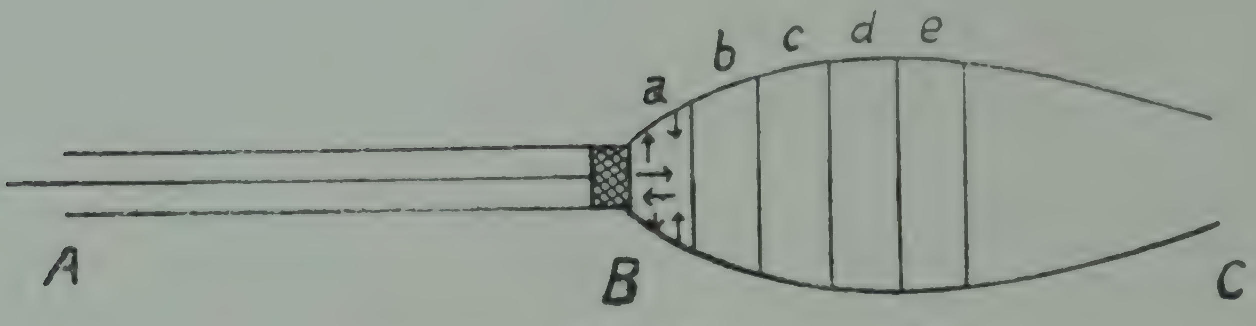

FIG. 429

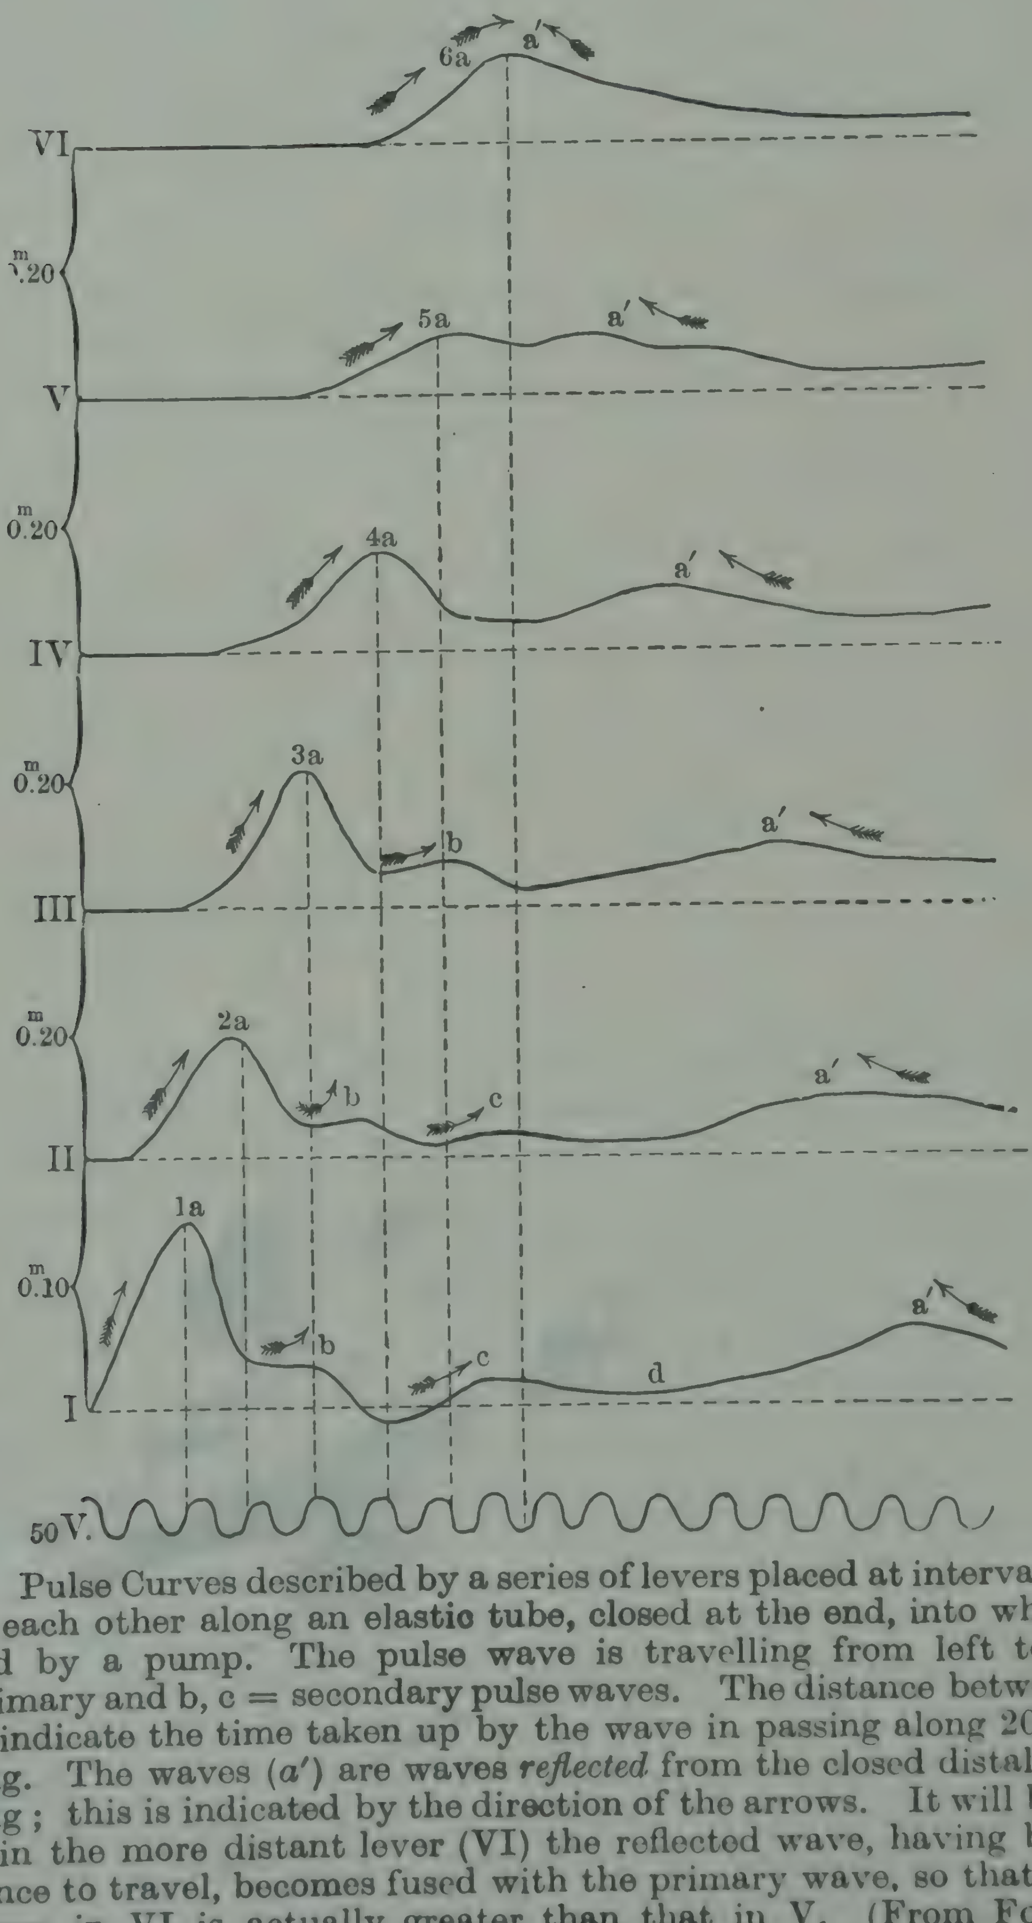

FIG. 430. Pulse Curves described by a series of levers placed at intervals of 20 cm. from each other along an elastic tube, closed at the end, into which fluid is forced by a pump. The pulse wave is travelling from left to right; a = primary and b, c = secondary pulse waves. The distance between vertical lines indicate the time taken up by the wave in passing along 20 cm. of the tubing. The waves (a') are waves *reflected* from the closed distal end of the tubing; this is indicated by the direction of the arrows. It will be observed that in the more distant lever (VI) the reflected wave, having but a slight distance to travel, becomes fused with the primary wave, so that the rise of pressure in VI is actually greater than that in V. (From FOSTER, after MAREY.)

In a rigid tube AB (Fig. 428) provided with a piston at the end A, and filled with fluid, an inward movement of the piston at A will cause a simultaneous outflow of fluid at the end B. If the end B is closed, the piston at A cannot be moved at all. Pressure applied to the piston will raise the pressure simultaneously at all points in the tube AB. The increased pressure applied at A is therefore transmitted with practically no loss of time to all parts of the tube AB. The transmission will be retarded if we have a tube whose wall is distensible and elastic. If we imagine (Fig. 429) an elastic tube BC filled completely with water and connected at B to a rigid tube, which is provided with a piston, the first effect of a rapid movement of fluid driven in by the piston will be a rise of pressure at the point immediately in front of the piston, viz. at *a*. The wall being distensible, and pressure being propagated along the fluid in every direction, the rise of pressure at *a* will be spent partly on the particles of fluid in front of it, viz. at *b*, but also on the walls of the tube, so that this is stretched and the cross section of the tube enlarged. The distended segment at *a* will then exert a pressure on the contained fluid, driving this backwards and forwards. The fluid on its side towards the piston will tend to come to a stop, while that towards the distal end of the tube will be accelerated. The distended wall therefore returns to its original diameter, and the next segment at *b* is stretched in its turn, so that a wave of increased pressure is propagated along the tube in the direction of the arrow.

The velocity with which this wave is propagated depends on the density of the fluid, *i.e.* its inertia, and on the resistance of the walls of the tube to distension, *i.e.* on the rapidity of its recovery. The velocity of propagation of the wave of increased pressure, or the wave of expansion of the artery, is expressed by the following formula : *

$$v = \frac{3 \cdot 57}{\sqrt{E}}$$

where v = velocity in m./sec., and E = per cent. increase in volume of vessel per mm. Hg increase of pressure.

The elastic coefficient of the arterial wall becomes larger as the arterial wall is distended. The velocity of propagation of a wave of pressure in the arterial system will thus be greater when the arterial pressure is high than when it is low.

If the end C of the tube is closed, the wave of positive pressure on arriving at C will be reflected back as a positive reflected wave. If a tracing be taken of the oscillations or variations of pressure in the tube, two waves at least are seen, one of which is the primary wave due to the movement of fluid caused by the piston ; the other is the secondary wave reflected back from the periphery. That the secondary wave is a reflected one is shown by the fact that the nearer to the closed end the pulse is recorded, the nearer is the secondary to the primary wave, as is seen in Fig. 430.

If the tube BC be widely opened at C, a reflected wave is also observed, but this time the wave is one of reduced pressure. The production of this wave is dependent on the momentum of the moving column of fluid. If in the tube *ab*, with a tap at *c* and a manometer *m* (Fig. 431), the current of fluid be suddenly checked by turning the tap *c*, the column in front of the tap, having a certain momentum, will tend to go on moving and therefore produce a suction or "negative pressure" behind it. When a wave of pressure arrives at the open end of a tube, there is a sudden drop in the resistance to the output, and the momentum of the mass of fluid which is thrown out causes a similar suction or "negative pressure," which

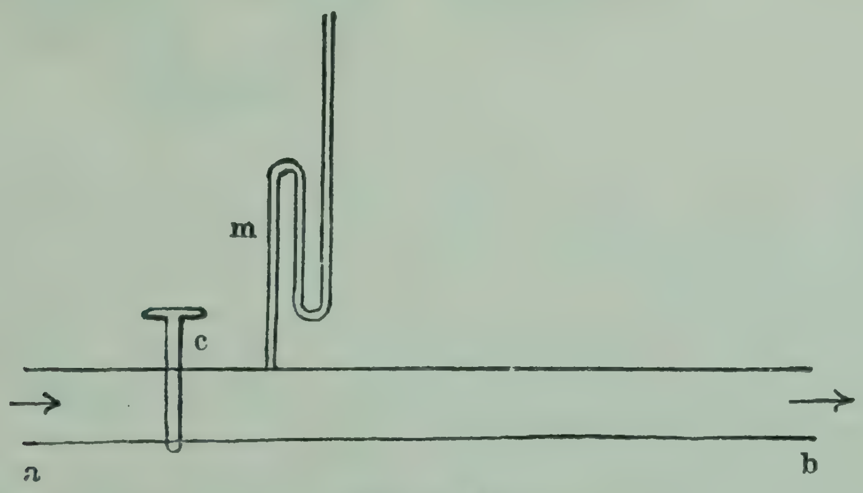

FIG. 431.

---

* BRAMWELL and HILL. *Proc. R. S.*, 1922, **93B**, 298.

travels back the whole length of the tube. If the end of the tube is only partially closed, every primary positive wave will be transformed into a reflected one which is partly positive and partly negative. Since both these reflected waves travel through the tube with the same velocity and will mutually interfere, the result may be either a positive or a negative wave or nothing at all, according to the degree of constriction.

In a branching system of tubes, such as the arterial system, reflection of waves must take place at every division. All the conditions for the origination and interference of such waves are present in the arterial system. It is impossible, however, to say *a priori* whether any reflected wave will form a marked feature on the pulse tracing. It is possible that the multitudinous reflections which must occur in every part of the arterial system may interfere with one another to such an extent that they mutually annul each other. The identity of any secondary wave in the pulse tracing must therefore be determined by exact measurement and experiment.

Pulse Tracings. To study the pulse it is necessary to obtain a graphic record of the expansion of the arteries or of the changes in pressure which produce this expansion. The former is the more accurate because, owing t the fact that the extensibility of an artery diminishes with rising pressure, given increment of pressure causes a greater expansion at the commencemen of the rise than towards its peak. For accurate records, a manometer whic has very little inertia, such as Wiggers' (p. 557), must be used, or the expansio of the artery may be recorded photographically. The expansion of the arter can be approximately registered by means of a lever, which may be made t rest upon an artery, *e.g.* the radial, and the movements of which are record on an appropriate surface. Such an instrument is called a *sphygmograph*.

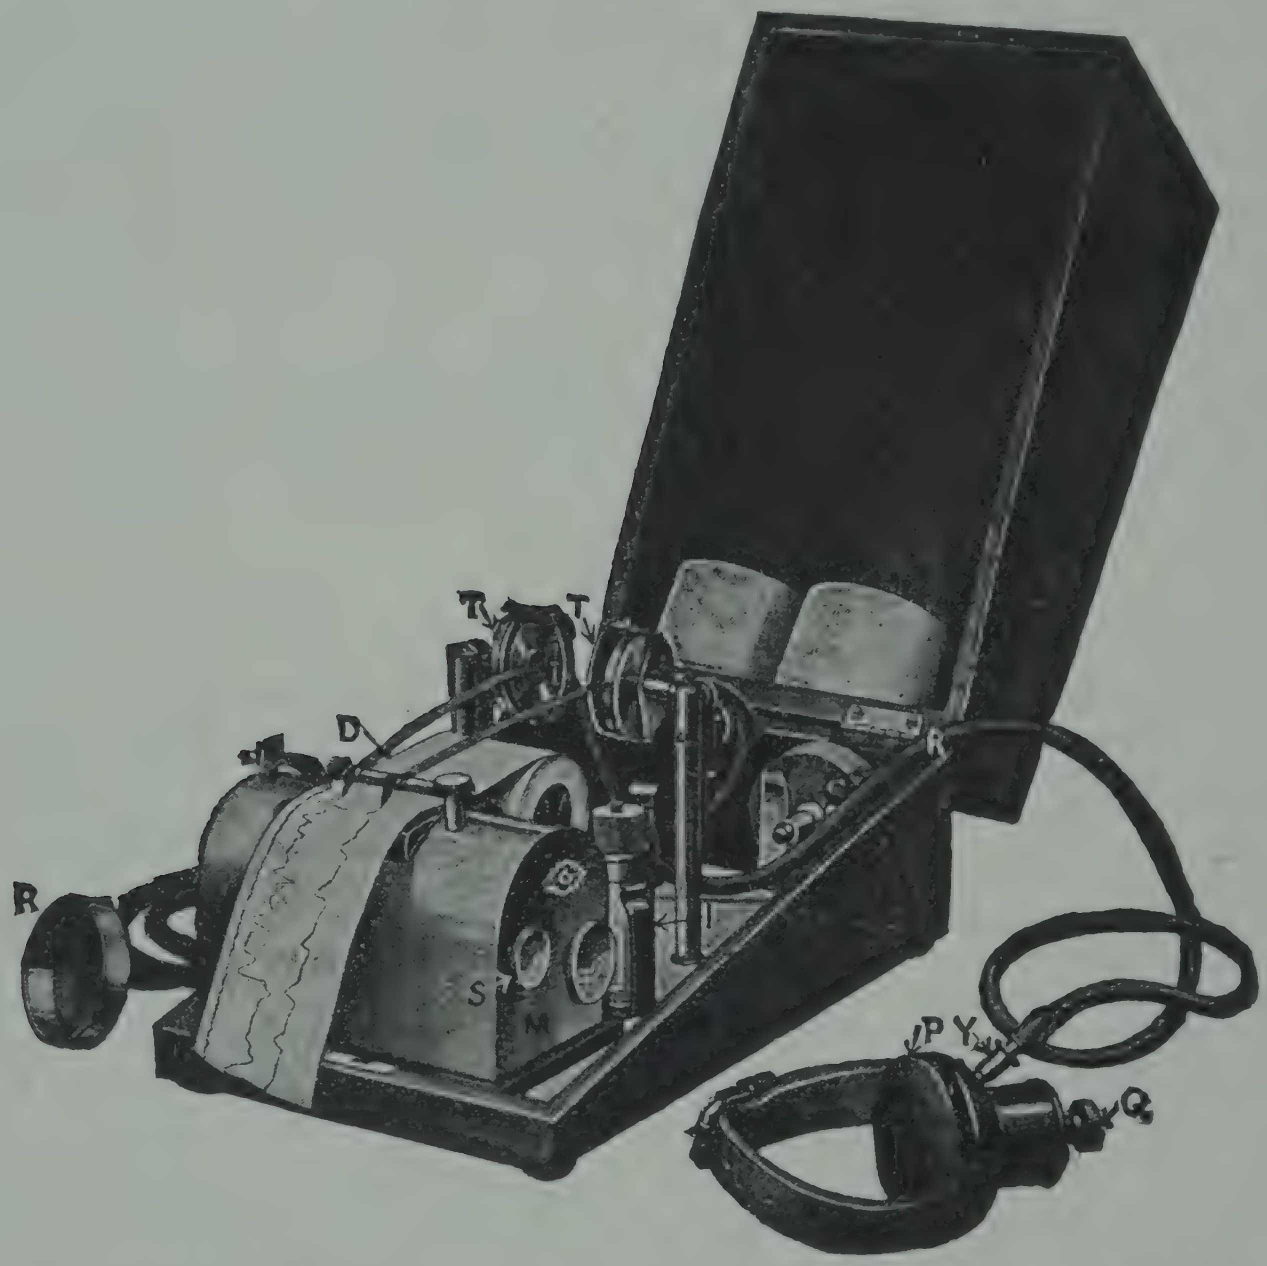

FIG. 432. The Polygraph. The record is made on the paper, wound out by clockwork from a roll, by the ink pens D. These are attached to levers of the tambours T-T, which are actuated by air-transmission from the receivers. P is the glycerin pelotte which can be strapped round the wrist; the pulsations of the radial artery cause movements of the air along the tube leading to the tambours, and so records the pulse tracing of the artery. R, an open capsule, can be used for application over the jugular vein, in recording the venous pulse. (CAMBRIDGE INSTRUMENT CO. LTD.)

Alternatively, one of the various forms of *polygraph*, depending on air transmission by tambours, may be used. They have the advantage that records from two or three sources, *e.g.* from two different arteries, or from artery and vein, or cardiac impulse, etc., may be made simultaneously (Fig. 432).

In all such instruments the moving parts have considerable inertia, so that the curve they give is always deformed. This fact must be borne in mind when comparing the pulse curves obtained by means of a sphygmograph or polygraph with those given by the more perfect forms with optical methods of recording. If an open cup be firmly pressed to the skin over an artery, such as the carotid or subclavian, and be connected by a tube with a "segment capsule," the excursions of which are recorded photographically, curves may be obtained reproducing in all particulars those given by optical manometers (Fig. 433).

The pulse wave undergoes considerable modification in shape and time relations as it passes along the arterial system. The time-pressure or time-volume curves taken in the aortic arch or its great branches, such as the subclavian or carotid, closely follow the time-pressure curve of left intraventricular pressure during the phase of ejection, and so are of importance in man as an index of the action of that chamber. This type of pulse is called the *central arterial pulse* to distinguish it from the *peripheral arterial pulse* as recorded in smaller arteries, such as the radial.

The differences between a *central* pulse as recorded in arteries such as the subclavian, and an intermediate or terminal pulse given by arteries such as the carotid, radial or dorsalis pedis * are due to the fact that the contour of the pulse, as it occurs at the aortic arch, is modified in its transmission to the periphery by friction, by incidental vibrations and by interference due to reflected waves. The central pulse, as recorded in Fig. 433 from the subclavian artery, shows the following features :

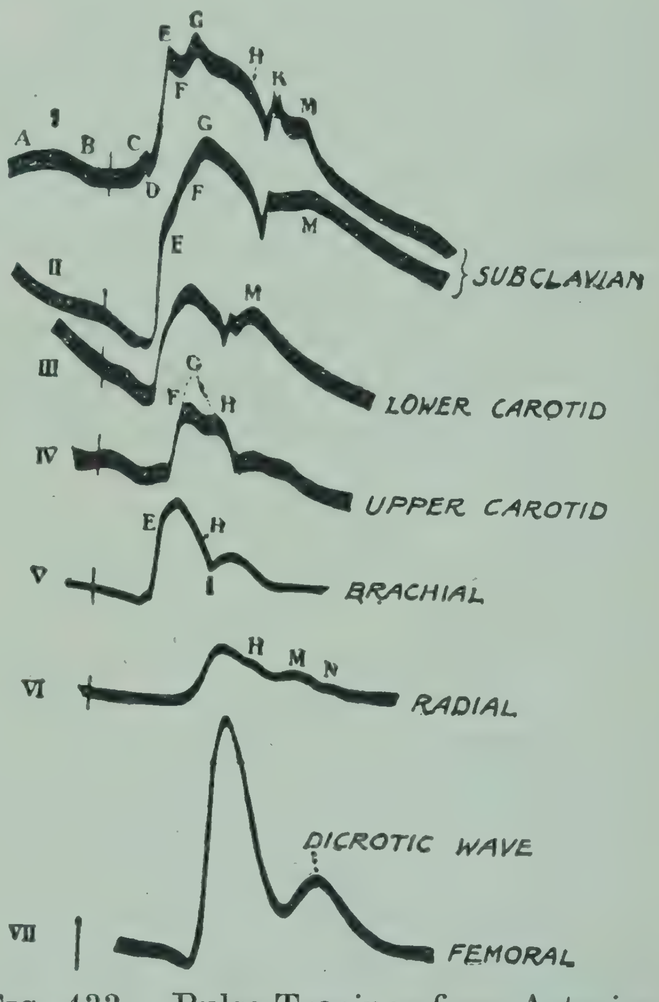

Fig. 433. Pulse Tracings from Arteries, taken by Air Capsules and Optical Recording. (Wiggers.)

(1) An oscillation between A and B, due to the auricular systole (transmitted).

(2) A second elevation between B and D which corresponds with the isometric part of the ventricular contraction. (1) and (2) are probably vibrations transmitted across the thorax.

(3) At D the semilunar valves open, and blood is rapidly ejected into the aorta, giving the main pulse between D and G. The sudden rise of pressure in the aorta sets the column of blood within the elastic vessel into vibration, giving the overshoot at E and the return wave or anacrotic halt, E F.

(4) The arterial curve now follows the intraventricular pressure (*vide* Fig. 364, p. 559), the flow of blood continuing quickly up to G, but then slowing off during the rest of the ventricular systole to H (Fig. 433).

(5) At the beginning of ventricular diastole there is a rapid backward movement of the blood towards the heart, causing the *incisura*, H I, and brought up rapidly by the closure of the aortic valves. The rebound of the blood from the valves causes one or two secondary elevations, K, after the incisura.

(6) The curve then falls gradually until the next ventricular systole supervenes, sometimes with slower waves at M.

The peripheral pulse gives similar features to the central pulse, but modified by the conditions mentioned above. The preliminary and anacrotic oscillations disappear (though the anacrotic oscillation may be counterfeited by a momentum swing of the lever in the ordinary imperfect sphygmograph); the incisura becomes less sharp, and is replaced by the *dicrotic* dip, and the wave K is replaced by the sometimes very conspicuous *dicrotic* wave; the main upstroke is delayed and its rise more gradual, while the amplitude of the whole curve is usually diminished. These changes are more marked as the periphery is approached, until finally in the smallest arteries and in the capillaries the pulse may disappear altogether.

---

* Wiggers. *J. Amer. Med. Ass.*, 1915, **64**, 1485.

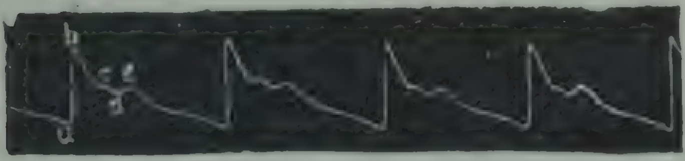

FIG. 434. Pulse Curve from Radial Artery.

Fig. 434 represents a pulse curve taken from the radial artery by means of a sphygmograph. It shows the anacrotic limb, or percussion wave, *a–b*, a peak at *b*, and a slower downstroke, or catacrotic limb which is broken by secondary waves, the most conspicuous of these being the *dicrotic wave*, with its preceding *dicrotic notch*, *c*. This sphygmogram should be compared with the curves, taken by more perfect methods, in Fig. 433, so as to appreciate the deformation by ordinary sphygmographs of the real curve of expansion of the arterial wall.

The pulse curve gives approximate information as to the condition of both the heart and the arterial system. Thus, the period between the beginning of the primary elevation and the dicrotic notch corresponds to the outflow of blood from ventricle to aorta. A large pulse curve does not necessarily indicate a big output, since the expansion of the artery is determined not only by events occurring in the aorta but also by the expansibility of the artery and the resistance in the peripheral branches.

The general form of the pulse curve varies with changes in the heart, in the arteries and in the peripheral resistance. Thus, some sphygmograph curves may present secondary elevations on the ascending part, and are called *anacrotic*.

A curve of anacrotic type is normally seen in the subclavian artery (Fig. 433), but in the radial artery usually only in cases in which, owing to aortic stenosis, there is an ascending plateau in the intraventricular pressure tracing. When the peripheral resistance is high, or when an extra large amount of blood is thrown into the aorta at each stroke of the heart (*e.g.* by slowing of the rate), the aortic pressure rises very abruptly at the commencement of the ejection phase, and then more slowly so long as blood is flowing in, and we get an ascending systolic plateau and an anacrotic pulse. If the pulse rate is quickened the anacrotic wave disappears.

The production of the dicrotic elevation is favoured by any influence which increases the distensibility of the arteries or causes the primary elevation of the pulse to be extensive and sharp. Thus it is much more pronounced in young people, and in aortic incompetence ("water-hammer pulse"). When the peripheral resistance is low through relaxation of the arterioles, and the heart is beating forcibly, as in fever, and also to some extent after alcohol, the dicrotic elevation becomes so large that it may be felt at the wrist, and the mistake has been committed of taking the dicrotic wave for a normal beat, and so doubling the actual rate of the pulse.

Reflected Waves. It has been suggested that, in the production of such a marked dicrotism, reflection from the periphery may play an important part. With a high blood pressure and rigid arteries, a reflected wave will travel back very quickly and will tend to add itself to the primary wave. With a low blood pressure, dilated arteries, and the output of the heart thrown rapidly into a relatively empty arterial system, the primary wave will rise and fall very rapidly, and the reflected wave will travel back along the arteries more slowly, so that its main effect might be to add to the dicrotic elevation normally proceeding outwards from the heart towards the periphery. The Fig. 430 VI would represent the condition as it is found in the femoral artery under normal circumstances when, according to Frank, the reflected wave adds to the height of the primary wave. In Fig. 430 V the reflected wave "a" would tend to add to any dicrotic elevation present at this point, and might represent the relation existing in the arterial system with relaxed arteries and a heart beating forcibly, but throwing out only a small amount of blood at each beat.

It would seem that the central pulse can be referred entirely to events taking place in the heart during systole, or at the beginning of the aorta at the commencement of diastole; and there is no reason to assume the co-operation of waves reflected from the periphery to explain any of the secondary waves observed. The effect of the dispatch of the sudden wave of pressure started in the aorta along an elaborate system of elastic tubes must be to diminish the rapidity of onset of each primary wave, and therefore to diminish the secondary vibrations of the curve. In an elastic system of tubes such as the arterial system, there are factors at work analogous in many respects to those responsible for the deformation of the curve given by an imperfect manometer.* These would be of two kinds—viz. oscillations of the column of fluid within the stretched arterial wall, and the reflection of waves from different points in the periphery. Many of these reflections will interfere with and annul one another. But in the arterial system there are certain points from which distinct reflections of waves can be expected—*e.g.* in the circle of Willis, at the bifurcation of the aorta into the two iliac arteries, and in the superficial and deep arterial arches in the hand and the foot. We have distinct evidence that such waves are set up and modify the form of the pulse in the femoral and brachial arteries and their branches. Thus in Fig. 433 V-VII, the primary rise of pressure in the femoral artery is higher than even the primary rise in the subclavian. This condition of things is explicable only on the assumption of a reflected wave passing back along the artery just after the passage of the primary wave, so that the two are summated. In the same way, although the dicrotic depression in the curve (Fig. 433, VII) is no doubt mainly the propagated effect of the incisura observed in the aortic pulse, it is probably deformed, and the subsequent elevation exaggerated, as a result of reflection of some wave from the periphery. The occurrence of reflected waves may serve to explain why the systolic pressure in the femoral artery is found higher, and the diastolic pressure lower, than in the brachial. The femoral artery being more rigid than the brachial, and the peripheral resistance more definitely localised, reflected waves occur in the artery at so short a time after the primary wave has passed down, that there is summation of the two waves, with production of a higher maximum and a lower minimum than was present in the waves as started in the aorta. If the leg be plunged into hot water, so as to dilate all its arterioles, this difference between the arm and the leg systolic pressures disappears. The varying development of reflected waves on the two sides may also explain why the systolic pressures in the two arms are rarely found to be identical.

It has been pointed out † that, as the pressure rises rapidly in the artery at each pulse and the wall becomes more rigid, there is a corresponding increase in the velocity of propagation of the wave along the artery which would tend to make the rise steeper towards the periphery. This will be more marked the more rigid the arterial wall, and may account for the primary elevation in the big arteries of the legs being higher than in the more extensible arteries nearer the heart.

As the pulse wave travels along it changes in form, and under certain conditions part of the wave front becomes steeper, and eventually unstable. The result is a turbulent motion which may be compared with the formation of breakers in water waves on a shore. Such a change gives the peculiar character to the " water-hammer pulse " and is also responsible for the cracking character of the Korotkov sounds when the pressure on the armlet is just above the diastolic pressure.‡

The *velocity of the pulse* wave can be measured by taking simultaneous tracings from two arteries separated by some distance from one another, such as the femoral artery and the dorsalis pedis, or from the carotid and radial arteries. In healthy individuals the velocity varies between 5 and 9 metres per second. The more rigid the arteries and the higher the arterial pressure the greater will be the velocity, so that the velocity of propagation gradually increases with advancing age,§ and is higher in the arteries of the lower extremities than in the more distensible arteries of the arm.

The length of the pulse wave can be found by multiplying the velocity of transmission by the time occupied by the wave in passing any given point (0·8 sec.), so that if the velocity of transmission be taken as 7 metres per second, the length of the wave is about 5·6 metres. The pulse wave thus begins at the periphery long before it has been completed in the aorta.

The Volume Pulse in Organs. Each heart beat, by causing a pulsatile expansion of the arteries throughout the body, results in the organs momentarily receiving blood faster than the veins carry it away. Hence there is a pulsating distension of all the vascular organs of the body, which may be graphically recorded by a delicate plethysmograph, one pattern of which, suitable for use with a finger, is shown in Fig. 435. The form of the volume pulse of the finger is seen to be similar to that of the radial pulse, though nearly 0·1 second behind it in time (Fig. 436).

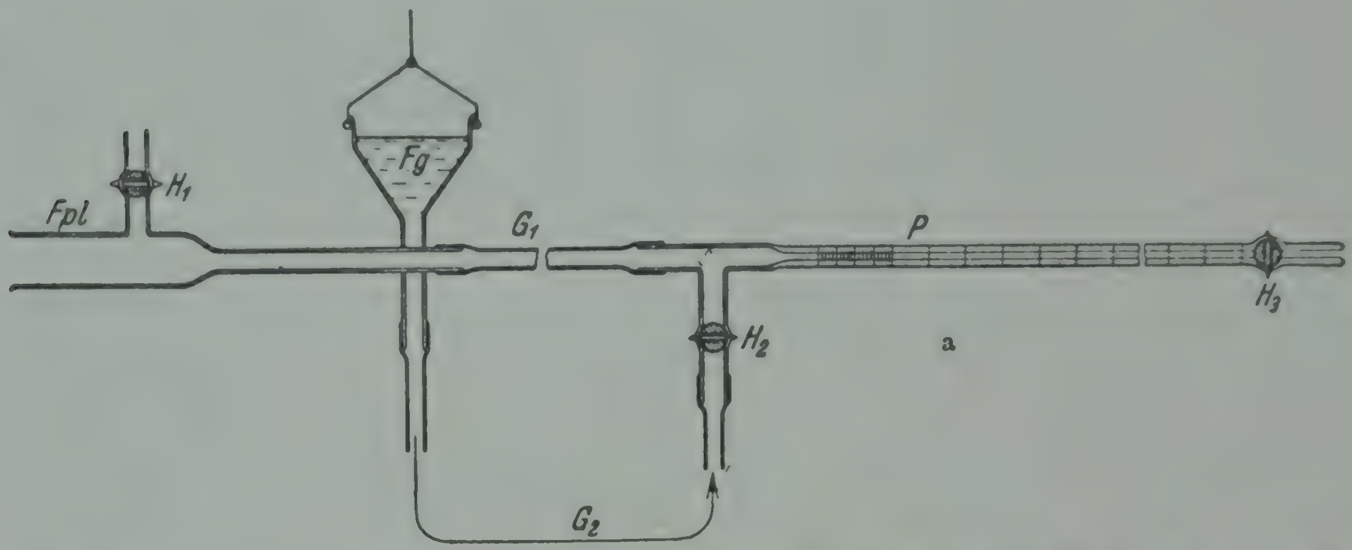

Fig. 435. Finger plethysmograph. The finger is placed airtight in *Fpl,* which is filled with warm water from *Fg.* The pulsations of the water meniscus in the capillary *P* are recorded photographically. (Goetz. *Pflüger's Arch.*, 1935, **235,** 271.)

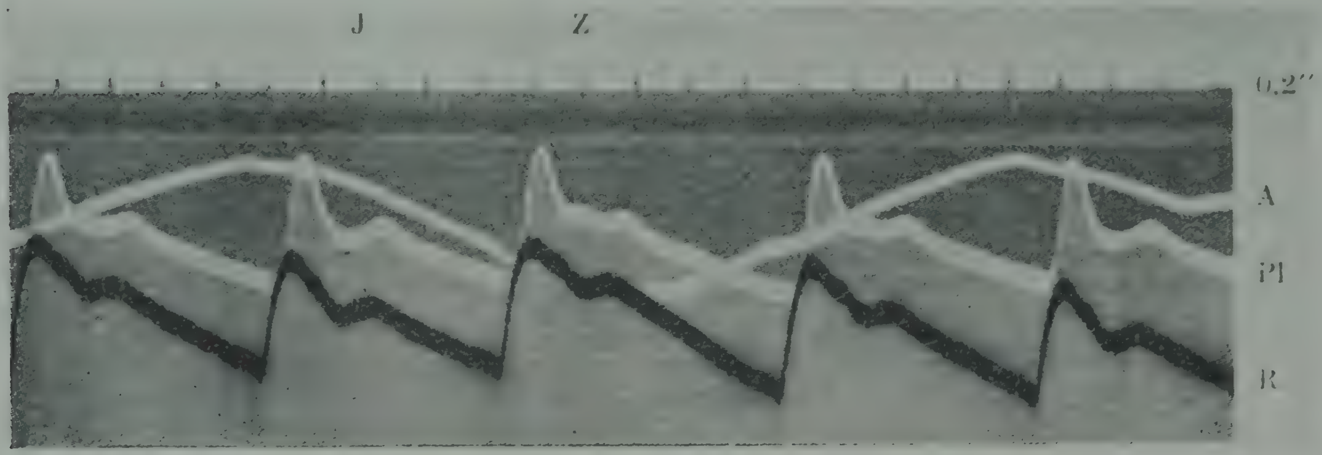

Fig. 436. Volume pulse of finger (Pl) recorded together with the radial pulse (R) and respiration (A) (inspiration upwards). Note the different character of the dicrotic waves at inspiration and expiration. (Goetz. *Pflüger's Arch.*, 1935, **236,** 271.)

When the tissues are tense with inflammatory œdema, the pulsatile distension causes the familiar throbbing pain because the tension is raised at each pulse wave, and pain fibres thereby stimulated.

THE CIRCULATION THROUGH THE CAPILLARIES

The circulation through the minute surface vessels of the skin in man, and in other tissues can readily be observed when a microscopic examination is made by reflected light. The skin is for this purpose covered with cedar oil or liquid paraffin (Fig. 437).

The capillary circulation is best demonstrated by examining under the microscope the tongue of the frog or the web of the frog's foot, when a network of vessels is seen, consisting of small arteries, capillaries and veins. The flow of blood in the arteries is rapid, in the veins it is slower, and is slowest in the capillaries. In the capillaries the flow is from arteries to veins, though, on account of the reticular arrangement of these vessels, the direction of the stream through some of them is not quite constant. If a group of capillaries be watched for some time, the blood may at first hurry through a number of them with rapidity ; the flow then becomes slower and later may quicken up to a moderate pace again. These variations in the capillary flow are probably associated with spontaneous alterations in the condition of contraction of the small arteries supplying the group of capillaries. It is easy to observe that the arterial flow is pulsatile, the pulsation being reduced, or disappearing, in the capillaries and veins. Another difference between the circulation in these three kinds of vessels is to be found in the condition of the peripheral zone. In the arterioles the blood stream is divided into two parts, the peripheral stream, consisting only of colourless plasma with occasionally a stray leucocyte—and an axial stream, in which all the red blood corpuscles are being hurried along. In the veins there is a similar peripheral plasmatic zone, but here we find regularly scattered leucocytes which travel rather more slowly than the axial stream of red corpuscles. The formation of this axial zone is purely mechanical, and may be imitated in any fluid containing in suspension particles whose specific gravity is somewhat higher than that of the fluid. In the capillaries there is no separation of the two zones, since the lumen of these vessels is so narrow that often the corpuscles, passing in single file, are squeezed out of shape as they progress. The corpuscles are highly elastic structures, and may be seen to bend if they impinge on the dividing point of two capillaries, before they are finally swept off by the stream into one or the other of them.

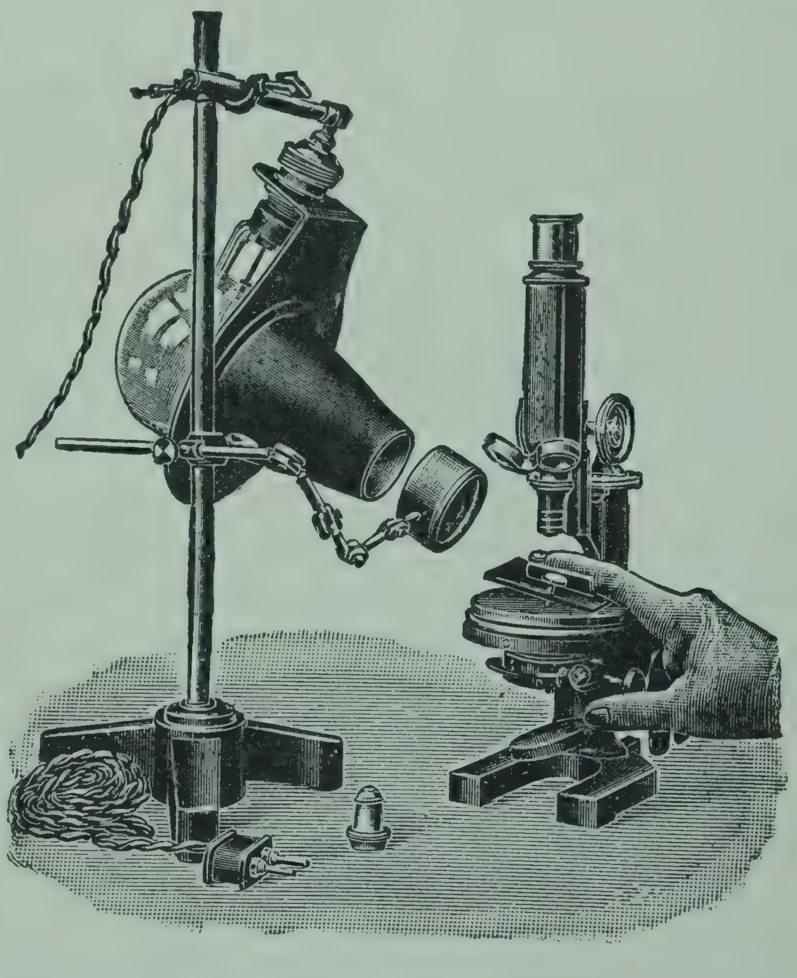

FIG. 437. Arrangement of Illumination for Viewing Skin Capillaries.

The capillary wall is composed of a single layer of flattened endothelial cells, which present little resistance to the passage through them by diffusion of dissolved substances. In this way the tissue cells obtain oxygen from the red blood corpuscles and nutriment from the plasma, and give off to the circulating blood carbon dioxide and other products of their metabolism. There is evidence that a sort of "contractility," due to a swelling of the nuclei of their endothelial cells when stimulated, is a universal attribute of the capillaries, and must play an important part in determining the amount of blood flow through an organ in accordance with its needs. In resting tissues many of the capillaries are so constricted as to allow of no flow at all.

The average length of a capillary is between 0·4 and 0·7 mm. The velocity of blood flow can be directly determined by observing under the microscope the time taken by any given corpuscle to travel a measured distance. The mean velocity determined in this way varies from about 0·5 to 0·8 mm. per second.

The blood pressure in the capillaries may be measured approximately by applying pressure to the outer surface of the skin or mucous membrane by means of a Recklinghausen capsule (Fig. 414) and noticing the point at which blanching of the surface commences. The errors of this method are considerable. The pressure in the capillaries, as found by this method, is low, and necessarily varies with the position of the part under investigation, *i.e.* with the hydrostatic pressure. It is raised, often greatly, when there is a dilatation of the arterioles, and lowered when these constrict.

Capillary pressures have also been measured in man by Carrier and Rehberg as follows: A fine glass capillary is filled at the point with saline solution and pushed into a skin "capillary" which is under observation under the microscope. Attached to the other end of the capillary tube is a water manometer, by means of which a definite pressure is applied to the column of saline solution in the capillary glass tube. When the blood capillary is pierced, blood will flow into the glass capillary if the capillary pressure is higher than that in the water manometer; if lower, no blood will enter: if the same, blood will pulsate in and out of the glass capillary at each heart-beat.

In man it has been found that the capillary pressure in the skin of the finger varies with the position of the hand with reference to the heart, and may be 40 cm. H_2O, or more, or as little as 4 or 5 cm.; but, however high up the hand is placed, it never falls below a certain level of about 4 to 5 cm. The reason for this is that the veins collapse and restrict the flow when the hand is held in such a position that the venous pressure becomes negative. The capillary pressure is thus always maintained at a positive value, which varies according to the position. In the feet the capillary pressure is normally prevented from attaining very high values, owing to the presence of valves in even the smallest veins, and to the occurrence of constant small muscular movements, which, by forcing the blood along these veins, enables them to act as a kind of pump. The pressure gradient along a systemic capillary is considerable. Landis* found the average pressure at the arterial end of skin capillary loops to be 32 mm. Hg and that at the venous end 12 mm. Hg. Pulmonary capillaries are wide, and their gradient small.

Owing to the fact that the resistance of the arterioles lies between the capillaries and the arteries, the pressure in the capillaries must stand in much closer relationship to that in the veins than to that in the arteries. One cannot therefore argue that a fall of arterial pressure necessarily involves a fall of capillary pressure in all parts of the body. We can only judge of changes in the capillary pressure by simultaneously taking the pressures in both the afferent and efferent vessels. If these both rise or fall together we may be certain that the capillary pressure also rises or falls. When the arterial and venous pressures move in opposite directions, it is difficult to say what alterations, if any, will be produced in the capillary pressure.

The resistance to the flow of blood through the capillaries is determined by the internal friction, *i.e.* the viscosity of the blood; as already explained (p. 618), when circulating in the blood capillaries, this is only about twice that of water. The velocity of flow through a capillary bed varies directly as the driving (arterial) pressure, provided this is above 20 mm. Hg, below which little flow occurs. The chief seat of the resistance in the vascular system is in the arterioles, and it is in this region that the chief fall of pressure occurs.

No part of the circulation shows greater variations than the capillary system. We must think of this as a vast irrigation system—the greater part of which is closed under normal circumstances, and open only when the tissue requires a large increase in the supply of blood. In muscle the capacity of this irrigation system may be increased 750 times during activity. Such changes (if of widespread occurrence) will affect arterial pressure by their influence on the total capacity of the vascular system as well as by alterations in the peripheral resistance.

Capillary Fragility. The walls of the capillaries are lined continuously with endothelial cells, which may not normally allow the proteins of the plasma to pass through

---

* LANDIS. *Heart*, 1930, **15**, 209.

When subjected to a sufficient pressure, however, the walls give way, and then blood escapes into the surrounding tissues, causing a local discoloration. When seen in the skin such patches appear as red spots called *petechiæ*. In certain conditions (*v.* Ch. XLII) such as scurvy, these petechial hæmorrhages occur very much more easily than in normal states. The tendency of the skin capillaries to rupture can be found by means of Göthlin's fragility test. A sphygmomanometer armlet is placed round the upper arm, and raised to, and kept at, 50 mm. Hg for fifteen minutes. The armlet is then removed and the skin of the antecubital fossa examined for petechiæ. Not more than eight should be present in a circle of 6 cm. diameter, when examined in a strong light.*

THE CIRCULATION IN THE VEINS

In the veins there must be a constant decrement of pressure as we pass from the periphery towards the heart. Owing to the fact that no appreciable resistance lies between the veins and the heart, the pressure gradient necessary to maintain a constant flow through these vessels is very small. Thus, in the horizontal posture, the pressure in the femoral veins may be from 5 to 10 mm. Hg, and in the external jugular vein from 0 to — 2 mm. It is convenient for clinical purposes to observe the extent to which the external jugular vein is filled with blood when the patient lies down with the head raised. The vein then acts as a manometer, and is seen to be distended to a level which is normally 0 to 2 cm. below a horizontal line passing through the junction of the sternum with the manubrium (Fig. 438). The pressure in the great veins near the heart is generally below that of the atmosphere, owing to the aspiration of the thorax, and becomes still lower during inspiration. Opening the thorax, therefore, causes a rise of pressure in all the large veins. In the latter, the pressure is lowered by vigorous action of the heart pump and raised when this fails in any way. In the peripheral veins the pressure is more dependent on the flow through the corresponding arteries. If an artery of a limb be ligatured, the pressure in the small veins of the limb sinks until it is reduced to the pressure in the nearest large trunk in which a flow of blood continues.

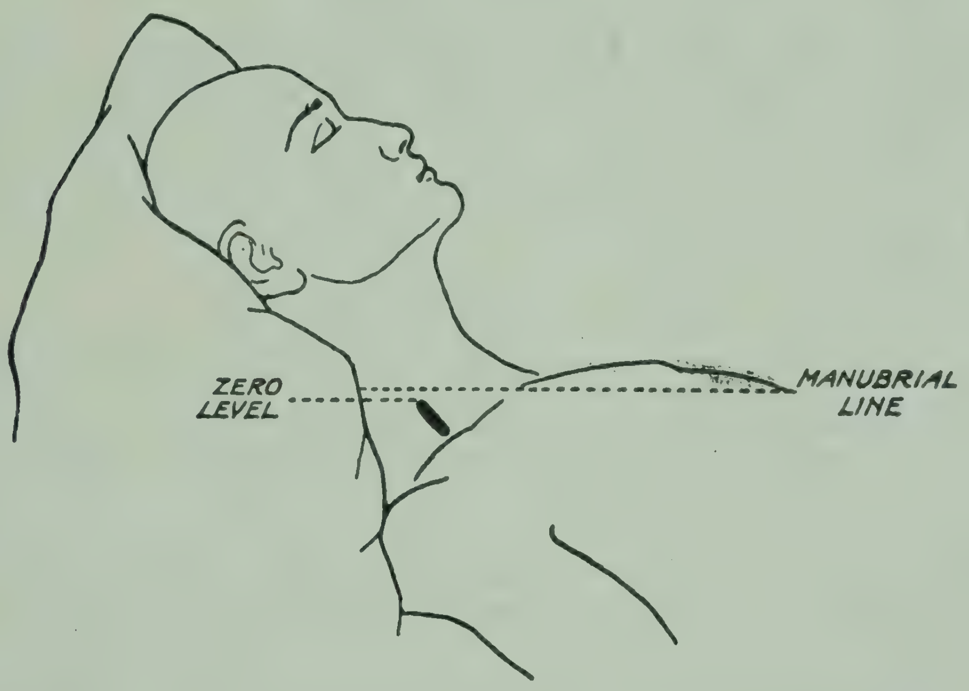

FIG. 438. Level of filling of external jugular vein. (LEWIS.)

If a vein is ligatured, the blood usually finds its way by anastomotic channels into another vein. But if the occluded vein is large, one result will be a rise of capillary and venous pressures distal to the occlusion, and this will continue until adequate anastomoses have been opened up. When all the veins leading from a part, such as a limb, are compressed, the capillary and venous pressures behind the occlusion will rise until they either overcome the resistance, or finally equal the arterial pressure. Thus, if a sphygmomanometer armlet be placed on the upper arm, and inflated to 50 mm. Hg, the venous pressure in the arm veins will rise until it exceeds 50 mm. Hg, so that all the veins are engorged, and if the pressure be raised to 70 mm. the venous pressure will rise accordingly, and so on.

---

* BELL, LAZARUS and MUNRO. *Lancet*, 1940, **239**, i, 154.

The Venous Pulse. Each cardiac cycle causes variations in the pressure in the great veins next the heart in two ways :

(1) By the transmission backwards along the veins of the alterations in the intra-auricular pressure.

(2) By the diminution in the volume of the heart in consequence of the expulsion of its blood along the arteries with each heart beat.

On this account the jugular veins show with each heart beat pulsations which are complex in character and resemble those occurring in the auricle (*vide* p. 561). They can be recorded by the use of the polygraph (Fig. 432, p. 632), by applying an open capsule over the lower part of the external jugular vein and leading to the recording tambour. Jugular tracings (Fig. 439 and 367, p. 564) give information as to the time at which auricular systole occurs, as compared with ventricular systole, which can be deduced from the arterial tracing. It will be seen that each heart beat gives rise to three positive waves of pressure within the veins. These three undulations are analogous to those given in Fig. 366, p. 561, as occurring in the auricular tracing. We regard *a* as due to auricular contraction, *c* as the elevation due to closure of the auriculo-ventricular valves, *v* as the elevation due to the accumulation of blood in the auricles during the ventricular systole ; the crest of *v* marks the end of ventricular systole. The curve *c* is probably due in part also to an impact transmitted from the underlying carotid artery. These venous pulsations are much more marked in cases of heart disease, where there is overfilling of the venous system, often combined with incompetence of the tricuspid valve.

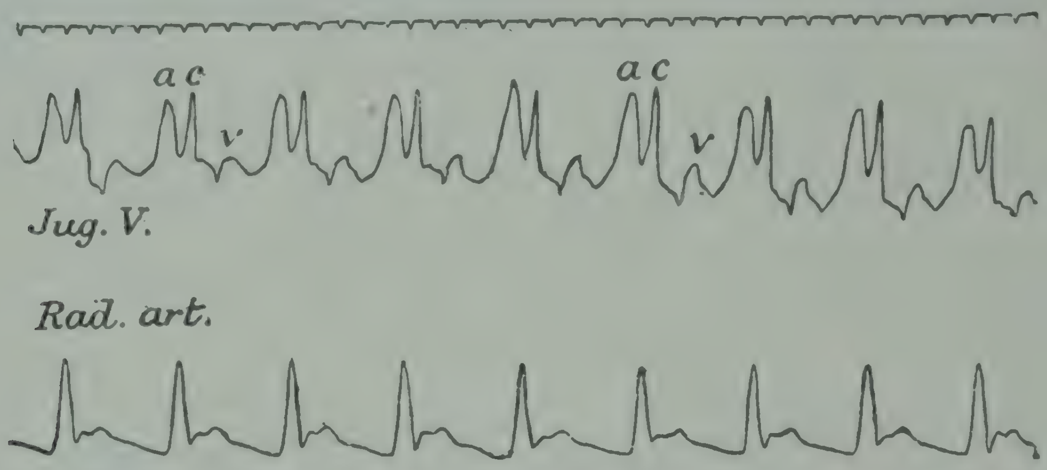

FIG. 439. Venous Pulse Tracing from Jugular Vein compared with the Arterial Pulse Tracing from the Radial Artery.

In cases of heart block (p. 554) the auricle and ventricle contract independently (complete heart block) or at a ratio of two or more auricular contractions to one ventricular. These altered conditions are shown on the jugular and arterial pulse tracings in which jugular tracings show the auricular contractions and the arterial tracings the ventricular contractions (Fig. 358, p. 554).

Valves. Besides the favourable influences exercised on the circulation through the veins by the aspiration of the thorax, a considerable part is played in the venous circulation by the emptying of the veins by outside pressure upon their walls. The adjuvant effect of muscular movement on the circulation through the veins is rendered possible by the existence in these vessels of valves, which are semi-lunar folds of the intima projecting into their lumen, and so arranged that they allow the passage of blood only towards the heart. Two such folds are, as a rule, situated opposite to each other. Every movement of a limb, active or passive, causes an external pressure on the veins and empties them towards the heart. Thus in walking, each time the thigh is moved backwards the femoral vein becomes empty and collapses, and fills again as soon as the leg is brought forward to its former position. When muscular movements become general, as in walking or running, the active compression of the veins thus brought about plays an important part in hurrying the blood into the right heart, so that the output of this organ is increased.

Effect of Gravity. Since the blood in the vessels is subject to the influence of gravity, we might expect to find that, in the erect posture, the pressure in the veins of the foot was equal to the pressure in the veins at the level of the heart *plus* the pressure of the column of blood between these veins and the heart, *i.e.* about a metre of blood, but it is nearly always less than this, and if the leg is exercised, may be little higher than that in the veins of the hand. When a man assumes the upright position, the arteries of the leg and foot contract until, under the combined influence of the heart's contraction and gravity, the blood supply to the capillaries is just adequate. The return of the blood from the dependent parts cannot be ascribed entirely to the negative intrathoracic pressure, but is largely due to the contractions of the muscles of the limb, which press on all the deep and superficial veins, and in virtue of the valves force the blood contained therein past Poupart's ligament into the abdomen. This explains why it is so difficult to stand for any length of time without moving, and emphasises the need of moderate exercise for the maintenance of a normal circulation.

CHAPTER XXXIV

LOCAL REGULATION OF BLOOD FLOW

THE NERVOUS CONTROL OF THE BLOOD VESSELS

EVERY organ of the body requires an increased blood supply during activity, which means that blood must be diverted from the inactive to the active tissues. This is chiefly effected through the central nervous system, though local and chemical mechanisms also play some part in the process.

The Vascular Nerves. Our knowledge of the nervous control of the blood vessels dates from the discovery, by Claude Bernard,* that if, in the rabbit, the cervical sympathetic on one side be divided, the vessels in the corresponding ear dilate. Vessels previously invisible come into prominence, and on account of the greater flow of blood, the ear on the side of the section becomes warmer than the normal ear. If the head end of the divided sympathetic nerve be stimulated, all the vessels of the ear contract, and the ear becomes colder than the other. The fact that the dilatation of the vessels produced by section lasts for months shows that the ear vessels are normally under the influence of "tonic," *i.e. continual*, constrictor impulses proceeding to them along the cervical sympathetic.

The paralysis of the ear vessels, though lessening the local resistance to the flow of blood, affects too small a vascular area to have any marked influence on the general arterial pressure. But if the spinal cord be divided at the first dorsal nerve, a wide area is deprived of vaso-constrictor control and the arterial pressure sinks considerably. The heart after the section beats more rapidly than before, so that the fall of pressure must be ascribed to a lowering of the resistance to the flow of blood.

The source of these impulses may be made out by studying the effect of sections through different levels of the nervous system. Division of the cord at, or below, the second lumbar nerve causes no effect on the blood pressure. On making a section above the first lumbar nerve, the effect produced increases progressively until the first dorsal roots are reached, where it is maximal; stimulation of the lower end of the cut dorsal cord causes widespread vascular constriction and a large rise of blood pressure.

We must therefore conclude that all the vessels in the body are kept in a state of tonic contraction by impulses arising from a higher centre, and then passing out of the cord by the dorsal and upper lumbar nerves.† This conclusion is confirmed by the fact that, whereas stimulation of the ventral roots of the cervical, lower lumbar and sacral nerves has no influence on the blood pressure, a rise of arterial pressure can be obtained by stimulating any of the ventral roots from the first or second dorsal to the second or third lumbar. The same effect is produced by stimulation of the white rami communicantes from these roots to the sympathetic system, and by excitation of the sympathetic chain itself, or of the splanchnic nerve.

Since the plain muscle of the blood vessels exhibits an automatic tonus, complete nervous control of these tubes can be secured only by the provision of two sets of nerves: one set—constrictor—which will increase the state of constriction; another set—dilator—which will diminish the tone of the arteriole muscle, and cause vascular dilatation. Our knowledge of the existence of this second class of nerve fibres to the vessels we owe also to Claude Bernard,* who observed that stimulation of the chorda tympani nerve increased the blood flow through the sub-maxillary glands.

---

* CL. BERNARD. *C. R. Soc. Biol.*, 1852, **4**, 168.
† GASKELL. *J. Physiol.*, 1885, **7**, 1.

Criteria of Vasomotion. In order to investigate the state of tone of the small blood vessels it is necessary to have means for investigating the condition of the blood flow through different parts of the body. It is obvious that if the arterioles A in the organ B dilate (Fig. 440), the first effect is a diminution of the resistance to the flow of blood into the capillaries beyond. If the arterial pressure in the trunk C remains constant, a local diminution of resistance in A will at once determine an increased flow of blood through the arterioles. If the organ is distensible, the increased pressure in the arterioles and capillaries will cause a swelling of the whole organ. But the same effect on intracapillary pressure and therefore on the volume of the part, may also be caused by obstruction to the flow of blood from the veins V. It is only when, the arterial pressure in C remaining constant, dilatation of an organ is *accompanied by an increased blood flow through it* that it may be taken as an expression of vasodilatation in the arteries with which it is supplied.

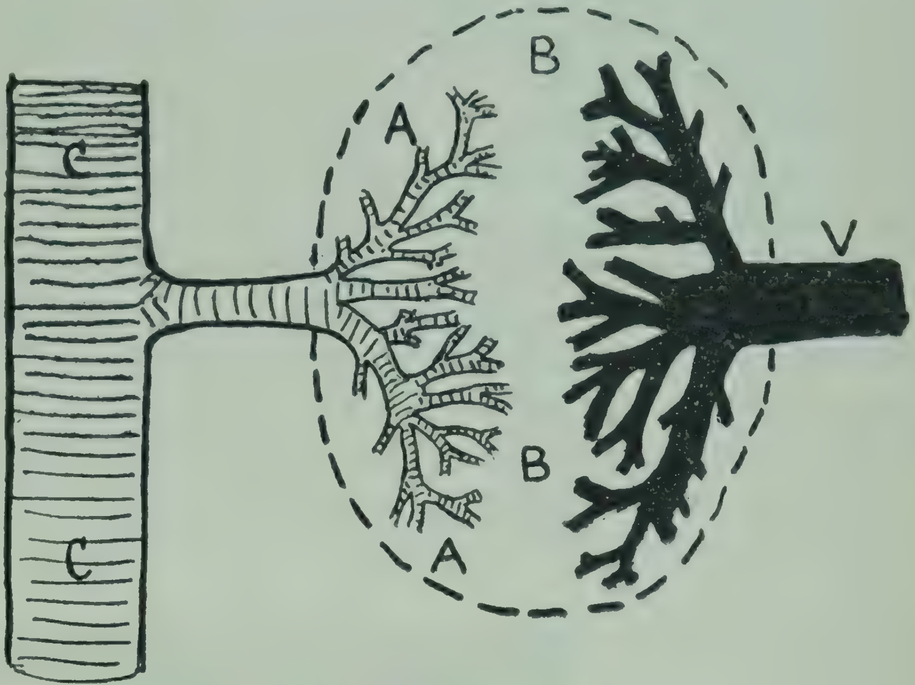

FIG. 440.

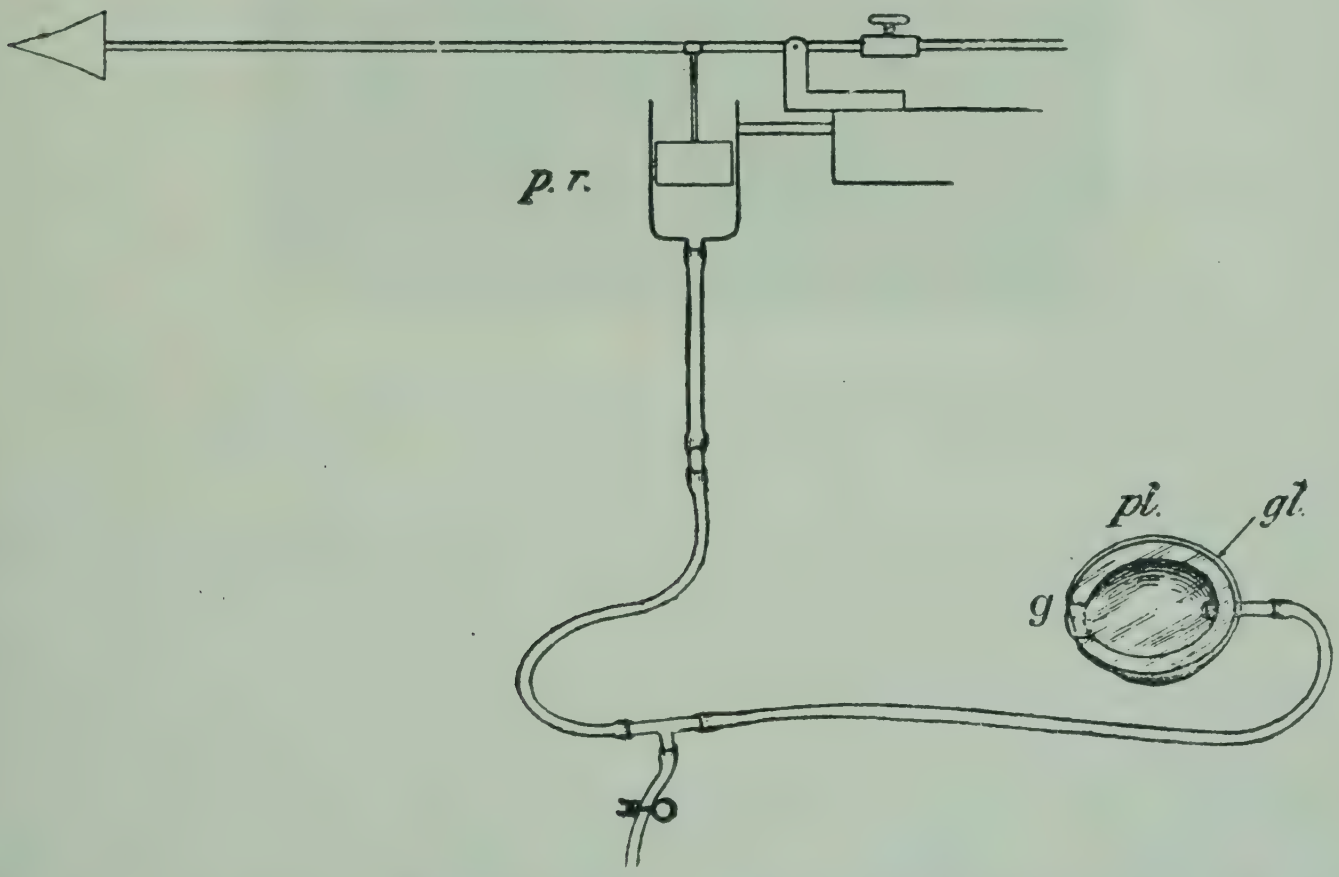

FIG. 441. Diagram of Plethysmograph. *pl.*, the plethysmograph, covered by a glass plate, *gl*; the vessels pass in through the groove *g*; *p.r.*, the piston recorder. (From SHARPEY SCHAFER'S "Experimental Physiology," Longmans, Green.)

We can therefore use the following criteria for the occurrence of a vasodilatation (and their converses for vasoconstriction) in the arterial supply to any part or organ :

---

* BERNARD. *C.R.*, 1858, **46**, 159.

(1) If the surface of the part is translucent, the increased filling of the capillaries will cause redness.

(2) The increased size of the vessels will cause an *increase in the volume* of the organ concerned.

(3) An increased velocity of blood flow will usually raise its temperature.

(4) An increased velocity in the arteries going to the part may be interpreted as due to vasodilatation.

(5) The increased flow may also be detected by measuring the total volume of blood which flows from the vein in a given time.

Of these methods the two most used are those based on determination both of the volume of the part, and of either the arterial inflow to, or of the venous outflow from, the part. A fallacy may arise, however, unless means be taken to ensure that the general arterial pressure remains constant during the experiment. A rise of arterial pressure will cause a *passive* expansion of the vessels and of the part supplied, and also increased velocity of blood flow through the part. In all cases, therefore, it is necessary to record the arterial pressure. We may take as an instance an experiment on the blood supply to the kidney.

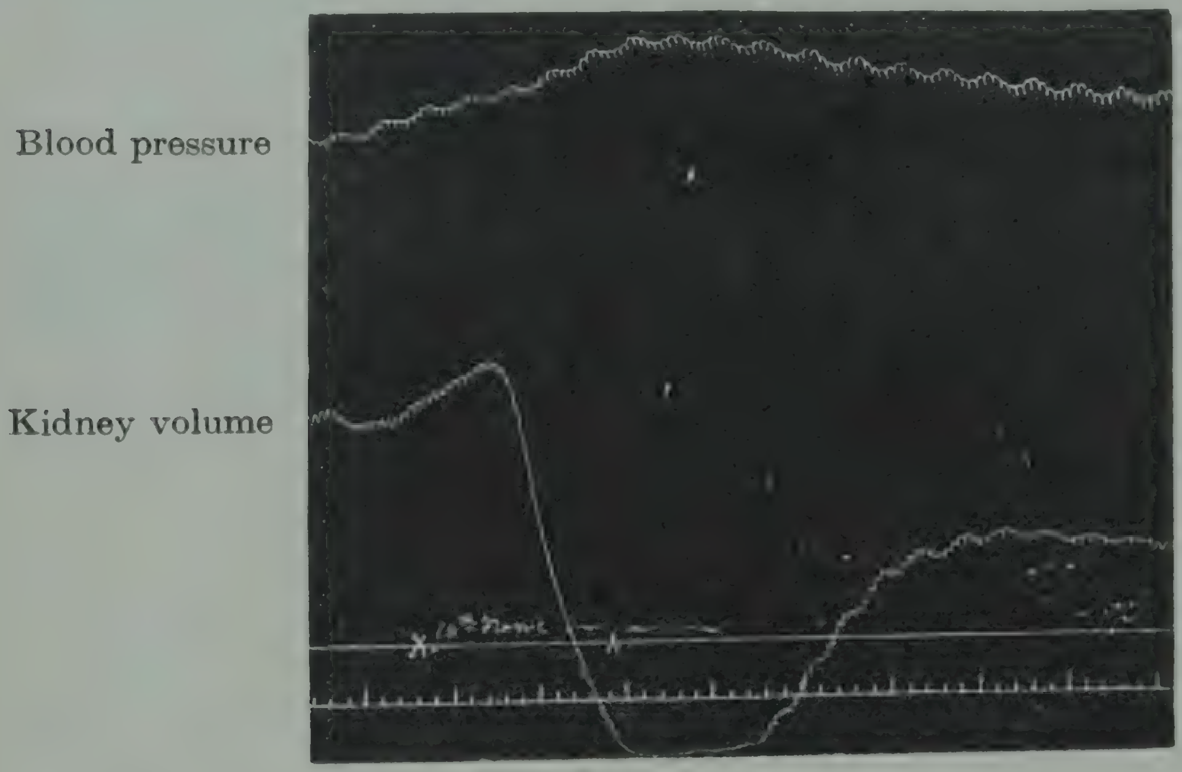

Fig. 442. Simultaneous Tracings of Carotid Blood Pressure and Volume of Kidney. Between × and × the peripheral end of the divided tenth dorsal nerve was stimulated. Time-marking = seconds. (Bradford.)

For this purpose we may determine the change in the volume of the organ by the use of a *plethysmograph*,* (Fig. 441); this can be made of Stent's wax previously moulded to the size of the organ whose volume is the object of investigation. In one side of the box a depression is left, sufficient to accommodate easily the vessels, nerves (and ureter) going to the kidney. The plethysmograph is covered with a glass lid which is made air-tight by means of vaseline, the space between the lid and the vessels being also packed with cotton-wool and vaseline. A tube from the plethysmograph leads to a piston recorder. Every variation in the volume of the organ causes a movement of air into or out of the plethysmograph and thus gives rise to a corresponding movement of the recording lever.

The kidney being placed in some such apparatus, and the arterial pressure being recorded, as in Fig. 442, the peripheral end of the anterior root of the tenth dorsal nerve was stimulated ; this was followed by a rise of blood pressure together with a diminution of the kidney volume. The increased blood pressure would by itself tend to force more blood into the kidney. Since the kidney volume diminished there must have been active contraction of the arterioles of the kidney. This contraction of the vessels must have taken some part at any rate in the rise in general blood pressure. If the plethysmograph had been used alone, it would have been impossible to determine whether the shrinkage of the kidney might not be due to a lowering of arterial pressure. On the other hand, without the volume record it would only have been possible to infer that there was increased peripheral resistance somewhere or other in the body.

---

* Schäfer and Moore, *J. Physiol.*, 1896, **20**, 1.

Instead of taking the volume of the kidney, it would now be more usual to measure the blood flow through its vessels; this would have been found to be diminished by the stimulation. The method is of great value in dealing with the circulation through small organs, such as the submaxillary glands. In such a case it is usual to prevent the clotting of the blood by the preliminary injection of heparin, and then, after placing a cannula in the efferent vein of the organ, to allow blood from the cannula to flow into an automatic measuring apparatus, *e.g.* that of Gaddum.*

For recording the arterial inflow the thermostromuhr is now often employed (p. 624).

Course of the Vasoconstrictor Fibres. The vasoconstrictor fibres belong to the sympathetic system.

The position of the synapses on the path of the fibres is shown by the use of nicotine.† After injection of nicotine, stimulation of the pre-ganglionic fibres is without effect, although the normal results follow stimulation of the post-ganglionic non-medullated fibres.

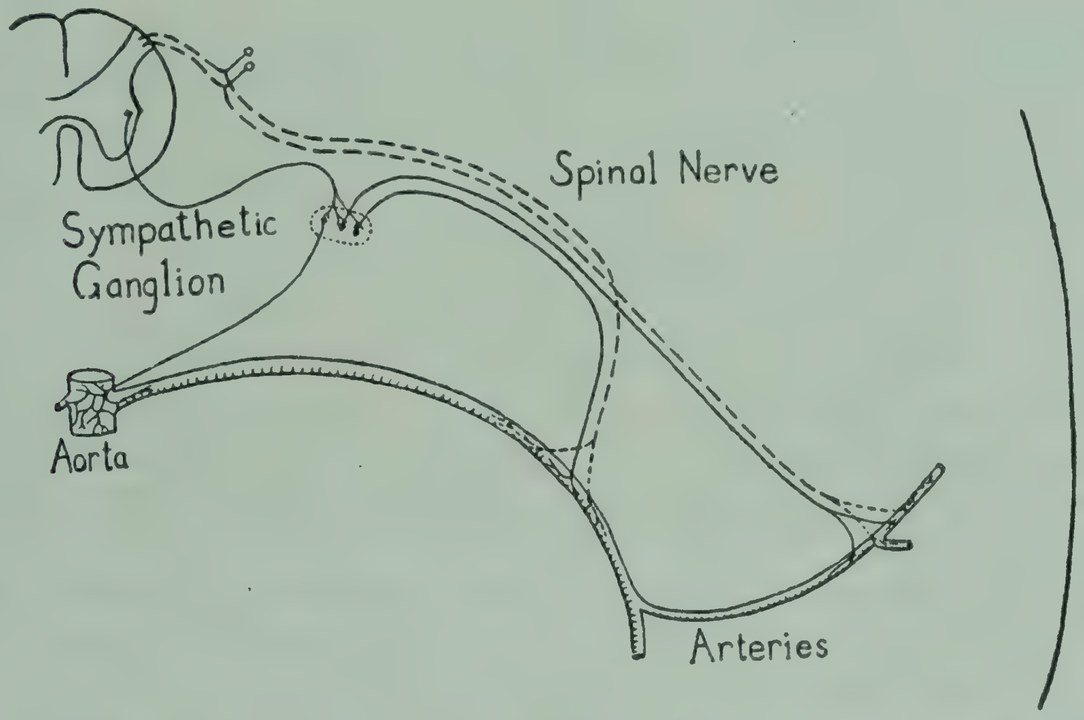

FIG. 443. Diagram showing the distribution of nerves to the arterial vessels. Sympathetic fibres continuous lines. Spinal afferent fibres dotted lines. (RANSON. *Ann. Int. Med.*, 1933, **6**, 1013.)

By this method it has been determined that all the vasoconstrictor nerves of the body leave the spinal cord by the ventral roots of the spinal nerves from the first thoracic to the third or fourth lumbar inclusive. From the roots they pass by the white rami communicantes to the ganglia of the sympathetic chain. Here they take different courses according to their destination.

The vasoconstrictor nerves to the periphery of the body (Fig. 443), including the skin and muscles, pass by the grey rami communicantes to the mixed spinal nerves and are distributed with them. The distribution is strictly unilateral,‡ stopping abruptly at the mid-line, in spite of the fact that the blood vessels themselves anastomose freely across the mid-line. It would seem therefore that, so far as the skin supply is concerned, the peri-arterial plexus described by Woollard § is not concerned with the transmission to a distance of vasoconstrictor impulses.

---

* GADDUM. *J. Physiol.*, 1929, **67**, 1.P.
† LANGLEY. *J. Physiol.*, 1890, **11**, 123.
‡ GILDING. *J. Physiol.*, 1932, **74**, 34.
§ WOOLLARD. *Heart*, 1926, **13**, 319.

The fibres to the head and neck leave by the first four thoracic nerves, and pass to the superior cervical ganglion. Here they end, and the impulses are carried by a fresh relay as non-medullated fibres on the walls of the carotid artery and its branches.

The constrictors to the fore limb in the dog leave the cord by the fourth to the tenth thoracic nerves. The fibres run to the stellate ganglion, where they all end in *synapses*. The impulses are carried on by the grey rami to the nerves which make up the brachial plexus, and run down in the branches of this to the vessels of the fore limb.

The constrictor impulses to the hind limb in the dog arise from the nerve roots between the eleventh thoracic and third lumbar roots, end in connection with cells in the sixth and seventh lumbar and first and second sacral ganglia of the sympathetic chain, whence the impulses are carried by grey rami to the nerves making up the sacral plexus.

The chief vasoconstrictor supply to the abdominal viscera is the *splanchnic nerve*. This receives fibres of the white rami from the lower seven thoracic and upper two or three lumbar roots, the latter fibres often taking a separate course as the lesser splanchnics. The fibres pass through the sympathetic chain of the thorax without interruption, and for the most part have their cell stations in the collateral ganglia, especially the cœliac ganglion, whence a thick meshwork of non-medullated fibres is distributed along all the vessels of the abdominal viscera. The area of the vessels innervated by this nerve is so large that section of it on both sides causes a definite fall in the arterial pressure.

CONSTRICTORS TO VEINS. Often the veins are also supplied with sympathetic vasoconstrictor fibres *; their functions are less conspicuous than those of the arteries, but must be borne in mind, particularly in the interpretation of plethysmographic tracings.

Vasodilator Nerves. Since the arteries are usually in a condition of moderate constriction, a dilatation can be brought about by an inhibition of the normal constrictor impulses proceeding to them. We find, however, in many parts of the body, also a vasodilator nerve supply.

There are three types of vasodilator fibres, viz. parasympathetic, sympathetic and dorsal root, or "antidromic", fibres. The clearest examples are found in certain parasympathetic nerves.

PARASYMPATHETIC VASODILATORS. If the *chorda tympani* nerve be cut, no change is evident in the blood vessels of the submaxillary gland. But if its peripheral end be stimulated, there is secretion of saliva, and all the blood vessels are largely dilated.† In consequence, the blood rushes through the capillaries so abundantly that the blood flowing from the vein is arterial in colour. Other examples of vasodilator nerves are the *small petrosal* nerve to the parotid gland, the *lingual* nerve to the blood vessels of the tongue, and the *pelvic visceral* nerves to those of the genitalia.

SYMPATHETIC VASODILATORS. Some of the fibres of the sympathetic system are vasodilator in function. This is notably the case for the sympathetic supply to the coronary vessels of the heart. Also, in the dog, dilatation of the vessels of the soft palate and gums can be produced by stimulation of the cervical

sympathetic of the same side, or of the stellate ganglion, or its *rami communicantes*. Again, in the muscles of the dog, sympathetic dilators preponderate. In other species, the sympathetic supply to muscles is mainly or wholly vasoconstrictor, as in rabbit and monkey. Usually, special conditions must be present in order to render possible the demonstration of sympathetic vasodilators. Thus, stimulation of the splanchnic nerves may cause a fall of blood pressure, provided that the constrictor fibres, which predominate, have been paralysed by the previous administration of large doses of ergotamine,* or of dibenamine.† Again, the presence of vasodilator fibres in the lumbar sympathetic chain supplying the hind limb in the dog can be demonstrated when this is stimulated, provided that some adrenaline is present in the circulating blood.‡ This effect is intensified by eserine and annulled by atropine. Hence it may be concluded that these vasodilators, though sympathetic, are cholinergic: they chiefly supply the muscles. Similar cholinergic vasodilators to muscle have been demonstrated in the cat after paralysis of constrictors by dibenamine.§

VASODILATORS IN SPINAL NERVES. In addition, there are in the mixed spinal nerves, fibres which are vasodilator. Since, however, the mixed nerves to the limbs also contain constrictor fibres, to muscles, but chiefly to the skin, the effect of the constriction overpowers any effects due to dilator fibres. Moreover, since the dilators apparently do not conduct any tonic influences, the only effect of section of a mixed nerve is that due to the removal of the tonic constrictor influences, and the vessels in the area of distribution therefore dilate.

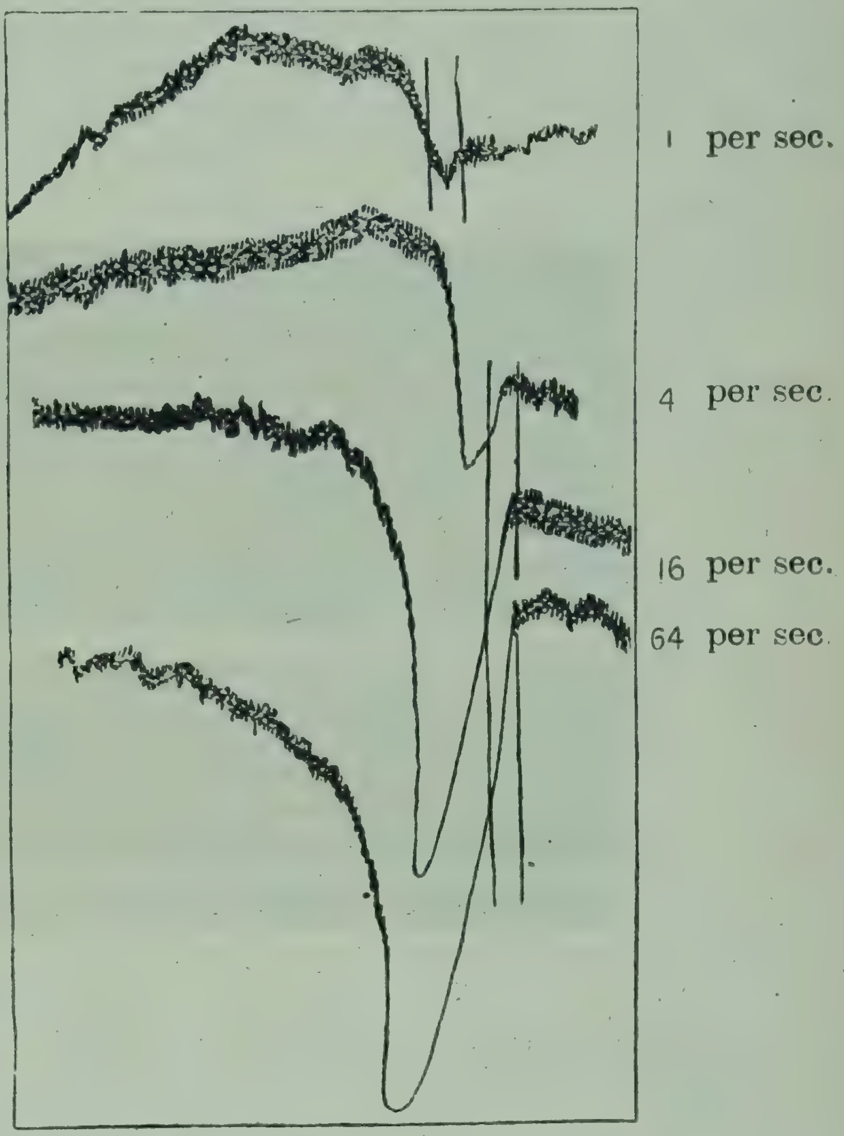

FIG. 445. Effect on the Volume of the Hind Limbs of the Cat of Stimulating the Sciatic Nerve with Induction Shocks at Different Rates. With one shock per second there is dilatation, whereas with 64 shocks per second the effect produced is vasoconstriction. Read *from right to left.* (BOWDITCH and WARREN.)

Various methods have been employed to show the presence of dilator fibres in such a mixed nerve trunk. One method is to remove the skin, which is supplied almost entirely by constrictor fibres, whereby vasodilator responses are more easily revealed.

Sympathetic vasodilators to the hind limb muscles have been shown (cat)|| by slow stimuli (15/sec.) to the sympathetic chain, or by stimulation after paralysis of vasoconstrictors by dibenamine; degeneration of afferent fibres in the chain did not eliminate these affects but degeneration of efferent fibres did; these vasodilators are cholinergic, though sympathetic.

ANTIDROMIC VASODILATORS. Vasodilators to the skin appear to fall into an entirely separate category; some of the muscle dilators may also be

included in this. The presence of vasodilators to the limbs in mixed nerves can be shown in various ways. Two of these depend on the unequal time taken for the constrictor and dilator fibres to degenerate, and on the varying excitability of the two sets of fibres to different kinds of stimulation.* Thus, if the sciatic nerve be cut, and after two or three days the peripheral end of the divided nerve be stimulated, dilatation of the vessels is brought about (Fig. 444). The constrictor fibres degenerate before the dilator fibres, so that only the latter respond to stimulation. On the other hand, it is often possible, even in the freshly cut nerve, to obtain dilatation by stimulating its peripheral end with induction shocks repeated at slow intervals—one to four per second, as shown in Fig. 445.

In the light of the evidence presented above, it would seem probable that some, at all events, of the vasodilators concerned are sympathetic vasodilators to muscle, and therefore emerge from the cord by ventral roots. But some limb dilator fibres are not connected with the sympathetic system, but with the *dorsal* nerve roots. It was shown by Stricker in 1876 that dilatation of the vessels of the hind limb could be produced by stimulating the dorsal roots of the nerves going to the limb, *i.e.* far below the point of origin from the cord of the constrictor fibres to the same part of the body. This has often been confirmed.† Stimulation of the dorsal roots, either before or after they have passed through their ganglia, causes dilatation of the vessels in the area of skin and muscle ‡ supplied by the roots (Fig. 446). This effect is not destroyed by previous section of the dorsal roots on the proximal side of the ganglia, showing that the fibres by means of which the dilatation is produced have the same course as the ordinary sensory nerves to the limbs. Since the impulses on artificial stimulation pass in a direction opposite to that taken by the normal impulses, Bayliss designated them *antidromic* impulses. The phenomenon of a nerve fibre functioning in both directions is without analogy in our knowledge of the other nerve functions of the body, and there is doubt as to the relation of the phenomena obtained by stimulation of the dorsal roots to those of vasodilatation in the normal state, as, *e.g.* to local stimulation by mechanical means or by irritants, such as mustard, applied to the skin.

The commonly accepted view of the normal vasodilator response which is effected through the dorsal root fibres is that it is an axon reflex, stimulation of the skin causing dilatation of its arterioles without the afferent impulse reaching the spinal cord. If the dorsal nerve roots concerned are divided, the vasodilatation resulting from local irritation of the skin, *e.g.* by mustard, still persists, but it disappears if the section is made distal to the dorsal root ganglion and time allowed for the fibres to degenerate. It also disappears if the skin is locally anæsthetised by injection of novocain. Hence it is assumed that the axons of some, presumably afferent, nerves branch, as shown in Fig. 447, one branch going to afferent receptors and another to the muscle cells of cutaneous arterioles. Afferent fibres of the trigeminal are believed to behave similarly.

However they reach the minute vessels, there is some evidence that the results there produced by the nerve impulses may be due to the liberation of potent chemical substances in the tissues of the locality. These may be histamine * or acetyl choline,† the former dilating capillaries, the latter the arterioles.

It may be noted that in certain inflammatory conditions in the dorsal root ganglia, there is reddening of the skin in the areas supplied by the respective roots, often followed by a vesicular eruption (Herpes Zoster) also confined to those areas.

The Vasoconstrictor Centre. The portion of the medulla concerned with the sending out of the tonic vasoconstrictor impulses is spoken of as the vasoconstrictor, or vasomotor, centre. Section of the crura cerebri, or of the brain stem at the upper border of the fourth ventricle, leaves the blood pressure unaffected. Destruction of a small region of the medulla situated on each side of the middle line in the neighbourhood of the facial nucleus, *i.e.* in the forward prolongation of the lateral columns, after they have given off their fibres to the decussating pyramids, causes an immediate and maximal lowering of the blood pressure. Stimulation of a point, the fovea inferior on the floor of the fourth ventricle, and also often of the facial colliculus, causes a rise of blood pressure, while excitation of a point, the obex, near the calamus scriptorius, causes a fall. The former effect is probably due to excitation of the vasoconstrictor centre,

and the latter has similarly been supposed to be the result of stimulation of a vasodilator centre.* The existence of a true vasodilator centre is doubtful, however, since there is evidence that stimuli applied to the depressor point act on some afferent tract which mediates reflex vasodilatation.†

The vasomotor centre is played upon by impulses from the higher centres of the brain, but especially by afferent impulses travelling from all parts of the body, including those carried by the vagi and aortic nerves and by the carotid sinus nerve. The last two produce an inhibitory effect on the centre, so that denervation of the carotid sinuses and section of the aortic nerves results in a rise of arterial pressure. Whether, in the absence of all afferent stimuli, the centre would be active is doubtful; all we know is that the sum of the stimuli acting upon the centre produces a state of average continued activity, which is responsible for the maintenance of arterial tone.

CHEMICAL EFFECTS ON CENTRE. The most important factor for the maintenance of the tonic activity of the centre is the presence of carbon dioxide in the blood. If this be lowered by forcible ventilation of the lungs, so as to remove much carbon dioxide out of the blood, a profound fall of blood pressure occurs owing to paralysis of the vasomotor centre. On the other hand, anything which interferes with the gaseous exchanges of the centre, whether obstruction to respiration, or a failure of the blood supply, as by ligature of the cerebral arteries, calls forth an increased state of activity of the centre. This can be illustrated by observing the changes in the blood pressure produced in a curarised animal by the cessation of artificial respiration.

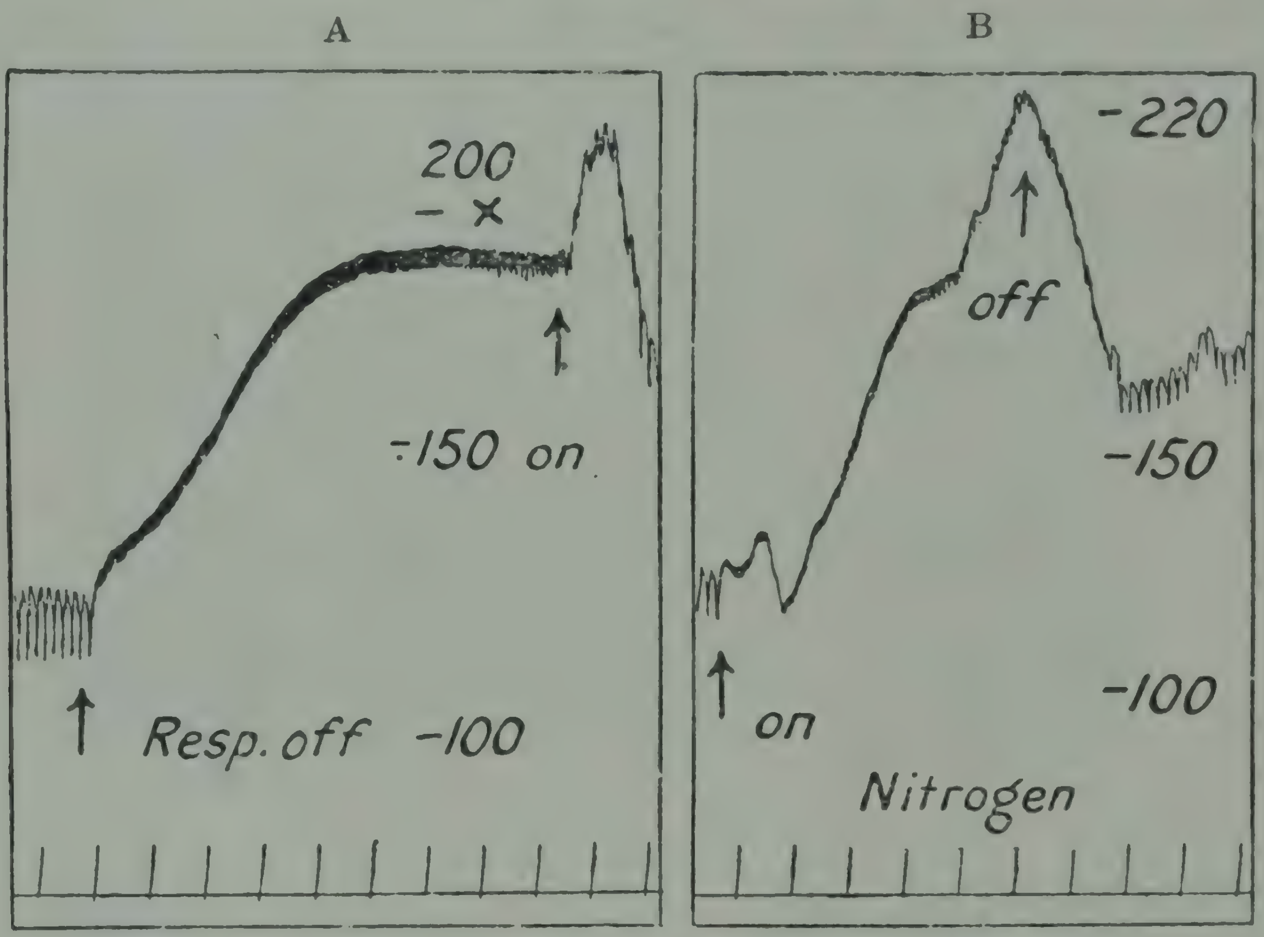

FIG. 448. Blood Pressure Changes in a Cat. (MATHISON.)

A. After cessation of respiratory movements. B. As a result of artificial respiration with nitrogen.

These changes depend partly on the stimulation of the vasomotor and cardio-inhibitory centres by the venous blood, partly on effects upon the carotid region, (*v.* p. 595), and partly on an action upon the heart itself.‡ We will first consider them with both vagi cut. For several seconds after leaving off the artificial respiration the only change noticed is the absence of the respiratory oscillations. Then the blood pressure suddenly rises rapidly (Fig. 448A) and in another ten seconds may reach a height twice as great as it was previously. The heart frequency is almost unaltered. The blood pressure remains at this height for about a minute and then gradually falls, the heart beats becoming smaller and smaller until the pressure has sunk almost to zero. *This fall in pressure is due to the failure of the heart.* The heart gets overfilled, heart block ensues, and it gradually fails. The vessels, however, remain constricted until the death of the animal. This is shown by two facts. If, while the pressure is sinking, artificial respiration be recommenced, the heart, again supplied with oxygen, at once begins to beat more forcibly, and the blood pressure may rise to an even greater height than immediately after the commencement of the asphyxia. Again, if the volume of the kidney be recorded by means of the oncometer, the rise of general blood pressure produced by asphyxia is seen to be accompanied by a rapid shrinking of the kidney, and this shrinking endures until just before the animal dies.

Similar results are obtained when the vessels to the brain are ligatured.

We have spoken above of the phenomena of asphyxia as being due to the circulation of venous blood. This, however, comprises two factors, viz. a diminished percentage of oxygen and an increased percentage of carbon dioxide; and the question arises whether one or both of these factors are concerned. It is easy to investigate the action of each separately. A pure oxygen lack may be brought about by allowing an animal to breathe some inert gas, such as nitrogen, or by injecting small amounts of cyanide into the blood;* while the effects of accumulation of carbon dioxide in the blood and tissues may be produced by the administration of mixtures containing excess of oxygen, with varying percentages of carbon dioxide. In the first case, not only will the oxygen supply be reduced, but the tension of the carbon dioxide in the blood will also be kept below normal; in the second case, while the CO_2 tension is raised, the tension of oxygen in the blood will be kept above normal. Mathison found that both conditions may concur in the production of the rise of blood pressure in asphyxia as shown by Figs. 448B and 449. There are certain minor details in these curves which are of interest. When the oxygen of the lungs is rapidly washed out with a neutral gas, the rise comes on about half a minute later than it would with pure asphyxia. In the latter case it seems that the first rise is due to the accumulation of carbon dioxide. The rise under nitrogen, however, when it occurs, is extremely abrupt, and the subsequent fall of blood pressure, *i.e.* the heart failure, is earlier in onset and more rapid than with ordinary asphyxia. When excess of carbon dioxide is administered, *i.e.* 5 to 10 per cent., a large rise of pressure occurs which is almost entirely due to stimulation of the vasomotor centres and resulting constriction of the peripheral arterioles. If a loop of intestine be placed in a plethysmograph, it will be seen that the rise of pressure coincides with a vascular constriction (Fig. 449). The rise of blood

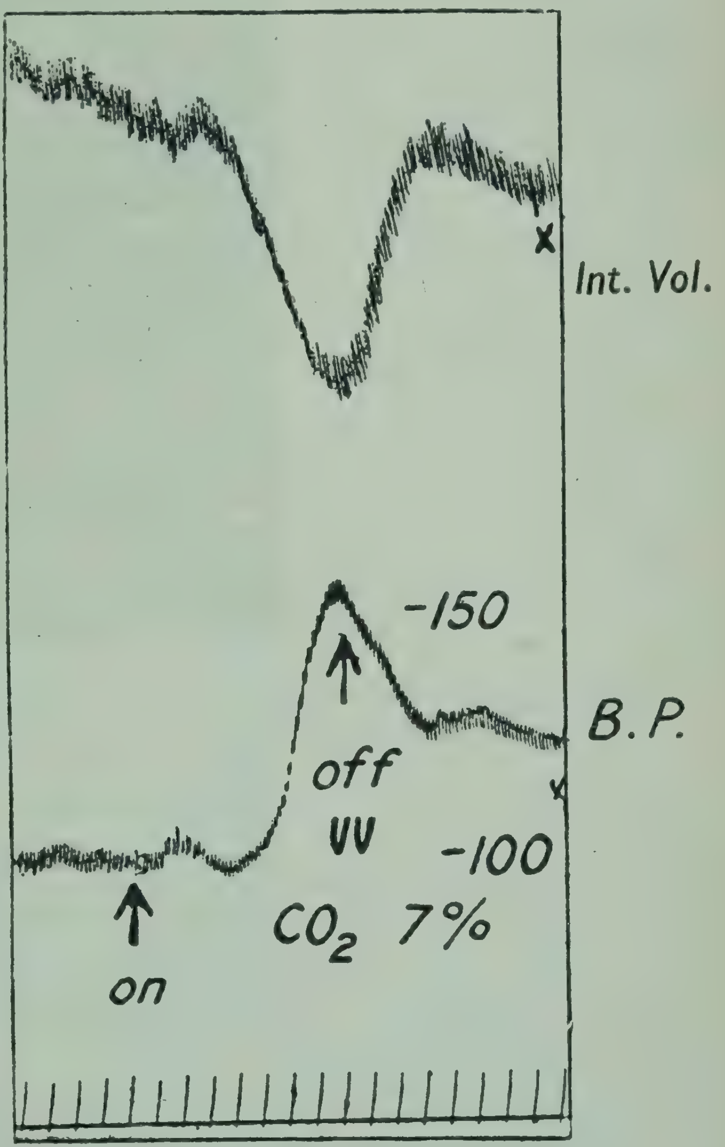

FIG. 449. Tracing of Arterial Blood Pressure and of Intestinal Volume, to show the Influence of a Moderate Increase in the CO_2 tension of the Blood. (MATHISON.)

---

* LOVATT EVANS. *J. Physiol.*, 1919, 53. 17.

pressure due to the vascular constriction may be maintained for a considerable period since we do not get the failure of the heart that is observed in an ordinary asphyxia tracing. If partial oxygen lack, or abnormally increased tension of carbon dioxide, be continued for some time, a state of narcosis or paralysis finally ensues, which affects not only the higher centres but also those of the medulla, so that death may result without convulsions or excessive rise of blood pressure.

The action of cyanide resembles that of nitrogen breathing in its main features, but differs from it in having a more rapid onset, and a slower recovery. This is shown by Fig. 450, which also illustrates another feature of asphyxia. The blood pressure curve shows a second rise ; this is abolished if the suprarenals are removed : it is due to the liberation of adrenaline into the blood stream, which constantly happens in oxygen lack.

Is there any common factor in the two conditions of oxygen lack and carbon dioxide excess, which may account for the similarity in their effects ? It has been shown that, whenever there is a deficiency of oxygen, lactic acid is formed. Lactic acid introduced into the blood stream also causes a rise of blood pressure similar to the asphyxial rise. When the cells of the vasomotor centre are deprived of oxygen, through lack of sufficient oxygenated blood, or are prevented from using it, as by cyanides, it is probable that they themselves produce lactic acid, which, like carbon dioxide, raises the H-ion concentration of their contents and thus excites them.

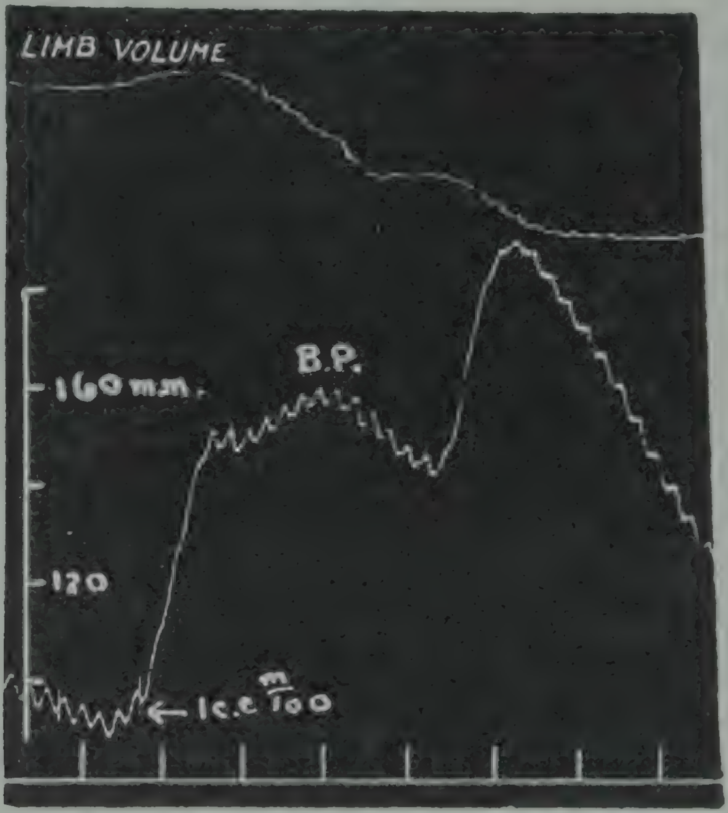

FIG. 450. Decerebrate Cat. Vagi divided. Upper tracing = limb volume. Second tracing = arterial pressure. Lower tracing = time (10 secs.). Injection of 1 c.c. of $\frac{M}{100}$ NaCN into femoral vein. (C.L.E.)

If the vagi be left intact, the blood pressure tracing during asphyxia has quite another appearance. In this case, there is at first only a slight rise of pressure, but the heart begins to beat very slowly. This slow beat is due to excitation of the vagus centre, and is at once abolished by section of the two vagi. The sparing of the heart by means of this vagus action enables it to last longer, so that heart failure comes on rather later than when the vagi are divided. In the increased vagus action, which occurs during asphyxia, three factors are probably involved. The cardio-inhibitory centre in the medulla partakes of the general excitation of the medullary centres, due in the first place to carbon dioxide excess, in the second to oxygen lack. Thirdly, the carotid sinus and aorta are stretched by the rising pressure, and further rise is prevented owing to this : it also causes reflex cardiac inhibition.

RHYTHMIC ACTIVITY. When the arterial pressure is high, especially in asphyxia, waves are often observed on the blood-pressure curve. These are of two kinds. In animals immobilised by curare we may observe oscillations of blood pressure corresponding in frequency with the respiratory rhythm before curarisation. They are due to irradiation of impulses from the respiratory centre to the vasomotor centre. These are the *Traube-Hering waves.** Besides these, others are occasionally seen which arise in a slow rhythmic variation of the constrictor impulses. These waves are known as the *Mayer waves* and are much slower in their rhythm than the respiratory waves. They are observed especially in dogs poisoned with morphia, or after hæmorrhage (Fig. 451). The presence of these waves may be ascribed to a state of rhythmically fluctuating excitability of the vasomotor centre. This excitation may arise in various ways. Often the rhythmicity is related to a rhythmically waxing and waning excitability of the respiratory centre.*

Spinal Vasomotor Centres. The great fall of blood pressure observed after section of the cervical cord is not permanent. After a short time (especially in the cat), the pressure begins to rise, and if the animal be kept alive, may attain a height equal to that found in normal animals.

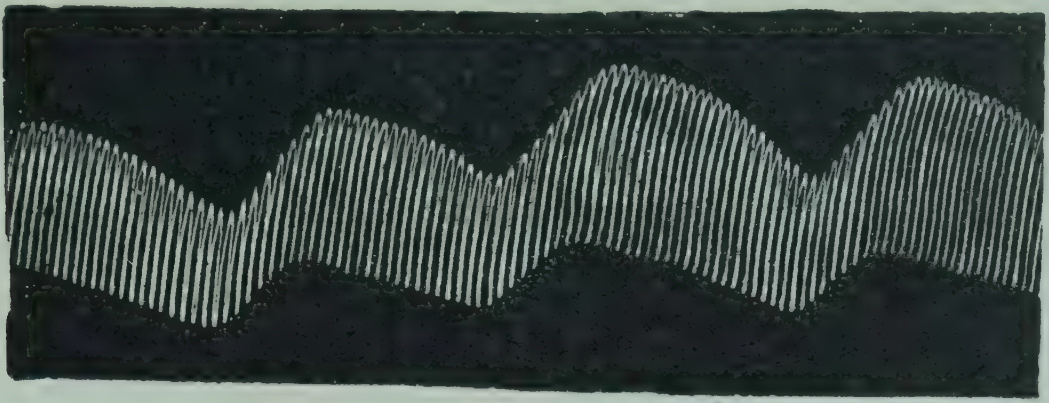

FIG. 451. Blood Pressure Tracing showing Mayer Waves. (C. J. MARTIN.)

If the spinal cord be now destroyed, the blood pressure sinks to a very low level, because the animal has been, so to speak, bled into its own dilated blood vessels. Subordinated to the chief vasomotor centre in the medulla, there is a series of subsidiary centres in the grey matter of the lateral horns of the cord, whence arise the fibres which enter the white rami communicantes. By means of these spinal centres a certain degree of adaptation of the blood supply to the various parts of the trunk is possible in the spinal animal. The important co-ordination between the state of the blood vessels and the rate of the heart is, however, wanting, since the spinal centres are now cut off from the medullary centres. In the intact body we must regard these spinal centres as subordinated to the higher vasoconstrictor centre in the medulla, forming, indeed, a relay on the outward path from these to the periphery; they are connected with the medullary vasomotor centre on each side by tracts of nerve fibres which descend in the lateral columns of the cord.

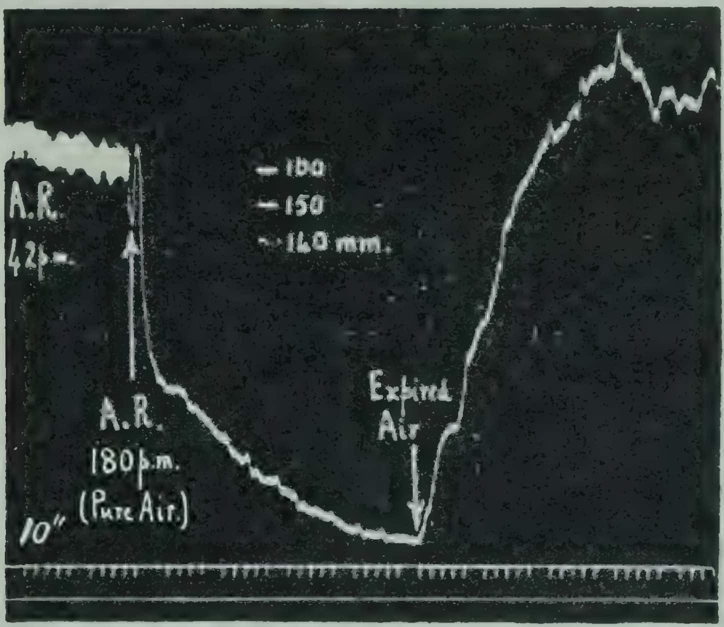

FIG. 452. Effect of Excessive Ventilation on Spinal Cat. Cord cut at second cervical level. With light artificial respiration (42 p. min.) the pressure is 160 mm.Hg; this rapidly falls on ventilation at 180 p. min., but is restored by respiration, at 180 p. min., with expired air. (DALE and LOVATT EVANS.)

The spinal centres are also susceptible to changes in the composition of the blood supplied to them. If an animal be kept alive by means of gentle artificial respiration after division of the cord just below the medulla, the blood pressure soon resumes a normal level. If artificial respiration be now discontinued the asphyxia excites the centres in the cord, and the pressure rises. Conversely, if the artificial ventilation be made excessive (acapnia), the blood pressure rapidly falls, but is speedily restored if ventilation, even at the same excessive rate, be continued with air containing 5 per cent. carbon dioxide, or with expired air (Fig. 452).* After destruction of the spinal cord, these effects disappear. The spinal centres are also excited by lack of oxygen. There is a difference between the sensitivity of the spinal and medullary centres; the common factor is probably increased H-ion concentration, but the excitation threshold for the medullary centres is lower than that of the spinal centres.

* AALKJÆR. *Skand. Arch. f. Physiol.*, 1935, **71**, 301.

THE PERIPHERAL TONE OF THE BLOOD VESSELS. Division of the sciatic and anterior crural nerves causes an immediate dilatation of the vessels of the lower limbs, in consequence of the loss of the tonic influence of the vasomotor centres. This dilatation diminishes in a day or two, and the vessels resume a tone, *i.e.* remain in a state of average constriction, which can be increased or diminished by local conditions. This recovery of tone has been ascribed to the tonus of the muscular fibres themselves. Division of the sympathetic supply to a limb (sympathectomy) is sometimes carried out as a surgical procedure. The blood flow in the limb is raised at first, but often returns to normal some months later; after ten years it is normal and the arterioles are hypertrophied.†

Vasomotor Reflexes. The vasomotor centre is constantly in receipt of impulses arriving both from the vascular system and from various other parts of the body. Hence reflex effects are produced by stimulation of various afferent nerves, and these may be classified, according to the area they affect, as general and local. If the reflex is sufficiently widespread, it causes a rise or fall of arterial pressure; such reflexes are distinguished as *pressor* or *depressor* reflexes respectively.

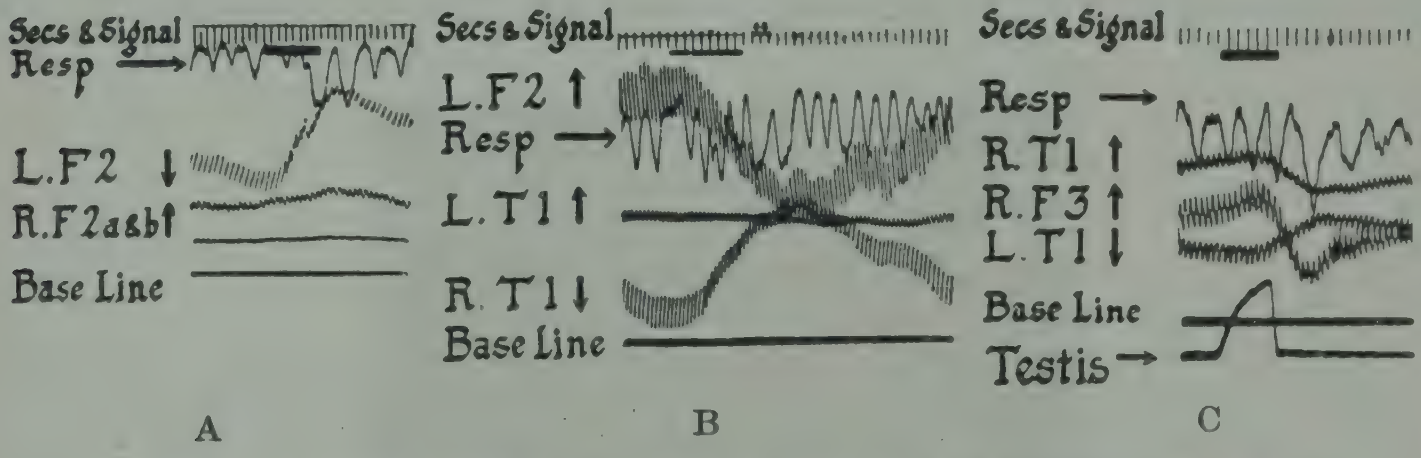

FIG. 453 Volume records of fingers or toes, and of respiration, in man.

R.F., right finger; L.F., left finger; R.T. and L.T., the right and left toes. The arrows show direction of dilatation.

A, lesion of right brachial plexus. Left arm pinched. No response of R.F.

B, left lumbar sympathectomy. Right arm pinched. No response in left toe.

C, lesion of cauda equina; motor and sensory paths to toes abolished, but sympathetic supply intact (from lower dorsal roots). Pressure on testis causes normal reflex. (STÜRUP *et al.*, 1935.)

Vasoconstrictor Reflexes. A *pressor reflex* is one which induces a rise of general blood pressure by widespread constriction of the arterioles, especially in the splanchnic area. Practically all impulses, which, if consciousness were present would be attended with pain or emotion, also cause vasoconstriction, which, if extensive and not otherwise compensated, causes a rise of arterial pressure. Thus a rise of pressure may be produced by the stimulation of almost any afferent nerve, including the central end of the splanchnic nerves.

These vasoconstrictor responses and the nervous pathways involved, have been elegantly demonstrated in man by Carmichael and his colleagues. One or more fingers or toes are placed in suitable plethysmographs and their volume curves are recorded. Stimulation of the skin, a loud noise, or the taking of a deep breath causes shrinkage of the digit by vasoconstriction.* During brief occlusion of the circulation in the arm by a sphygmomanometer armlet, the vasoconstrictor response still occurs in the fingers, showing that it is not a passive change. In cases of hemiplegia from lesions of the cerebral hemisphere the response in the affected side was normal.† Division of the whole nerve supply to the limb abolished the reflex, as did removal of the sympathetic supply alone (Fig. 453, A, B); division of the cerebrospinal supply without removal of the sympathetic supply left it unchanged (Fig. 453, C). Hence the path of the reflex in man is similar to that in the lower animals. It will be evident that the pressor reflexes are due to an increased sympathetic vasoconstrictor tone.

---

* DALE and LOVATT EVANS. *J. Physiol.*, 1922, **56**, 125.

† ESSEX, *et al.* *Amer. J. Physiol.*, 1943, **139**, 351.

So far as the general arterial pressure is concerned, the most important impulses arriving at the centre are those from the vascular system itself, especially from the heart, aorta and carotid sinus, and those from the higher parts of the brain. Whatever the condition of the heart, the brain always demands a high arterial pressure. A failing heart therefore indirectly evokes constriction of the systemic vessels, a fact which may lead to a vicious circle in cases where the heart is unable to empty itself against the resistance of the blood vessels.

An important part is played by these reflexes in enabling the body to counteract the effects of severe hæmorrhage. This, by causing a fall of general arterial pressure, would set in action the pressor aspect of both the aortic and carotid sinus reflexes, thus causing vasoconstriction and cardio-acceleration, so that the fall of pressure would be much less than it would be without this regulating mechanism.

Another aspect is that which concerns the effect of posture on the circulation (see later).

Vasodilator Reflexes. The chief examples of *depressor* nerves, viz. the depressor or aortic nerve itself, and the nerve of the carotid sinus, we have already studied in dealing with the heart reflexes. The carotid sinus apparatus is probably at least as important as the aortic depressor nerve, with which it normally collaborates. By their co-operation a rise of arterial pressure excites a depressor reflex, with cardiac slowing, thus reducing or checking the rise. The depressor reflex is mainly due to a suppression of vasoconstrictor tone, but

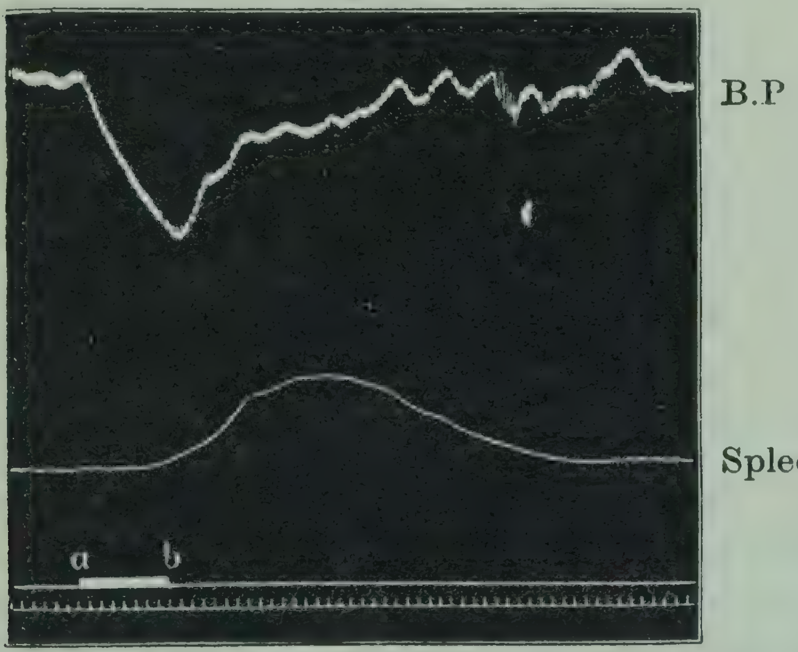

FIG. 454. Simultaneous Tracing of Arterial Blood Pressure and Splenic Volume from a Rabbit, showing the marked swelling of the spleen associated with fall of general blood pressure, on stimulation of the central end of the depressor nerve. The nerve was excited between *a* and *b*. (BAYLISS.)

---

* BOLTON, CARMICHAEL and STÜRUP. *J. Physiol.*, 1936, **86**, 83.

† STÜRUP *et al.* *Brain*, 1935, **58**, 456.

may be reinforced by the mediation of vasodilators, the two systems being reciprocally connected. The reflex fall of pressure produced by stimulation of the central end of the depressor nerve is effected chiefly by dilatation of the splanchnic area (Fig. 454), though, as Bayliss showed, practically all the vessels of the body partake in the relaxation.

Vasodilator reflexes arising from the carotid sinus and aortic zones may be reinforced by similar, but minor, reflexes arising from other vaso-sensitive zones, especially in the areas supplied by the cœliac and superior mesenteric arteries,* where the sensitive structures are the Paccinian corpuscles.†

Stimulation of the central end of the vagus, after section of both vagi, usually gives a depressor reflex because the nerve contains depressor fibres; but in some cases this may be preceded, or even replaced, by a rise of arterial pressure. This *vago-pressor* reflex appears to be normally in action when the blood pressure has been greatly lowered by hæmorrhage; in such conditions section of the vagi produces a further fall of arterial pressure (McDowall).‡

FAINTING. Often when the return of blood to the right heart is considerably reduced, fainting, or syncope, occurs. Thus it may happen after standing still for long periods, after considerable hæmorrhage, or when invalids attempt to stand. Fainting can be studied experimentally by performing a large venesection (1 l.), or by combining a smaller bleeding (500 c.c.) with "bloodless hæmorrhage." This is done by placing sphygmomanometer cuffs round the thighs of the sitting subject, and inflating to diastolic pressure. The legs become congested by retention of up to 700 c.c. of venous blood, which is thus removed from general circulation.§ After the faint has occurred, release of the cuffs restores this blood to circulation and the subject to consciousness. Prior to the attack there has usually been a steady rise in pulse-rate, and a definite decline of arterial blood pressure, and this, at or immediately before the faint, suddenly slumps to a low level, accompanied as a rule by a considerable drop in pulse-rate. The subject at the same time becomes pale, and perspires. The attack was called the "vasovagal syndrome" ‖ and was likened to the effects of stimulation of the carotid sinus, but its explanation is not so simple as that.

Closer study showed that as bleeding proceeded prior to the faint, the cardiac output and right auricular pressure steadily fell. The arterial pressure also declined somewhat, but calculation showed that the total peripheral resistance (= B.P./C.O.) increased considerably. This means that up to this point the falling arterial pressure caused by lowered cardiac output is opposed by widespread vasoconstriction and cardiac acceleration due to reduction of carotid sinus and aortic reflexes. But suddenly (Fig. 455), this opposition seems to melt away, the heart rate falls steeply, the peripheral resistance drops, and consciousness is lost because the blood supply to the brain becomes inadequate. The cardiac output may fall, or be unaltered, or even show some increase. The drop in heart rate is due to vagal inhibition: the fall of blood pressure is largely due to sudden extensive vasodilatation. Search for the site of the vasodilatation by plethysmographic methods (p. 627), showed that it is in the muscles, since the forearm blood-flow showed an increase (Fig. 456), but that of the hand (skin), a reduction.

Finally, in subjects with a sympathectomised arm, the forearm dilatation does not occur in that arm. It would appear, therefore, that sympathetic vasodilators (*v.* p. 646), convey the impulses to the muscle vessels.¶ The afferent path of the reflex is uncertain.

COMPENSATORY ADJUSTMENTS. Very commonly a vasoconstrictor reflex in one part of the body is accompanied by a vasodilator reflex in other areas, so that the arterial pressure may show no change, or may even fall. Under normal circumstances, every part of the body receives just enough blood for its metabolic requirements. Hence, activity must be associated with an increased flow of blood through the part. Two mechanisms are involved in this adaptation. In the first place, there is reflex dilatation of blood vessels in the part concerned, and in the second place, constriction of the blood vessels in the rest of the body, so that a normal or raised blood pressure is available for driving an increased supply of blood through the dilated vessels of the part. Thus, if both hind limbs of an animal be placed in a plethysmograph, it will be seen that stimulation of the central end of the anterior crural or peroneal nerve in the left leg causes dilation of this leg and constriction of the leg of the other side.* At rest, the organs of the chest and abdomen contain more than half of the total quantity of blood in the body, so that very little change in the capacity of these organs suffices to furnish the extra supply of blood needed by any part during a state of increased activity.

The local axon reflexes, referred to above, also play an important part in bringing about adjustments of the blood flow in a part, and it has been shown by Fleisch that the reflex vasodilatation associated with activity of a tissue is in part a reflex due to chemical stimuli, as will be explained later. In the control of the blood supply to the tissues, the constriction and relaxation of the capillaries also probably play a large and special part.

These regulating reflexes provide yet another example, if any be needed, of one of the most fundamental of biological laws, namely that of the maintenance of constant conditions in the internal environment of the tissues, whereby a small change in the conditions gives rise to reactions which oppose further change, and oppose it with a force which increases as the change to be opposed augments.

Cephalic Pressure. The head regulates its blood supply according to its needs. If the head be supplied with blood by means of a circulation distinct from that of the rest of the body, it is found that any rise of pressure in the arteries of the head brings about the inverse change in the arteries of the rest of the body—so that rise of pressure in the head vessels means a fall of pressure in other parts of the body, and *vice versâ*.* This phenomenon, like the reflex cardio-inhibition which accompanies it, is a reflex from the *carotid sinus* (*v.* p. 595),† and is not a consequence of the effect of pressure on the brain itself. The effect is reduced or abolished by denervation of the carotid sinuses.

THE CHEMICAL REGULATION OF THE ARTERIOLES

Vasodilator Substances. Metabolites. A factor involved in the production of the increased blood flow through active organs is a chemical stimulation of the vessels themselves, by means of substances (metabolites) produced as a

result of activity. These substances are continually being produced, though in smaller amount, by the resting tissues, and when the blood supply is stopped for a time, they accumulate. If the blood is readmitted to the tissue, its vessels widely dilate—a condition called *reactive hyperœmia*. This is illustrated by Fig. 457. The great increase in the flow through the muscles, which accompanies muscular exercise, is probably brought about largely by similar means.

The exact nature of the metabolites concerned is still uncertain. Lactic acid and carbon dioxide cause some dilatation of the blood vessels of a limb, but the dilatation in activity is greater than could be accounted for by these substances. Several other possible metabolites have been found to exert a dilator effect on the arterioles. Thus, it may be (1) acetyl choline, or some closely related substance; when a vasodilator nerve or an antidromic sensory nerve is stimulated, there is a liberation, in the region of its distribution, of acetyl choline; (2) adrenaline has a vasodilator action on some vessels, *e.g.* in man a transient one on those of muscles; (3) adenosine, adenylic acid or adenyl pyrophosphate are all common in tissues, but particularly in muscle; (4) some not yet identified substance, such as Gaddum and Euler's * "substance P," extractable from intestine and brain, or "kallikrein," present in urine, and various extracts of protein nature.†

It might be asked, however, why the arterioles should be affected by a substance which enters the blood down-stream from them, in the capillaries. The explanation, according to Fleisch,‡ is that an ascending local reflex is effected through the nerves in the vessel walls. These nerves may be supposed to be stimulated by the various metabolites, and by a local reflex to cause arterial dilatation.

Vasoconstrictor Substances. (1) ADRENALINE. This substance has a powerful vasoconstrictor action: if 1 c.c. of a 1 in 10,000 solution be injected into the jugular vein, there is within a minute a widespread constriction of the arterioles, with the exception of those of the muscles, heart and brain. The same results occur after the nervous system has been destroyed, proving that adrenaline acts directly on the blood-vessels. Owing to the large rise in arterial pressure, the action is therefore to divert the supply of blood from skin and internal viscera, and to augment the flow through muscle, brain and heart.

When the splanchnic nerve is stimulated, there is a release of adrenaline, and the rise of arterial pressure shows a stepped curve, the first rise being due to the action of the vasoconstrictor nerves on the blood vessels, the second to the discharge of adrenaline into the general circulation (Fig. 458). Similarly in Fig. 459 is shown the effect of brief stimulation of the splanchnic nerve on the blood pressure and on the volume of the limb of the cat. It will be noticed that the volume of the hind limb first increases passively with the rise of pressure, and then diminishes to much below its previous volume. This diminution is due to the discharge of adrenaline into the blood stream and is absent if the suprarenals have been removed. During asphyxia, the rise of arterial pressure is associated with the discharge of adrenaline. Similarly, when any pressor reflex is set up, as, *e.g.* by a reduction of tension in the carotid sinus, it is accompanied by an increased discharge of adrenaline into the circulation.

The most intense action of adrenaline is on the skin vessels. The arterioles of muscle are transitorily dilated, and those in the small intestine only feebly constricted by adrenaline, while the coronary vessels of the heart are intensely dilated by it.

(2) NOR-ADRENALINE (*v.* p. 361), has still more powerful vasoconstrictor actions and no vasodilator actions. It is formed and liberated together with adrenaline, and probably in about equal amount.

(3) RENIN AND HYPERTENSIN. In 1898, Tigerstedt and Bergman observed

a prolonged rise of arterial pressure after intravenous injection of extracts of kidney cortex and gave the name *renin* to the responsible substance.* An interesting story has eventuated, which provides a possible hypothesis for the ætiology of the hypertension met with in chronic nephritis. Goldblatt [*] showed that if the renal blood flow is restricted by constriction of the renal artery, a pressor substance is released from the kidney into the circulation, and a persistent hypertension results. The extractable substance, renin, is not, however, itself a pressor substance : it is an enzyme, which acts on a plasma globulin ("*hypertensinogen*") to produce a pressor agent called "*hypertensin*" [†] which appears to be a polypeptide or proteose.[‡] The vasoconstriction produced by hypertensin is widespread, but affects the skin relatively little. The renal blood flow is reduced ; the substance is slowly destroyed in the body by an enzyme. Its possible function in the body is to prevent urine formation from failing when the reduced access of blood to the kidney threatens this : it constricts the efferent arterioles of the glomeruli, so keeping up the intraglomerular pressure.

---

* Pronounced "*reenin*," for obvious reasons.

(4) VASOTONINS. These are constrictor substances, of unknown nature, produced in blood when it clots, and perhaps continually in the body at a slow rate. They are therefore present in defibrinated blood, from which they can be removed by perfusion of the blood through the vessels of excised lungs.

THE REGULATION OF THE BLOOD FLOW THROUGH THE CAPILLARIES

Although the arterial blood pressure and the state of contraction of the arterioles play a large part in regulating the supply of blood to the tissues, we cannot regard the capillaries as merely inert channels. The calibre of the capillaries is determined to a great extent by changes in their own walls ; these changes consist in a swelling or shrinkage of the nuclei of the endothelial cells whereby the lumen of the capillary is narrowed or widened.[§]

When a tissue is in a state of rest, many of its capillaries close down completely, and so reduce its blood supply to a level commensurate with its small oxygen requirement. On activity, as the oxygen needs of the tissue increase, more and more capillaries open up, so that in a tissue like muscle there may be at least a hundred times as many capillaries in use as there were in the resting state.

Capillaries can be caused to contract by direct stimuli, or through the action of nerves, or by alteration in their chemical surroundings.

Action of Nerves. The capillaries are abundantly supplied with nerve fibres, and capillary constriction has been observed under the microscope on stimulation of the sympathetic nerve supply.[||] There is also a connection between nerve lesions and the calibre of the capillaries in the area supplied by the nerves. Thus, if in the cat the sciatic nerve be cut on the right side, for the next few hours the pad of the foot on that side is flushed and warmer than the left foot. The next day the flush has disappeared, in fact the pad of the right foot may be paler, though still warmer, than that of the left. This may be because, although the arterioles are still dilated and arteriovenous anastomoses open, so that there is a more rapid flow of blood through the pad, the capillaries are contracted.

It would be expected that section of the sympathetic fibres, by causing dilatation, would make the capillary walls more permeable. But actually the reverse appears to be true, *i.e.* the dilated sympathectomised capillaries are less permeable than normally.[¶]

Whether there are dilator nerves to the capillaries is uncertain, but some claim that axon reflexes are demonstrable, similar to those affecting arterioles.

Skin Reactions. The independent contractility of the minute vessels is well illustrated in the human skin, the colour of which is determined chiefly by the number and size of its minute vessels ("capillaries" or "sub-papillary venous plexuses").

If a blunt point be drawn over the skin, a mark, or *tache*, is left behind. On gentle stroking or on applying pressure with the finger, the *tache* is white, and appears in fifteen to twenty seconds, being preceded by transient flushing. When the point is drawn over the skin with a firmer pressure, there is first a light flush (capillary dilatation), followed in fifteen seconds or so by (*a*) a much deeper flush along the actual track of the instrument (wide dilatation of capillaries and other vessels), and (*b*) at either side of the red *tache* so produced there appears a white *tache* (capillary constriction). These fade in from three to eight minutes. Microscopic inspection shows that the capillaries and venules in the pale area, though constricted, are in connection with vessels filled with blood, and the emptiness of these vessels can only be due to the fact that they have actively contracted against the pressure of blood with which they are supplied.

An experiment by Lewis, called the occlusion test, conclusively demonstrates capillary contractility. A Riva-Rocci armlet is placed in position and *rapidly* inflated to a pressure greater than the arterial pressure, *e.g.* 200 mm. Hg. The circulation in the arm is thus suddenly stopped, and the pressure in arteries, capillaries and veins then becomes equal; as the inflation was rapid, this pressure, though higher than the usual capillary pressure, is not very great. On now applying the skin reaction test, the white *tache* will be found to develop in the usual manner. Now, since the colour of the skin is due to blood contained in its minute vessels, it is evident that in such a limb, with occluded vessels, a contraction of arterioles could not deprive the capillaries of their contained blood, as might be objected if the circulation were proceeding.

Lewis has shown that the red reaction consists of two distinct reactions—a localised one, due to relaxation of *all* the skin vessels, and a spreading flare, due to an axon-reflex, which causes relaxation of the skin arterioles, often for considerable distances, when powerful stimuli have been used.

In a certain number of subjects, the skin after the *tache* tests shows some urticaria, while in others a definite wheal results, owing to the production of local œdema—a condition called *dermatographism.* The *triple response, i.e.* local vasodilatation, spreading flare and local œdema, may be obtained by stimulation of the skin by mechanical means, heat, cold, electricity and by various chemical substances, especially histamine.

Whether these reactions characteristic of the minute vessels of the skin are properties of the capillaries in other regions is uncertain. It would be expected that the skin would be best adapted to show responses to mechanical stimulation, but there is a certain amount of evidence for similar responses in other parts to stimuli equally appropriate.

METABOLITES. The dilator effect of metabolites on the arterioles, which we have already studied, seems to be shared by the capillaries. In such a case, it is difficult to dissociate the effects of arterial dilatation from those of capillary dilatation. Acetyl choline, or substances akin to it, chiefly relaxes the arterioles. At least one chemical substance is known, however, which has diametrically opposite effects on the two sets of vessels, viz. *histamine.* This substance has been shown to have a slight constrictor effect on the arterioles and a powerful dilator effect on the capillaries.* Its effects are antagonised by the drug *benadryl.* Moreover, it so increases the permeability of the capillary walls, that fluid rapidly passes out from the blood stream into the tissues. It has been suggested that when tissues are subjected to damage, histamine or something resembling it (H-substance) is either liberated from or produced in the cells, and results in local capillary and venule dilatation as seen, for instance, in the skin reactions. If a minute amount of histamine is introduced beneath the skin by pricking through a drop of 1 : 1,000 solution, a typical triple response is seen at the site.

CIRCULATORY SHOCK

Circulatory shock is a state of circulatory failure, which results from loss of blood, or extensive damage or prolonged suspension of blood supply to the tissues, particularly muscle. It is seen after severe surgical handling, bomb damage, burns, prolonged application of tourniquets to limbs, etc., and is studied in the laboratory by applying tourniquets for several hours to the limbs of anæsthetised animals, and then removing them, or by inflicting crush damage to the limbs or trunk. All the effects are magnified if hæmorrhage also occurs.

The essential features are lowered venous pressures, and diminished venous return, so that the cardiac output is reduced. The prime factor in its causation appears to be loss of circulating fluid, whether of blood by external or internal hæmorrhage, or of plasma as in burns, or in " toxic " shock ; or of blood plus plasma in crush injuries. Ultimately a vicious circle is set up in the peripheral circulation, with deficient tissue oxygen supply, widespread capillary dilatation, and increased capillary permeability, resulting in a continually increasing reduction in blood volume, due to loss of plasma. Consequential phenomena are, " hæmoconcentration," increase of blood viscosity ; vasoconstriction of arterioles, which reduces the supply of blood to the tissues, but which may keep the arterial pressure from falling until the loss of blood volume reaches some 25 per cent. ; fall of venous pressure, which reduces cardiac output ; oxygen lack of the tissues leading to a fall of temperature, production of lactic acid, fall in alkali reserve, etc., so completing the vicious circle. The heart is accelerated as a compensatory effect, but ultimately the arterial pressure falls so low that the heart weakens and finally fails from oxygen lack. There may be kidney damage, due to low arterial pressure. [Another kind of kidney damage may be present after extensive crushing injuries : it may be due to the setting free of myoglobin from injured muscle, and this, when acid urine is excreted, leads to damage of the kidney tubules and renal failure.*]

Three types of theory have sought to explain this complicated syndrome. (1) That part, at least, is of reflex origin, and leads to exhaustion of the vasoconstrictor centres, or of the suprarenal medulla. It has been stated that if the nerves from the damaged tissues are divided, or blocked by novocaine, shock is reduced or absent. Most of the force of this argument is destroyed by the clear proof that the vasoconstrictor apparatus and the adrenal medulla function quite well, even at advanced stages of shock. (2) That loss of fluid by its retention in the damaged area may be enough to cause the results. But if a limb is clamped off for seven hours, and the clamp released, amputation within the next two hours may prevent death, though even after further time the damaged limb shows no great increase in weight. (3) That the source of the trouble is chemical. Thus, lapse of function of the suprarenal cortex has been suspected, and administration of corticosterone advised. The chief chemical view is that some toxic substance arises in the damaged tissues and raises the permeability of the capillaries throughout the whole body.

Search for the responsible chemical agent has only met with partial success. That the effects may be due to the liberation of histamine, or some closely-allied substance, is mainly circumstantial. For instance, histamine can, on injection into the circulation, often cause shock ; or, when injected into the tissues, cause local changes similar to those produced by local injury. There are reasons, however, for not accepting all this evidence at its face value.†

There is no evidence that the histamine content of the blood from a traumatised part, or of that in general circulation in shock patients, is much, if at all, increased

A more promising approach attributes the effects to the liberation, especially from muscle, of a substance, or substances, called the muscle shock factor(s).*

Again, there is some evidence that Kallikrein may be the responsible substance.†

CHAPTER XXXV

THE PULMONARY, HEPATIC AND CEREBRAL CIRCULATIONS

THE PULMONARY CIRCULATION

In the lungs the alveoli are supplied by a close network of wide arterioles and capillaries carrying venous blood derived from the pulmonary artery, and presenting very little resistance to the flow of blood ; there is a much smaller supply of arterial blood, to the bronchial tubes, by way of the bronchial arteries. There is a certain amount of anastomosis between the pulmonary and bronchial circulations, though mainly only in the smaller vessels, so that probably but little bronchial blood reaches the alveolar capillaries.* The mean pressure in the pulmonary artery probably does not exceed about one-sixth of the mean aortic pressure. By catheterizing branches of the pulmonary artery and vein in dogs with thorax intact, the pressures were found to be 10 mm. Hg and 6 mm. Hg respectively : the pulmonary capillary pressure is therefore about 8 mm. Hg.†

The capillaries of the lungs may vary passively in size, according to the conditions. Thus, whereas at the height of inspiration the blood contained in the lungs is about one-twelfth of the whole blood in the body, this amount is said to be diminished during expiration to between one-fifteenth and one-eighteenth, and by forcible artificial inflation of the lungs may be lessened to one-sixtieth. Such changes may exercise a considerable effect on the systemic blood pressure. Again, if the circulation rate is increased, the whole of the pulmonary vascular bed will be distended, and as much as one-fifth of the blood may be in the lungs (Kuno ‡). On the other hand, the distensibility of the lung capillaries may play an important part in enabling the lungs to act, so to speak, as a reservoir for the left side of the heart. If there is a temporary excess of output on the right side that cannot be dealt with at once by the left heart, the excess is taken up for a time in the lung vessels.

The mean pressure in the pulmonary artery depends on the output of the right ventricle and the resistance in the lungs, and of these the one most subject to variation is the former. The mean pressure in the pulmonary veins is very low, being at or about zero, and somewhat greater than that in the left auricle. Because resistance is low, the gradient between pulmonary artery and pulmonary vein is not so steep as might be expected in view of the high velocity of the blood in the pulmonary circuit. Although an increased output of the right heart leads to a rise of pressure in the pulmonary artery, the pressure in the pulmonary veins is little increased. This fact, which is because the left auricle is normally competent to keep the pulmonary veins adequately drained, results in steepening of the gradient of pressure which drives blood through the lungs.

An important question is raised as to the influence of changes of aortic pressure, due to alteration of systemic resistance, on the pressures in the pulmonary circuit. Experiments on the heart-lung preparation showed that a rise in the aortic pressure, while the inflow into the heart from the venous reservoir was kept constant, was accompanied by a rise in the pulmonary artery pressure. This was at first ascribed to " back pressure," *i.e.* to a relative failure of the left auricle to deal with the blood flowing into it. This cannot be the case, however, for the mean left auricular pressure is not raised (Fig. 460). The phenomenon is due to increased output of the right heart caused by increased flow through the coronary arteries,[*] and to a lesser extent through the bronchial arteries[†] induced by the rise of aortic pressure. In the closed-circuit heart-lung preparation, with constant ventricular output a rise of aortic pressure has little or no effect on pulmonary arterial pressure.[†] Similar conditions contribute to the parallelism between pulmonary and systemic arterial pressures in the intact animal. Only when the left ventricle is greatly dilated (and the mitral valve incompetent) are there likely to be pronounced back pressure effects.

* Berry and Daly. *Proc. Roy. Soc.*, 1931, **109B,** 319.

† Hellems *et al.* *Amer. J. Physiol.*, 1948, **155,** 98.

‡ Kuno. *J. Physiol.*, 1917, **51,** 154.

The pulmonary arterial pressure shows considerable variations, about 30 mm. Hg with each heart beat, so that the pulse pressure is greater than the average pressure[‡]; this means that the resistance in the pulmonary bed is low. The pulsations resemble those of the systemic arteries (Wiggers). There are also slower variations of pressure due to the respiratory movements; the pressure falls during inspiration and rises during expiration. In the pulmonary veins the pressures vary less with respiration, and probably in the reverse direction. These results are due to a lowering of resistance in the pulmonary capillaries during inspiration.[||]

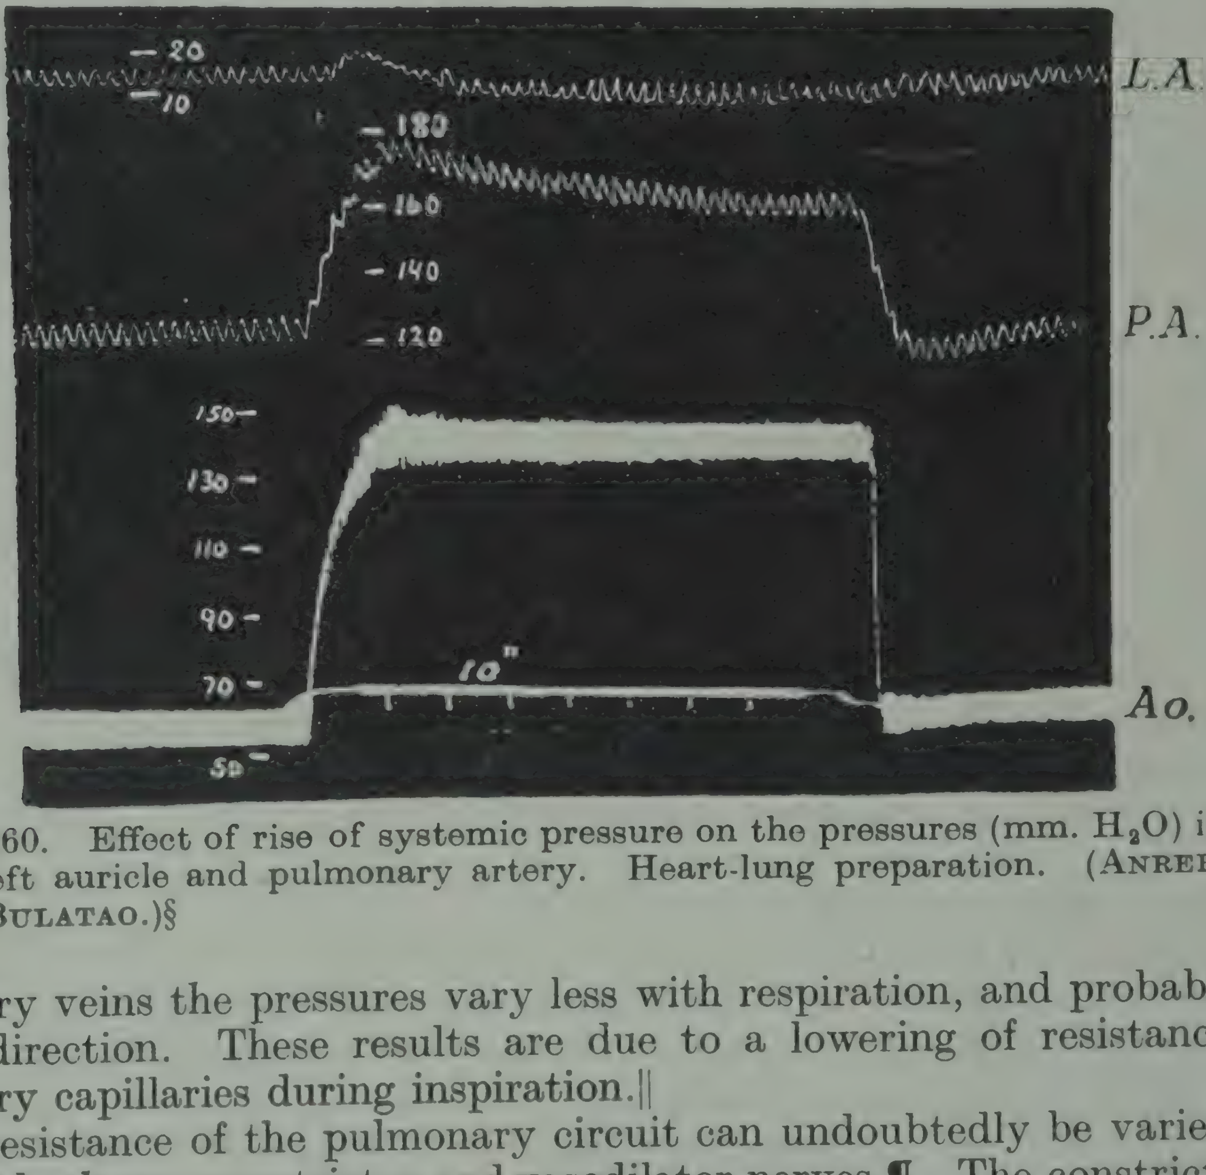

FIG 460. Effect of rise of systemic pressure on the pressures (mm. H_2O) in the left auricle and pulmonary artery. Heart-lung preparation. (ANREP and BULATAO.)[§]

The resistance of the pulmonary circuit can undoubtedly be varied by the action of both vasoconstrictor and vasodilator nerves.[¶] The constrictor fibres are sympathetic from the upper thoracic nerves, *via* the vago-sympathetic nerves. Addition of adrenaline to the circulating blood causes pulmonary vasoconstriction with rise of pulmonary artery pressure. The dilator fibres are probably derived from the vagi. Stimulation of the vago-sympathetic may therefore cause either vasoconstriction or vasodilatation, according to which of the component fibres are most affected. Reflex pulmonary vasoconstriction has been claimed to result as a consequence of the stimulation of sensory nerve roots and of the central end of the splanchnics, and reflex dilatation from stimulation of the depressor nerve. It is uncertain to what extent the nervous control of

the pulmonary bed is exercised under normal conditions or what its function may be, apart from altering the amount of blood in the pulmonary circuit.

Effect of Respiration on Systemic Blood Pressure. A tracing of the general arterial pressure shows that with each inspiration the blood-pressure rises, and with each expiration it falls. These undulations are in part due to an irradiation from the inspiratory centre to the vasomotor centre (p. 652) (Traube-Hering waves): in part therefore they are independent of mechanical changes in the thorax. The synchronism of the rise and fall with the respiratory movements is not exact, and varies with the rate of the respiratory movements, since the rise continues for a short time after the beginning of expiration, and the fall continues into the beginning of the next inspiration, so that in slow breathing the highest point of the curve occurs at the beginning of expiration and the lowest point at the beginning of inspiration. During the rise at inspiration, the heart beats often become accelerated. This is due to a "Bainbridge reflex," the acceleration being caused by the increased filling of the right heart by aspiration of blood into it during inspiration. On dividing both vagi, this difference in the pulse rate during inspiration and expiration disappears, but the main features of the blood pressure curve remain; when respiration is artificially produced by forcing air into the lungs, the effect of the movements is reversed, *i.e.* the rise now occurs during the expiratory phase; these various facts indicate that some mechanical factor must also be concerned in the explanation of the respiratory undulations.

As we shall see later, under normal conditions the lungs are in a state of stretch, and in consequence of this condition they are constantly exerting a pull on the chest wall. As the chest expands in inspiration it drags the lungs still more open, so that their pull on the chest wall becomes greater, and hence the negative pressure in the pleural cavity is much increased during forcible inspiration. The heart, great veins and arteries in the thorax are practically exposed to any pressure which may exist in the pleural cavity, whereas outside the thorax all the vessels are exposed to a positive pressure.

Any fluid will always flow from a point of higher to a point of lower pressure. Hence, when the thorax enlarges during inspiration, there must be an aspiration of blood into it from peripheral parts. This aspiratory force will not influence arteries and veins alike. The arteries, having thick walls, will be very little affected by the increase of negative pressure in the thoracic cavity, whereas the thin-walled distensible veins, auricles and right ventricle, will be largely influenced. The total result, then, of the increasing negative pressure in the pleural cavities, is to increase the flow of blood from the veins into the heart, especially on the right side, without affecting to any appreciable degree the outflow of blood from the heart into the arteries. The inspiratory descent of the diaphragm will, moreover, tend to increase the inflow into the heart by raising the pressure in the abdomen, so that the blood is pressed out of the abdominal veins, and sucked into the heart and the thoracic veins. *During* inspiration, therefore, the inflow into and output from the right heart will be more rapid than during expiration, and this factor in itself will tend to raise the arterial blood pressure. During expiration, all these effects are reversed.

Although extreme expansion of the lungs increases the resistance to the flow through their vessels, presumably by lengthening and narrowing the latter, expansion of the lungs in normal inspiration considerably distends the vessels, and so increases the capacity and lowers the resistance of the pulmonary circuit.* The increased circulation rate produced by inspiration also distends the vascular bed. When the thorax expands, the immediate effect of the pull on the vessels that have thin walls is to fill them up with blood, and this blood being checked in its onward movement leads at first to a reduced flow into the left ventricle. Hence, at the onset of inspiration, the systemic blood pressure falls even further than during expiration. For the converse reason that the expanded vessels partly empty at expiration, and add the blood so expelled to the pulmonary current, the systemic pressure at the commencement of expiration continues still further the rise established during inspiration. Lewis * regarded the pericardial pressure, *i.e.* the direct influence of the thoracic movements on the heart, as playing a much more important part than changes in the pulmonary circulation in the production of the respiratory undulations in the blood pressure. He showed, moreover, that, in man, the effect of respiration on arterial blood pressure may vary according to the type of respiratory movement, a deep costal inspiration (not prolonged) causing a pure fall, while a deep diaphragmatic inspiration gives a pure rise of blood pressure. In expiration the reverse effects hold. He concluded that, in man, it is not possible to make any *general* statement as to the nature of the blood pressure response to a particular respiratory act.

THE HEPATIC CIRCULATION

The blood flow through the liver is very large, about 1.5/min. in an adult man. The liver is supplied by two main vessels, the hepatic artery and the portal vein, and the former probably contributes at least one-quarter of the blood flow and about 40 per cent. of the oxygen to the liver.†

The liver, on section, is seen to be divided off into lobules composed of columns of polygonal cells, radiating from the centre. The portal vein, which drains the blood from the spleen and alimentary canal, breaks up into branches which lie at the periphery of the lobules, forming the interlobular veins, and send off numerous sinusoids which pass inwards between the columns of cells to join the intralobular vein lying at the centre of the lobule. From the intralobular vein the blood passes by the large sublobular veins into the hepatic veins and inferior vena cava. In an injected specimen it is easy to see that every liver cell is adjacent to at least one blood capillary. The portal vein conveys only venous blood to the liver. The lymphatics run in Glisson's capsule.‡

The hepatic artery principally supplies the connective tissue of Glisson's capsule, in which it breaks up into capillaries, and these are drained partly into venules which join the portal vein branches and partly into the sinusoids near to the margins of the liver lobules,§ so that the whole of the venous blood derived from the hepatic artery supply mingles with the general portal blood stream.

Complete loss of its arterial supply leads to necrosis of the liver,‖ though owing to the existence of anastomotic connections between the hepatic and diaphragmatic arteries, occlusion of the main hepatic artery may not be incompatible with life, even in man.

Complete and sudden obstruction of the portal vein leads to speedy death, with engorgement of the abdominal viscera which drain into the portal vein, while the occlusion of one of its branches leads to atrophy of the lobes of liver supplied by it.

The resistance to the flow of blood through the liver is normally very slight, as is shown by the fact that the pressure in the portal vein, which drives so large a blood flow through the liver, is only about 8 mm. Hg. The pressure shows respiratory fluctuations, rising at inspiration, owing to a massaging action of the rhythmically descending diaphragm.

When there is a permanent increase of the resistance, as happens in diseases attended by portal cirrhosis, the blood flow along the portal vein finds its way into the inferior vena cava partly through a short circuiting of the liver by the enlargement of anastomotic connections which normally are insignificant, *e.g.* between the gastric and the œsophageal veins, the inferior mesenteric and the hæmorrhoidal branches of the internal iliac veins or between the coronary veins of the stomach and branches of the phrenic veins: the spleen becomes enlarged and the surface of the abdomen is covered with the enlarged veins subserving the anastomosis. It is possible to create such a condition experimentally in animals by constricting the portal vein,* and use has been made of this fact as a preliminary to extirpating the livers of animals for experimental purposes.

It is impossible to remove the liver directly in mammals, since ligature of the portal vein, which would be a necessary step in the operation, causes the blood to be dammed up in the portal area, and the animal dies within a few hours, being bled to death, so to speak, into its portal vessels. A way of partially obviating this difficulty was suggested by Eck.† Before ligature of the portal vein, this vessel was joined side by side to the vena cava, so that after the ligature the portal blood could flow directly into the general circulation without passing through the liver (Eck fistula). The liver was not removed, and a path to it was still open by the hepatic artery. As liver extirpations, the experiments were inconclusive, because the liver was still present and provided with a large, though abnormal, circulation. The operation still has its uses, however, in cases where it is desired to short circuit the portal circulation.

More satisfactory extirpations were performed by Mann and Magath ‡ and their collaborators. The operation is performed in three stages. First an operation like an Eck fistula is performed, except that after connecting the portal vein laterally with the vena cava, the vena cava and not the portal vein, is tied above the anastomosis. All the blood from the vena cava below the liver is thus diverted into the portal vein. After recovery from this it is found that owing to the increased pressure in the portal vein a bye-pass circulation is soon established between the portal vein and thoracic veins, *e.g.* the internal mammary and azygos. When this has occurred, the second operation, viz. ligature of the portal vein at the portal fissure, is performed. Now all the portal blood flows by the collaterals to reach the inferior vena cava above the liver. Lastly, the hepatic artery is ligatured and the liver removed, together with the length of inferior cava into which its vessels drained.

The portal area also plays an important part in the circulation by acting as a variable reservoir for blood.§ Not only is the volume of blood which passes the liver great, but the channels through which it is conducted are wide, so that the amount of blood present in the liver at any moment is considerable. The portal vein, with its rootlets (including the spleen), represents a reservoir intercalated between two resistances, viz. the arterioles of the splanchnic area centrally and the small liver vessels peripherally. This reservoir when distended can hold about a third of the blood in the body. Filling of the portal reservoir can be effected by dilatation of the primary (splanchnic) resistance or by constriction of the secondary (hepatic) resistance, and conversely a partial emptying of the reservoir results from constriction of the primary and/or dilatation of the secondary resistance.

The regulation of the splanchnic arterioles, by which the rate of entry of blood into the portal vein is controlled, is by the usual vasoconstrictor nerves of the splanchnic area. On stimulation of the splanchnic nerves the portal vein pressure, which is usually low (about 8 to 10 mm. Hg), at first falls a little and then rises abruptly ‖ to about double the normal value. The cause of the small and transitory initial fall is probably the immediate reduction of the flow of blood into the portal vein in consequence of constriction of the splanchnic arterioles. The subsequent rise is due to several causes, and is no doubt similar to the rise produced by adrenaline.¶ Part of it is due to constriction of the smallest branches of the portal vein within the liver. There is, however, another mechanism of considerable importance, viz. the communication, in the liver, between the hepatic artery and portal vein circulations. In consequence of this, the rise of general arterial pressure, which results when the splanchnics are stimulated, or when adrenaline is given, causes more blood to pass to the liver by the hepatic artery and so to raise the pressure in, and thus act as a resistance to the flow through, the vessels supplied by the portal vein.

¶ McMichael. *J. Physiol.*, 1932, **75**, 241.

That there is a connection between the hepatic artery and portal vein circulations is shown by the further fact that when the superior mesenteric artery or vein is tied off, the portal vein pressure, though it falls, does not fall to a low level. Clamping of the hepatic artery alone also causes a fall of portal pressure for the same reason. A further factor which causes an increase of portal pressure after the administration of adrenaline is that the moderate constriction of the mesenteric arterioles is afterwards overcome by the high arterial pressure,[*] so that more instead of less blood enters the portal vein.

When there is general vasoconstriction of the splanchnic area and of the liver vessels, as occurs after administrations of vasopressin, the portal pressure falls, owing to restriction of inflow, since the arterial pressure is unable to overcome the high resistance of the constricted vessels.

In some animals, notably the dog, it is found that on perfusion of the liver outside the body, the flow soon declines unless a very high pressure is used for the perfusion. This is because there is, at the outlet of the hepatic veins, a strong layer of plain muscle which can contract and so control the outflow from the liver. It is caused to contract by histamine and relaxed by adrenaline or sympathetic stimulation,[†] and by oxytocin.[‡] Under conditions of artificial perfusion, and in certain shock-like states, these sphincters are tightly contracted, with the result that the portal pressure rises and the liver rapidly swells.

THE CEREBRAL CIRCULATION

The grey matter of the brain is very richly supplied with blood vessels from the *pia mater*. For anatomical reasons it is difficult to determine the blood flow in the brain, but it has been accomplished, both directly [§] and indirectly [||] in animals, and indirectly in man.[¶] The indirect method is by an application of the Fick principle. A mixture containing 15 per cent. nitrous oxide, and 21 per cent. oxygen is given to breathe for about 10 minutes ; simultaneous samples of arterial blood and of blood from the right internal jugular vein are drawn at intervals during 10 minutes, and analysed for N_2O content. The arterial content rises more rapidly than the venous, and by suitable calculations the amount of N_2O lost per 100 c.c. of blood passing through, and the total N_2O absorbed up to a given time, can be calculated, and hence the blood flow. Such experiments show that the blood flow is normally about 54 ± 12 c.c./100 g./min., and the oxygen consumption 3·3 ± 0·4 c.c./100 g./min. The cerebral vascular resistance, mm. Hg/c.c. blood/100 g. brain/min. can also be measured, and is 1·6 ± 0·4. In man, the A—V glucose and oxygen differences between arterial and internal jugular blood are respectively about 9·5 mg. and 6·3 vols. per cent. The above data would give therefore, a blood flow of about 740 c.c./min., a glucose usage of 70 mg./min., and an oxygen usage of 45 c.c./min., for a brain of 1,360 g. weight.

The smaller arteries derived from the pial vessels penetrate into the substance of the brain and anastomose freely with one another. Capillaries are abundant, especially in the grey matter of the cerebral cortex, where they aggregate about 1 m. of capillary vessel per c.mm. of nerve tissue, a figure which, however, is low compared with, say, cardiac muscle. The white matter is less vascular and uses less oxygen than the grey.

In all higher animals, the brain is enclosed in a rigid bony cranium. In the child, before the cranial vault is fully ossified, part of this vault consists of membrane, the anterior fontanelle. The fontanelle bulges with each heart beat, as well as with rise of venous pressure, such as that produced during strong expiratory efforts. When ossification is complete, such alterations in the volume of the cranial contents are impossible. When viewed through a skull window, little movement of the pial arteries is visible, apart from a straightening out at points where they change direction, at each heart beat. If any expansion of the arteries occurs, room for this expansion has to be found by displacement of some other part of the cranial contents. The rapidly variable contents of the cranium are the blood and the cerebrospinal fluid. Hence, if a lumbar puncture needle be inserted into the thecal space, it is seen that on occlusion of the venous return from the cranium by an inflated cuff, cerebrospinal fluid gushes out by the needle at 250–400 c.c./min., the cerebral vessels being simultaneously distended with blood at the same rate.*

Each arterial beat is associated with a corresponding compression of the veins, and if a cannula be introduced through the occipital bone into the torcular Herophili, the venous blood is seen to pulsate out with each arterial pulse. If there is a rise of arterial pressure, although the arteries may expand somewhat at the expense of the veins, there can be little dilatation of the whole organ. The first, and chief, effect of the rise of pressure will be to cause an increased pressure slope in the cranial vascular system, and, therefore, augmented velocity of flow through the system. As a result of a more prolonged rise of pressure a certain amount of dilatation of the vessels may ensue, but only at the expense of the cerebrospinal fluid. Since this is small in amount, any expansion of the brain due to vascular causes must be limited. The converse applies for shrinkage when the general arterial pressure is lowered.

BRAIN PRESSURE. If a trephine opening be made into the cranial vault, the brain bulges into the opening. By screwing a window into the trephine opening, we can find the pressure necessary to force the brain back to its previous position. This is known as the intracranial pressure ; it is, as might be expected, approximately equal to the cerebrospinal pressure and to the pressure in the venous sinuses, and is closely dependent on the latter. Forced expiratory efforts may raise the pressure from 30 to 50 mm. Hg. In the vertical position, in man, the pressure may be slightly negative, in consequence of the tendency of the venous blood to run downwards towards the heart.

Regulation of the Blood Supply to the Brain. The free anastomoses in the circle of Willis ensures an adequate distribution of blood to all parts of the brain, even should one or more of the contributory arteries get accidentally occluded. The blood supply to the brain is primarily dependent on the arterial pressure, and this, as we have seen, is specially controlled by the carotid sinuses. Hence, any tendency for the carotid arterial pressure to fall is at once counteracted by systemic circulatory changes of such a nature as to tend to restore it to normal again. If this pressure fails, the oxygen supply of the brain is affected and loss of consciousness rapidly ensues. This is what occurs when a person, who is weak from long illness, faints on suddenly getting up from bed. In the normal individual, the change in the circulation with alteration of bodily position, which would be produced by the action of gravity, is at once counteracted through the vasomotor system.

As a subsidiary means of regulation, the vessels of the *pia mater* are themselves supplied with vasomotor nerves. In order to demonstrate these it is necessary to observe the pial vessels through a window let into the skull, so as to ensure the normal rigid enclosure of the brain.† It can then be shown that stimulation of the central end of the cervical sympathetic nerve causes constriction of the pial vessels ‡ (Fig. 461). Stimulation of the vagus depressor fibres causes reflex vasodilatation, the efferent vasodilator fibres apparently reaching the cerebral vessels from the VIIth nerve.

‡ FORBES and WOLF. *Ibid.*, 1928, **19**, 1057.

The action of drugs is on the whole similar to that on other vessels. Intravenous injection of small amounts of adrenaline may cause constriction, but often this is so weak that it easily gives way to passive expansion of the vessels owing to the rise of general blood pressure * (Fig. 461). Acetyl choline causes dilatation of the vessels, though if the arterial pressure falls, there may be no increase of cerebral blood flow. Histamine gives similar results; most anæsthetics also cause vasodilatation. The action of pitressin is doubtful.

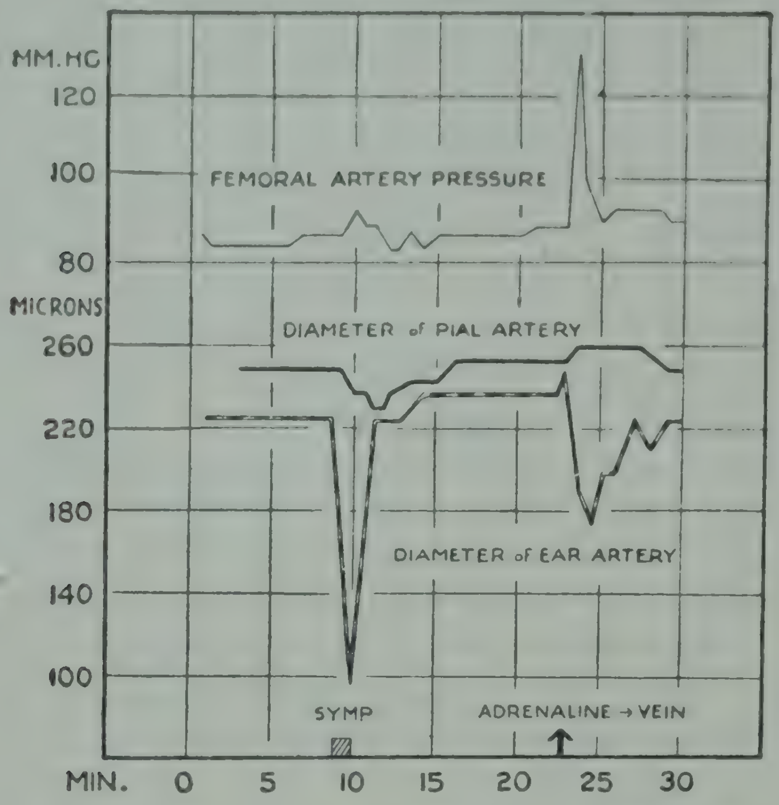

Fig. 461. Showing diameters of pial artery and of a small ear artery in the cat, together with femoral artery pressures. Observe that stimulation of the cervical sympathetic at "symp" causes much greater constriction of ear artery than of pial artery. Injection of 0·01 mg. adrenaline intravenously causes constriction of ear artery, and a large rise of arterial pressure, on account of which the pial artery passively dilates. (Forbes, Firnley and Mason.)

Under asphyxial conditions, local or general, there is dilatation of the cerebral vessels. Both oxygen lack and carbon dioxide excess act in this manner. Thus, inhaling 5–7 per cent. CO_2 may increase the cerebral blood flow 75 per cent., while 10 per cent. O_2 will increase it by 35 per cent.: increase of inhaled O_2 to 95 per cent. will reduce the flow by 13 per cent.† All these changes are due to alterations of vascular resistance.

There is some evidence that the vessels of the brain are dilated during states of increased activity.

When the intracranial pressure is increased, the arterial pressure rises, and if it exceeds the intracranial pressure, the circulation through the brain continues (or re-commences): but the resistance to the flow is raised, and so the blood flow may be reduced. When this falls below a certain level, or if the arterial pressure does not rise high enough to overcome the intracranial pressure, death results owing to asphyxia of the medullary centres.

CHAPTER XXXVI

EXAMPLES OF CIRCULATORY ADAPTATION

1. THE CIRCULATORY CHANGES DURING MUSCULAR EXERCISE

In the preceding chapters we have analysed somewhat artificially the factors which are normally involved simultaneously in the adaptation of the circulation to the necessities of the body. In order to effect a synthesis of these isolated mechanisms we may take as an example the adaptations which are involved in muscular exercise. To a large extent we can investigate the subject on man.

On initiating such experiments we meet at once with a new fact—viz. that the reflex adaptations are forestalled and reinforced by the intervention of impulses proceeding from the brain. Thus, the willed effort, or the emotion of fear or anger gives rise at the same time to impulses, starting in the brain, which excite changes in the circulatory and respiratory systems such as anticipate those which will be later excited reflexly as a result of the exercise. With a man seated on a stationary bicycle the mere question " Are you ready ? " evokes increase of muscular tone in the act of attention, increased pulmonary ventilation, and a rise of pulse rate and of blood pressure. And these changes are increased as soon as the word " go " is given. The reinforcing impulses from the cortex, which put these various mechanisms into action, are effective especially at the beginning of muscular work. The subsequent adaptations of the different organs of the body are probably chiefly automatic.

We have seen that the oxygen intake, and the CO_2 output, may undergo at least a twelve-fold augmentation during violent muscular effort carried out for a short time ; as much as a twenty-fold increase has been observed, and a five-fold increase is common and may last for many hours. A necessary condition of all muscular exercise is that the muscles shall be supplied with oxygen in proportion to their requirements. Since the arterial blood is, under normal conditions at rest, about 95 per cent. saturated with oxygen, such increases in the oxygen usage by the muscles must imply a great increase in the blood supplied to them, though a certain extra amount of oxygen may be gained by a more complete utilisation of the oxygen of the blood as it flows through the working tissues. This increased oxygen traffic involves, in its turn, an increase in the blood flow through the lungs and in the ventilation of the lungs. The circulation through the lungs has been investigated in the healthy man during rest and during exercise.*†‡ In Fig. 462 are shown results obtained by Means and Newburgh. It will be seen that the blood flow through the lungs, *i.e.* the output of the right ventricle per minute, and also the lung ventilation, increase in a manner almost absolutely proportional to the consumption of oxygen, and that all three increase *pari passu* with the work done per minute. How is this admirable adjustment of the activity of the heart and circulation to the oxygen needs of the muscles effected ? The output of the heart depends on the inflow into it, so that our problem is to determine the factors which increase this. At or before the onset of muscular exercise, unless this is quite moderate, there is relaxation of the muscle vessels and contraction of the splanchnic vessels, so that the increased output of blood is passed to the muscles, and later on also to the skin, rather than to the viscera ; the latter, owing to the raised arterial pressure, may receive about the same amount of blood as in rest. Other things being equal, it is evident that, since the blood moves in a circle, any circumstance which favours the passage of blood through the circuit as a whole will lead to an acceleration of circulation rate, and this will take the form of a more

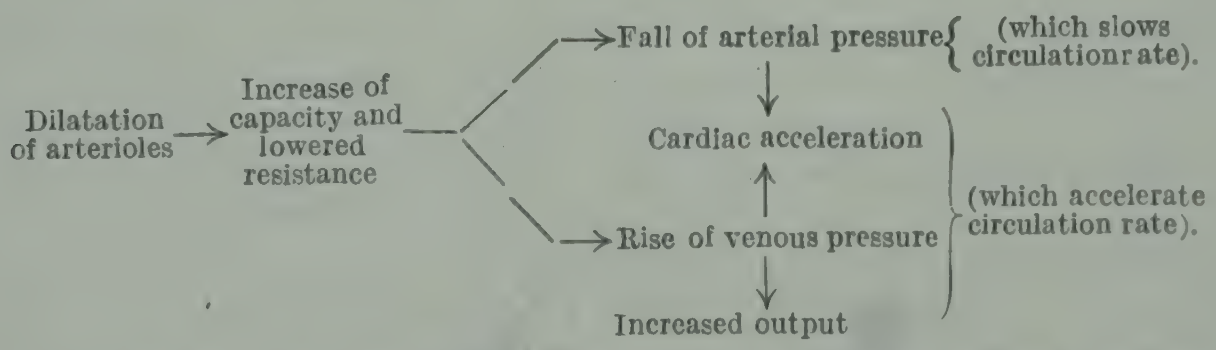
rapid return of blood to the heart. But there will also be accompanying changes operating in the opposite direction, by which the result is to some extent complicated. Thus, if we imagine a simple circulation, it is clear that extensive dilatation of the arterioles will give rise to the following chain of events :



Dilatation of arterioles
Increase of capacity and lowered resistance
Fall of arterial pressure
(which slows circulation rate).
Cardiac acceleration
Rise of venous pressure
(which accelerate circulation rate).
Increased output

In consequence of such changes, a tendency to a fall of arterial pressure is more than compensated for by the accompanying alterations in the cardiac output. This is further augmented in exercise in a variety of ways. Probably the prime mover in accelerating the venous return, and so the circulation rate, is the effect of the contractions of the muscles themselves upon the rate of blood flow through their vessels. During actual contraction the flow through the muscle is slowed or even stopped.* But during and after relaxation it is agreed that the flow is increased, sometimes greatly. In the larger veins, by reason of their valves, the muscular contractions tend always to drive the blood onwards to the heart, even against a pressure of 90 mm. Hg.† The circulation through the big veins of the abdomen and chest is aided by the respiratory movements which are also augmented in proportion to muscular activity, each inspiration driving the blood out of the big veins in the abdomen and aspirating it into the thorax. The blood flow into the heart is thus increased in proportion to the activity of the muscles. The first effect of muscular exercise will be to increase the heart output at each beat. The increasing tension on the venous side of the heart evokes reflexly a quickening of the heart rhythm, chiefly by inhibition of the vagus tone, possibly also by reflex stimulation of the sympathetic accelerator nerves. Further increase in the inflow into the heart is met by corresponding quickening of the heart rhythm and the output of each ventricle per minute is increased seven to ten times. The part played by increase of output per beat, and by increase of pulse rate respectively, in augmenting the total output of the heart is shown in Fig. 463. In this figure, the first rise in pulse rate from sixty-eight to ninety-eight, and the corresponding increase in output per beat, can be regarded as associated with the initial changes originated by the act of attention and volition. It will be seen that between 270 and 600 kilogrammetres of work per minute the pulse rate remains practically unchanged, while the output per beat increases steadily with the work. After this point, there is very little further increase in the output per beat, which towards the end begins to diminish, while there is a steady increase in the pulse rate.

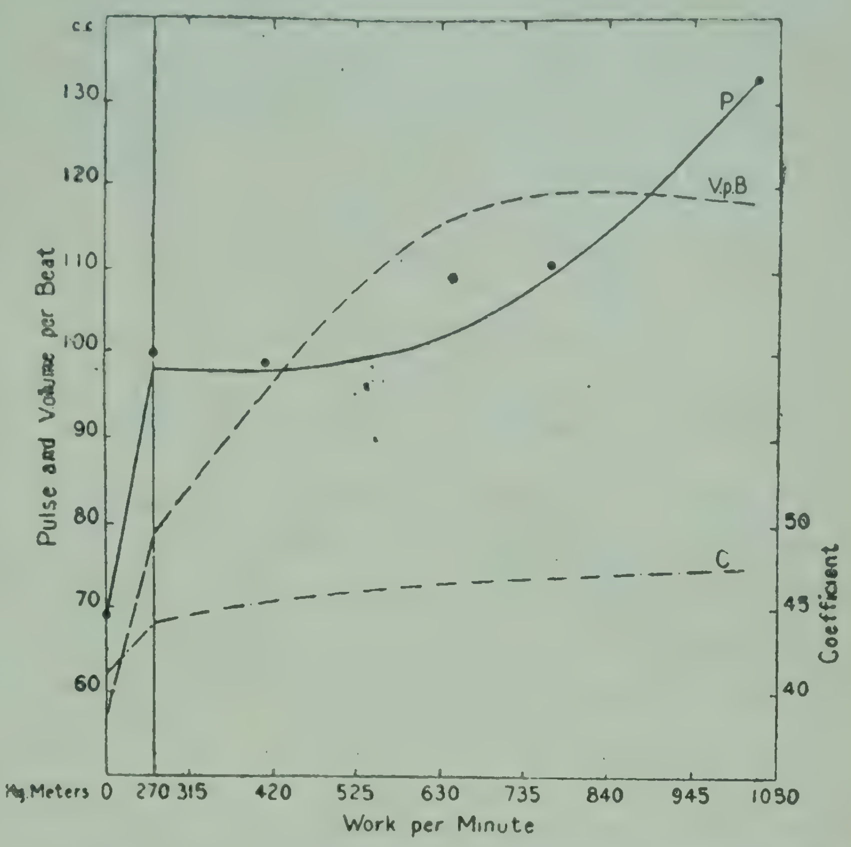

FIG. 463. Chart showing the Effect of Increasing Amounts of Muscular Work on the Pulse Rate, P, shown by dots; on the Heart Output per Beat, VpB, and on the Co-efficient of Oxygen Utilisation in the Blood, C. (From MEANS and NEWBURGH.)

By this means, the blood is driven through the lungs at a rate corresponding to the increased needs of the muscles for oxygen. The passage of this blood through the muscles is provided for by two mechanisms. In the first place, owing to the increased cardiac output, the arterial pressure is raised,* and since the muscular vessels are relaxed and the splanchnic ones constricted, a large fraction of the circulating blood can be driven through the working tissues. The total available blood is also increased by partial emptying of the portal system. In the second place, the muscles in their activity produce various metabolites, which cause further dilatation of the arterioles and capillaries in the muscles themselves. A third way in which muscular circulation is increased may be by reflexes initiated in the tissue by the presence of metabolites formed by contraction. During rest, it is probable that the majority of the capillaries are closed; during activity these dilate and are filled with blood, so that the capillary bed in the muscles may be increased many times in area, and each element of the muscle is brought into close relation with a dilated capillary, through which is flowing a rapid stream of oxygenated blood. Krogh † has shown that the number of blood-containing capillaries in each square millimetre cross-section of the muscle may be increased 40 to 100 times during maximal activity of the muscle. As a result, the oxygen tension in the muscle fibres becomes almost equal to that in the capillaries themselves.

* L. HILL. *J. Physiol.*, 1898, **22**, *Proc.* xxvi.; BOWEN. *Amer. J. Physiol.*, 1904, **11**, 59.
† KROGH. *J. Physiol.*, 1919, **52**, 409, 457.

Complex physico-chemical changes taking place in the blood * aid the dissociation of the oxyhæmoglobin passing through the capillaries, and therefore set free oxygen for the use of the muscles. On this account, we find almost invariably that the utilisation of the oxygen of the blood is more complete during exercise. Except during the most exhausting exercise the arterial blood is as fully saturated with oxygen as when at rest, † but in working to exhaustion it may fall to 85 per cent. saturation.‡ The fraction of the oxygen content of the arterial blood which is abstracted as it flows round the circulation is known as the "co-efficient of utilisation." Thus if 328 c.c. of oxygen were used per minute and the blood flow were 4·5 litres per minute, $\frac{328}{4\cdot5} = 73$ c.c. oxygen would be utilised per litre of blood. If the oxygen capacity of the blood were 193 c.c. per litre, the co-efficient of utilisation would be $\frac{73}{193} = 0\cdot38$. In Fig. 463 the co-efficient of the oxygen utilisation is given by the curve C. It has been found that the co-efficient of utilisation rises during severe exercise from a resting value of about 0·3—0·5 to 0·7—0·8.§

It has been shown by Cannon that every state of excitement, and especially fear and anger, is attended with increased secretion of adrenaline into the blood stream. During violent exercise associated with emotional stress, there will be an excess of adrenaline circulating in the blood, and this will reinforce the activity of the circulation. Thus, it will increase the constriction of the splanchnic area, already excited reflexly and by the central effects of the increased CO_2 or lactic acid in the blood. In the heart, the adrenaline will increase the contractile power and also the rate of beat, while, by its dilator action on the coronary vessels, it will aid the supply of oxygen to the heart

muscle. At the same time, it will cause a rapid conversion of the glycogen of the liver into sugar, so that the contracting muscles will be adequately supplied with a food which they can utilise. It is doubtful whether these effects of adrenaline are to be reckoned with, except in cases of severe emotional stress.

After the conclusion of exercise, the changes which accompanied it disappear. Arterial pressure falls quickly, and usually drops to below the normal, slowly to return. Pulse rate also drops very suddenly in those with efficient hearts, and sometimes shows a second slight rise accompanying the rapid fall of blood pressure. Oxygen usage and cardiac output drop simultaneously, and sooner than pulse rate, while pulmonary ventilation falls more slowly, and blood lactate falls most slowly.*

Training. The muscular efficiency of a man is measured by the extent to which he can call upon his body for increased efforts, *i.e.* by his margin of response. Over a moderate period of time, the individual may increase his muscular work, his respiratory exchange, and the rate of his circulation six times above that which obtains during rest. In a sudden or short-lasting effort, a much greater amount of energy can be put out, the muscles "going into debt" for the necessary oxygen. The performance of a normal individual can be increased by training, the essential features in which are graduated exercise and healthy diet, so that the muscle grows and becomes free from interstitial fat, while the fluid parts of the body and of the blood are diminished so that a larger amount of oxygen can be carried per unit volume of blood. The well-trained individual may have a margin of as much as 1,200 per cent. Disease is marked by a diminution of the margin. In Fig. 464 is given diagrammatically the response of the circulation and respiration of a man with heart disease affecting the aortic and mitral valves. This man had no discomfort and was able to do ordinary work without ill effects. On testing him on measured muscular tasks, it will be seen that, although at first he reacts like the normal individual, his margin is diminished, and when doing only 315 kilogrammetres of work per minute, the rise in the oxygen intake and in the heart output fails to keep pace with the increase in the work and also loses the parallelism which is so marked a feature in normal individuals. With increasing disease, the time would finally come when the margin was reduced to 100 per cent. or 50 per cent., so that even the act of changing from a recumbent to an erect position might be too much for the enfeebled adaptive mechanisms of the body, and the patient would have to keep to his bed. There is thus no definite dividing line between health and disease, the change from one to the other being but a progressive diminution of margin or extent of adaptation.

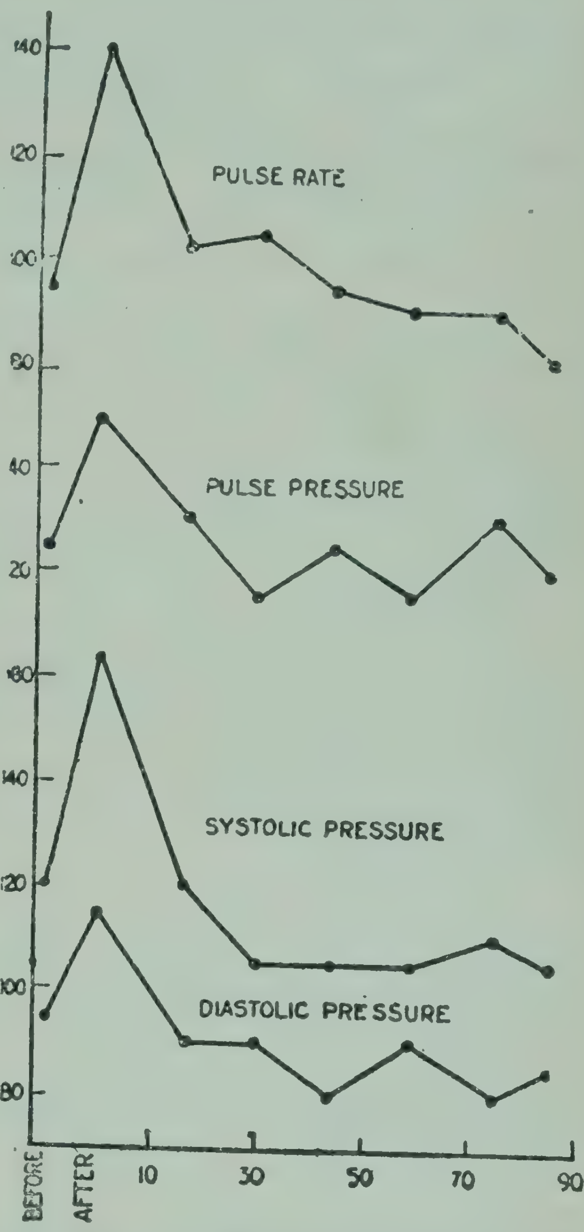

FIG. 465. Curves showing the Influence of Exercise on the Circulation. The exercise was a six-mile run. Ordinates = mm. Hg pressure and rate per minute. (O. S. LOWSLEY.†)

We have seen that the physiological condition of the heart is measured by the dilatation of its cavities, *i.e.* of the shortest length of its muscle fibres, required in order that in its beat it may set up a contractile stress adequate to expel its contents against the arterial resistance. Thus a degree of filling of the heart, which in a well-trained man may be adequate to ensure a contraction sufficient entirely to empty its cavities, in a weaker heart would be inadequate, so that blood would accumulate at each diastole until the stretching of the fibres was sufficient to ensure that the amount entering during diastole was expelled at each systole. The trained man—*i.e.* with a heart in good condition—will therefore have a considerable range over which the output per beat can be increased with increasing inflow, without alteration of rhythm. In the untrained man this margin will be smaller, so that the second mechanism of adaptation, viz. quickening of the heart beat, will be sooner brought into action to cope with the increased inflow associated with muscular exercise. Thus, one finds a considerable difference in the effect of exercise on the pulse rate in trained and untrained individuals respectively,* and this is especially shown in the promptness of recovery of the pulse when the exercise comes to an end, the effects lasting much longer in the untrained. In all cases exercise not carried to exhaustion tends to be followed by a prolonged diminution both in pulse rate and in blood pressure (*cf.* Fig. 465).

Ischæmic Pain. When muscles contract under such conditions that the blood supply does not increase in keeping with their increased needs, a peculiar cramp-like pain is experienced in the muscles concerned. It is met with in cases of narrowing of the arteries to a limb, and the condition is called intermittent claudication. It may be imitated by placing a sphygmomanometer armlet round the upper arm, inflating it suddenly to 250 mm. Hg, and then making gripping movements of the hand every second. The pain commences in about 35 seconds and becomes intolerable in 70 seconds; it persists as long as the occlusion of the circulation is kept up, but, on restoring it, is abolished in 3 seconds. If the circulation is again stopped, no pain is felt unless the muscles are once more exercised, but, if they are, it appears much sooner than in the first instance. These various acts led Lewis † to the conclusion that the pain is due to the accumulation during muscular contraction of a substance, which he called the " P-factor "; this under normal conditions is removed by oxidation, but when this is not done the substance stimulates pain fibres. The cardiac pain accompanying coronary occlusion is believed by Lewis to be explicable in a similar way.

2. THE INFLUENCE OF VARIATIONS IN THE TOTAL QUANTITY OF BLOOD

Plethora and Hydræmic Plethora. The effects of increasing the total volume of circulating fluid may be studied by injecting several hundred cubic centimetres of defibrinated blood or normal saline solution into a vein. The condition resulting has been called *plethora* or *hydræmic plethora* respectively. In the latter state the plasma is made more dilute and the corpuscular concentration and blood viscosity lowered. On the arterial pressure the result of such an injection is not very marked. There is a slight initial increase in the pressure, but the increase is by no means proportional to the amount of fluid injected, showing that the excess fluid is not to any large extent retained in the arterial system. On examining the pressure in the veins, however, we find a very great relative rise of pressure, and on opening the abdomen it is seen that all the veins are distended and that the liver is swollen. This is in part due to the effect of lowered viscosity of the blood, which now passes more readily through the finest vessels. The organism further prevents the rise on the arterial side by relaxing the whole system of arterioles, so that the distribution of pressures is altered, and the venous

---

[*] PEMBREY and TODD. *J. Physiol.*, 1908, **37**, *Pr.* lxvi.

[†] LEWIS. *Arch. Int. Med.*, 1932, **49**, 713.

approximates more closely to the arterial pressure (Fig. 466). This arterial dilatation and lessened viscosity augments the velocity of the blood : *e.g.* the velocity may be accelerated to six or eight times the normal rate by injecting an amount of salt solution equivalent to 50 per cent. of the total blood.

The high venous pressure causes increased diastolic filling of the ventricles, and therefore augments the output per beat. If the vagi are intact, the frequency is also reflexly raised, in consequence of the greater distension of the auricles. Thus, the work of the heart is increased in three ways—viz. by

(1) Rise of arterial pressure.
(2) Greater frequency of beat.
(3) Increased output at each beat.

These series of changes result in the relief of the vascular system. The rise of pressure in the aorta causes a reflex dilation of all the arterioles of the body, through the afferent fibres of the cardio-aortic and carotid sinus nerves. The heightened pressure in the abdominal veins and capillaries, together with the lowered colloid content of the blood, if saline is given, cause a great leakage of fluid, in the form of lymph, from the capillaries of the intestines and liver, while similar changes in the blood in the glomeruli of the kidney induce a copious secretion of urine, so that within a couple of hours after the injection of salt solution, the volume of the circulating fluid may have returned to normal.

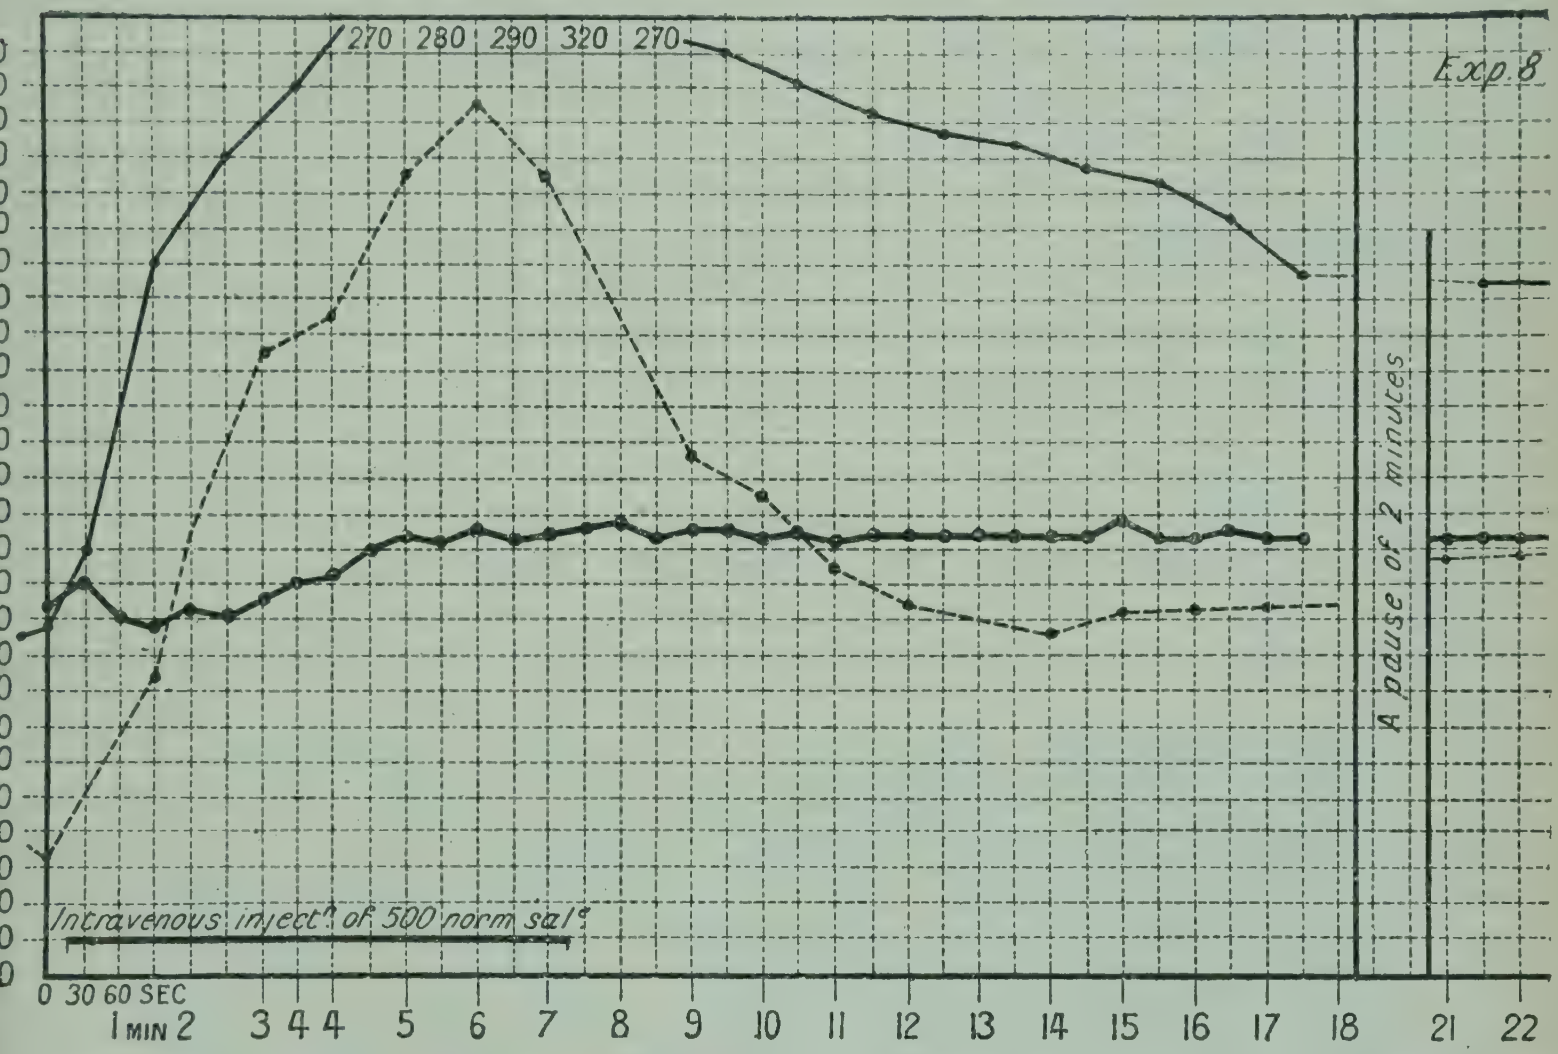

FIG. 466. Effects of Hydræmic Plethora on the Pressures in the Carotid Artery (thick line), Portal Vein (thin line), and Inferior Vena Cava (dotted line). The arterial pressure is in mm. Hg ; the venous pressures in mm. H_2O. (BAYLISS and STARLING.) *

This recovery is effected with greater difficulty if the plethora has been brought about by the injection of blood, serum, or saline containing 8 per cent. of gum arabic, since these fluids exert a colloidal osmotic pressure, and cannot escape so rapidly from the capillaries, nor be excreted unchanged by the kidneys. Hence it is easy to kill an animal by wearing out its heart, if too large quantities of blood be injected.

Hæmorrhage and Anæmia. Any diminution of the total volume of the blood, as by bleeding, would tend to lower the pressure on both sides of the system. The vasomotor centre, however, reacts to maintain the normal arterial pressure, and so the circulation through the brain, unaltered. This is attained reflexly by an excitation of the sympathetic system, which includes an outpouring of adrenaline into the blood stream. In consequence there is considerable vascular constriction, which diminishes the total capacity of the system and tends to keep the blood on the arterial side. Hence, a slight loss of blood has no influence on the arterial blood pressure, and even considerable loss may only cause a small reduction, but it causes a fall of pressure in the veins, increased respiratory movements, blanching of the skin, an increase of blood sugar, and diminished flow of urine. The heart beats more frequently, and so aids in keeping up the cardiac output.

---

* BAYLISS and STARLING. *J. Physiol.*, 1894, **16**, 159.

The compensatory vasoconstriction produced by hæmorrhage is, however, not exerted equally or indiscriminately throughout the body.* It is greatest in the skin, and next in order come the spleen, glands, and mucous membranes: the alimentary canal and organs concerned with swallowing are less affected. This is a reasonable adaptation, since if absorption were affected, as it would be if there was widespread splanchnic constriction, the lost blood could not be readily replaced.

The constriction of skin vessels after hæmorrhage persists for an hour or more after the removed blood has been replaced by transfusion. Even if more blood is restored than was lost the constriction still remains for some time, though a generalised reactive hyperæmia might have been expected.† Thus the capacity of the circulatory system is kept small and shock is warded off.

The deficiency of circulating fluid caused by bleeding is soon remedied by a transfer of fluid from the tissues to the blood. This transfer is independent of the flow of lymph from the thoracic duct into the blood, and is the direct consequence of the universal fall of capillary pressure which results from the bleeding. The abstraction of fluid from the tissues is responsible for the extreme thirst which is one result of hæmorrhage. The transfer of fluid from tissues to blood is often rapid; even during the course of a bleeding, it is found that the later samples of blood are more dilute than those obtained at the beginning. The blood also clots more rapidly. Thus the loss of fluid is replaced and further bleeding checked. After a bleeding, however, an animal has lost proteins and blood corpuscles, and these constituents of the blood are but slowly restored, the former indirectly from the food, the latter by an increased activity of the red marrow.

Physiological Alterations in the Filling of the Vascular System. The volume of blood in circulation is not quite constant, but often undergoes small and rather rapid fluctuations owing to an altered balance of loss and gain of fluid through the capillary walls. Thus, a rise of general arterial pressure, or of capillary pressure, is accompanied by concentration, and a fall by dilution, of the red corpuscles, as if to compensate. This alteration of corpuscular content is, however, sometimes in part due also to alterations in the volume of the spleen, as is explained later.

The general capacity of the vascular system is also variable. Great variations can be produced by the opening or closing of the capillary network in large masses of tissue. Among the larger vessels the most variable in capacity are the great veins; these in the human subject can hold 500 c.c. or more when distended, but usually they form baggy reservoirs of very variable content. The capacity of the venous system is very important in relation to the portal circulation, discussed in an earlier chapter. The portal vein, with its rootlets, represents a reservoir which when distended can hold about a third of the blood in the body. Partial depletion of the portal venous system is what happens, for instance, in exercise; the result is a fall of portal pressure, a rise of caval pressure, and a greatly increased venous return and cardiac output, which is due to a virtual increase in the amount of blood in the circulatory current.

† Gilding and Rous. *J. Exp. Med.*, 1929, **50**, 471.

The Spleen. The spleen may be regarded as a further special part of the portal system which, in some animals, acts especially as a reservoir for red cells. The investigations of Barcroft showed that the size of the spleen varies with physiological requirements, as such a view would anticipate. It may be extirpated without ill-effect, and occasionally is congenitally absent.

This organ is formed of a framework of connective tissue and unstriated muscular fibres, in the interstices of which is contained the *splenic pulp*. This consists of a fine fibrillar network, the meshes of which contain the cells of the splenic pulp. These are monocytes, and closely related cells giving origin to them, red cells and leucocytes. The blood from the splenic pulp is collected into large venous sinuses which run along the trabeculæ to the hilum, where they unite to form the splenic vein. These sinuses are lined by cells belonging to the reticulo-endothelial system, and called histiocytes or macrophages. They, and the monocytes of the pulp, are actively phagocytic.

The arteries to the spleen are beset in their course along the trabeculæ with small nodules of lymphoid tissue, which are known as the Malpighian follicles. These contain germinal areas in which, by division, new lymphocytes are produced, and find their way into the blood. The arteries yield a few capillaries which supply the Malpighian follicles, but for the most part open either directly into the venous sinuses, or else, by way of curious perforated sacs, into the pulp. From the pulp, the blood can pass by numerous spaces into the venous sinuses, and so into the splenic vein.

There are thus alternate paths for the circulation through the spleen; that from arteries direct to sinuses is probably free, but it is evident that the blood must meet with considerable resistance in passing through the close meshwork of the splenic pulp. This path of the circulation is, however, assisted by the occurrence of rhythmic contractions of the plain muscle forming the capsule and trabeculæ. If the spleen volume be recorded, it will be seen to be subject to a series of slow variations, each contraction and expansion lasting about a minute and recurring with great regularity (Fig. 467). In addition to these rhythmic variations in size the spleen can also alter its mean volume very greatly.

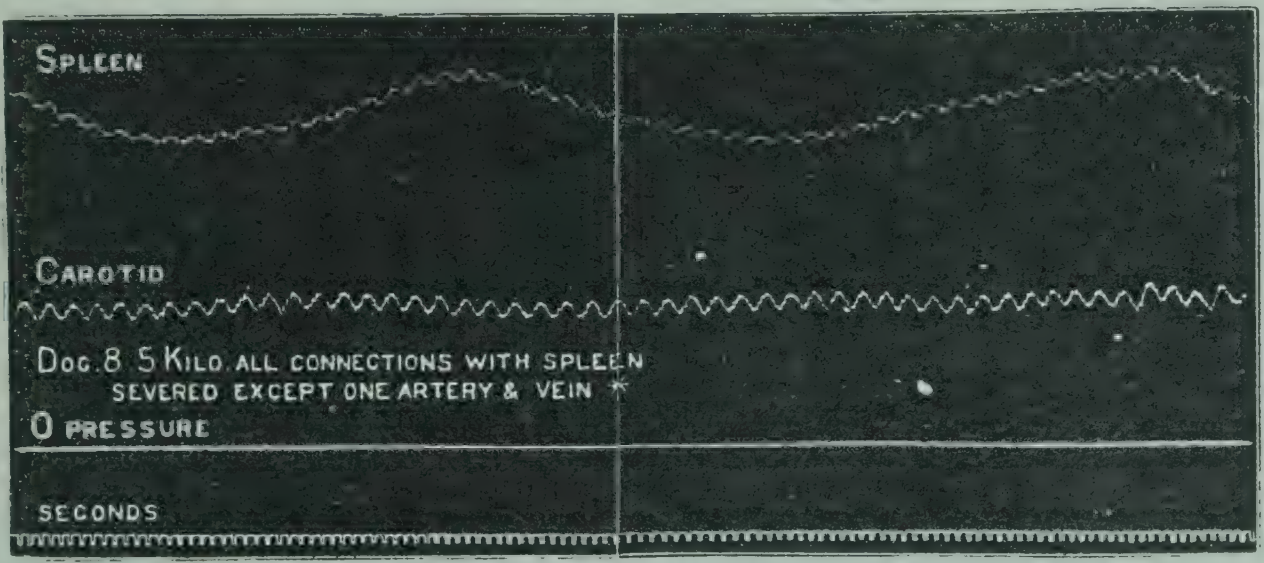

FIG. 467. Plethysmographic Tracing of Spleen (upper curve) from a Dog, showing the Spontaneous Contractions of this Organ. (Reduced from a tracing by SCHAFER.)

In spite of these rhythmic contractions, however, the normal pulp circulation is probably very sluggish. Thus when rats were slowly poisoned with carbon monoxide, it was a long time before the splenic blood, drawn by puncture, became as saturated with CO as that in the general circulation.* The alteration of the mean volume of the spleen is under the control of the nervous system, and a rapid and extensive contraction may be induced by stimulation of the splanchnic nerves,* and during asphyxia or anoxæmia.† Under these conditions, a considerable volume of blood, which may be very rich in red cells, is expressed into the general circulation.

* BARCROFT, J., and BARCROFT, H. *J. Physiol.*, 1923, **58**, 138.

FUNCTIONS OF THE SPLEEN. A consensus of opinion considers the spleen to have important functions in connection with the destruction of red blood cells. Erythrocytes of the splenic pulp are less resistant to hypotonic salt hæmolysis and more resistant to saponin hæmolysis than are the red cells of the general circulation.‡ After removal of the spleen the hypotonic fragility of the red cells is for a time reduced. Microscopic examination shows that the macrophages and monocytes of the spleen are full of particles of brown iron-free pigment (hæmofuscin) or fragments of red corpuscles,§ and we have already discussed the destruction of red corpuscles and the formation of bilirubin in these cells (p. 521). Part of the iron liberated from the disintegrated hæmoglobin is retained in the reticulo-endothelial cells in some form of combination with other substances (hæmosiderin). Probably most of the iron-containing substances are carried away by monocytes and detached reticulo-endothelial cells and temporarily stored in the liver. In some forms of anæmia (associated with hæmolytic jaundice) the reticulo-endothelial cells in the spleen are overabundant and hyperactive and the spleen is enlarged ; relief of the condition is effected by removal of the spleen, after which operation the number of red cells in the blood is increased and the bilirubinæmia is reduced.

In many cases of infectious disease, such as recurrent fever, the splenic phagocytic cells are observed towards the end of the attack to be full of the organism—a spirillum—which is the cause of the disease. In fact, these cells can take up foreign solid particles of all sorts held in suspension in the blood plasma. We must, indeed, look upon the spleen as the great blood filter, purifying the blood in its passage by taking up particles of foreign matter and effete red corpuscles. It also produces lymphocytes and monocytes, as we have already seen. In embryonic life, and in the adult in certain types of anæmia, it also produces leucocytes and red cells, just as the red marrow does.

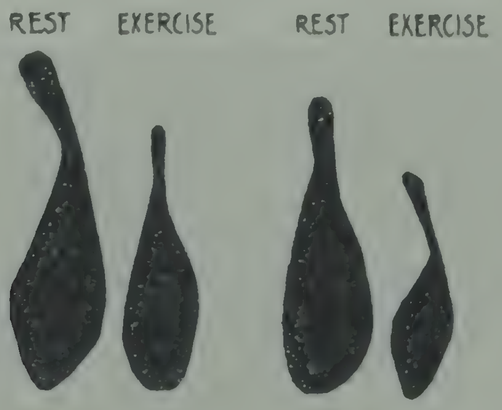

FIG. 468. Shrinkage of the Spleen of the Cat with Exercise. Reconstruction from X-ray outlines as seen from the side. (BARCROFT, *Lancet*, 1925 (I.), **208,** 319.)

Barcroft has shown that in some species the spleen may serve as a reservoir of red blood corpuscles. When there is a deficiency of hæmoglobin or of oxygen in the blood, the spleen contracts, driving some of the corpuscles it contains into the general circulation.‖ Thus it contracts in exercise, in asphyxia, after hæmorrhage, etc., to such an extent that it may be reduced to a fraction of its former size (Fig. 468). No doubt the liberation of adrenaline into the blood also greatly assists the contraction of the spleen under these conditions. After removal of the spleen, carbon monoxide is more rapidly fatal than to normal animals.* The human spleen does not store red cells in appreciable amounts.†

3. THE INFLUENCE OF GRAVITY

A physical factor which may alter the pressures in the large arteries, or large veins, is that of hydrostatic pressure, due to gravity: its effects are often considerable.

As regards the arterial system, in which the pressure is normally high, the effects of gravity are relatively less than in the venous system, and, under most circumstances, the arterial pressure is able to look after itself. In the horizontal posture the mean pressures in all the larger arteries are roughly equal: in the erect posture the pressure in, say, the femoral artery is higher than that in the brachial artery by an amount equal to that of a column of blood of the height of the vertical distance between them, say about 55 cm. (= 40 mm. Hg): in the vertical head-down position there would be the same difference, but in the opposite direction. It is well known that when we rise from the recumbent to the erect posture there is a compensatory vasoconstriction and cardio-acceleration, the effect of which is to prevent the arterial pressure from suddenly falling, especially in the head vessels. We can suppose that, on standing on the head, the reverse happens. These phenomena must play a large part in regulating the arterial pressure in the cerebral arteries of a long-necked animal, such as a giraffe, in which the fluctuation in hydrostatic pressure, if not so corrected, would be of the order of at least 150 mm. Hg when the head was moved from the ground to its highest position. The arteries have thick walls, however, and except for animals like the giraffe the differences of arterial pressure between head and feet usually presents no major problem.

With the venous system it is totally different, and altogether less simple. The veins have thin walls, are often of considerable capacity, and the blood pressure within them is so low as often to be outweighed by quite moderate hydrostatic effects. If a length of a large vein, or other thin-walled elastic tube, is filled with fluid and held vertically, it tends, in consequence of hydrostatic pressure effects, to collapse above and distend below, and this tendency is inseparable from the whole of the venous system *in situ*, though it is subject to various modifications. Consequently, when we stand erect, blood tends to drop into, and accumulate (with hæmoconcentration) in, the lower parts of the body, the veins of which become distended, while those of the head and neck become empty. In the cat, and perhaps in other species too, much blood accumulates in the liver.

This tendency is offset in a variety of ways, some of them purely physical, some physiological. Among the physical factors is one referred to on p. 641, viz., that when the blood is flowing along the veins in the same direction as the pull of gravity, the collapse of the higher parts prevents the venous pressure in those parts of the vein still further up (and hence in the capillaries) from falling below a certain level. Another help is that in many parts which are normally dependent, the adventitial coat of the vein is thickened, and the walls supported by surrounding structures, so that a limit is placed to the degree of distension which may be reached. The abdominal contents, together with the tonic state of the abdominal musculature, play an important part in preventing an accumulation of blood in the capacious abdominal venous reservoirs. A third important factor is the collaboration of valves, together with muscular movement, in continually massaging blood onwards towards the heart, as already explained (p. 640).

Among the physiological factors which help to compensate the effects of gravity on the venous system, the most important is effected through the vasomotor system. As soon as blood begins to accumulate in the large veins, the venous return to the heart is reduced, and with it the cardiac output, so that the arterial pressure begins to fall, and this is aided by the direct effect of gravity on the arterial pressure. In consequence, the carotid sinus mechanism is set in operation, and there is also a reduced blood supply to the medulla. Both of these happenings result in widespread splanchnic constriction, which reduces the capacity of the circulation, and raises the cardiac output again. If this does not suffice, the respiratory centre is soon brought into a state of increased excitability, and there is increased activity of the diaphragm, the muscles of the thoracic and abdominal walls, and the levator ani, all of which by expanding the thorax and compressing the abdomen hasten the venous return.

---

* BARCROFT *et al.* *J. Physiol.*, 1925, **60**, 79.

† PARSON *et al.* *Amer. J. Physiol.*, 1948, **155**, 239.

The effect of these various factors may be shown experimentally by observing the effect of altering the position of an animal from the horizontal to the vertical head-up position. In some animals, *e.g.* snakes, or hutch-bred rabbits, compensation is so inadequate that the effect of this change is to allow the blood supply to the head to fall to so low a level that consciousness is soon lost. In most healthy mammalia, including man, compensation is usually adequate to maintain a sufficient circulation to all parts. If a normal man tries to stand perfectly still for some time, however, as with a soldier on parade, the lack of massaging action of the leg and other muscles may lead to withdrawal into the lower veins of enough blood to cause fainting : the same thing may occur when a person first stands up after having been confined to bed for some days, particularly if the abdominal muscles have become weak and flaccid.

When an animal is suddenly brought to the head-up position, the arterial blood pressure shows a sudden fall, which is normally followed by a more or less complete recovery, sometimes to above normal. In the cat, evisceration does not prevent the fall, though it reduces the subsequent compensation ; but removal of the liver does prevent the fall.* Denervation of the carotid sinuses may reduce the extent of the return of arterial pressure, while section of the lower cervical cord, or of the splanchnics, greatly reduces the power of compensation, the arterial pressure remaining at a low level as long as the vertical posture is maintained.

All the effects of gravity can be increased by the introduction of centrifugal force, and it has been shown for instance that when animals are spun in the hind-feet-outwards position in a centrifuge, they are soon killed, because the normal compensatory mechanisms are inadequate to prevent the retention of a large fraction of the blood in the legs and lower abdomen. These facts are important in high-speed aviation. Gravity normally acts in man in a head-to-feet direction, and when an aviator performs a tight inside (*i.e.* head-to-centre) turn its effect is increased by centrifugal force, in proportion to the value of $+ g$. This puts a good deal of strain on his compensatory mechanisms, and, when the force reaches a value equal to about $+ 5\ g$., the aviator in about 4 seconds first becomes temporarily blind (" black-out "), due to insufficient blood supply to the retina, and then loses consciousness.† The effect is reduced, as might be expected, if the aviator lies or crouches in a plane parallel to the direction of the turn being made, and is somewhat diminished by the wearing of a tight abdominal binder or water-filled suit.‡

When flying inverted, or performing outside (*i.e.* head-to-circumference) loops, the normal effect of gravity is reversed ($-g$.), and this, by increasing arterial pressure in the head, introduces a danger of cerebral hæmorrhage. Up to about $-5\ g$., however, there is little risk of this, because of the support provided in the rigid cranium by the cerebro-spinal fluid,§ in which pressure also rises.

CHAPTER XXXVII

LYMPH, TISSUE FLUIDS, AND CEREBRO-SPINAL FLUID

LYMPH AND TISSUE FLUID

In all parts of the body the blood flows in capillaries with definite walls and is thus separated from the tissue-elements by these walls and by a varying thickness of tissue. In some organs, such as the liver and lung, every cell is in contact with the outer surface of some capillary; while in others, such as cartilage (which is avascular), a considerable thickness of tissue may separate any given cell from the nearest capillary. A middleman is thus needed between the blood and the tissues, and this middleman is the *tissue fluid,* which fills spaces between all the tissue elements, so that any tissue can be regarded as a sponge soaked with fluid exuded from the blood capillaries; as any substance, oxygen or foodstuff, is taken up by a tissue cell from the fluid surrounding it, this latter recoups itself at once at the expense of the blood.

Throughout these spaces we find a close network of vessels, lined and separated from the tissue spaces* by a layer of extremely thin endothelial cells, and this plexus communicates with definite channels—lymphatics, by which any excess of fluid (*lymph*) is drained off. New lymphatic vessels have been seen to grow by sprouting from previously existing lymphatics.† The lymphatics all run towards the chest, where those of the hind limbs join a large vessel (the *receptaculum chyli*), which receives the lymph from the alimentary canal, to form the *thoracic duct.* This, after receiving the *left cervical duct* from the left fore limb and the left side of the neck, opens into the venous system at the junction of the left internal jugular with the subclavian vein. A small *right lymph duct* drains the lymph from the right fore limb and right side of the chest and neck.

The lymph may be looked upon as derived from the tissue fluid which exudes from the plasma, through the capillary wall, supplies all the tissue elements, and contributes to the formation of secretions of glands; the excess of fluid (Fig. 469) passes between or through the endothelial cells into the peripheral lymphatic network, whence it is carried by lymphatic trunks into the thoracic duct, by which it is returned again to the blood.

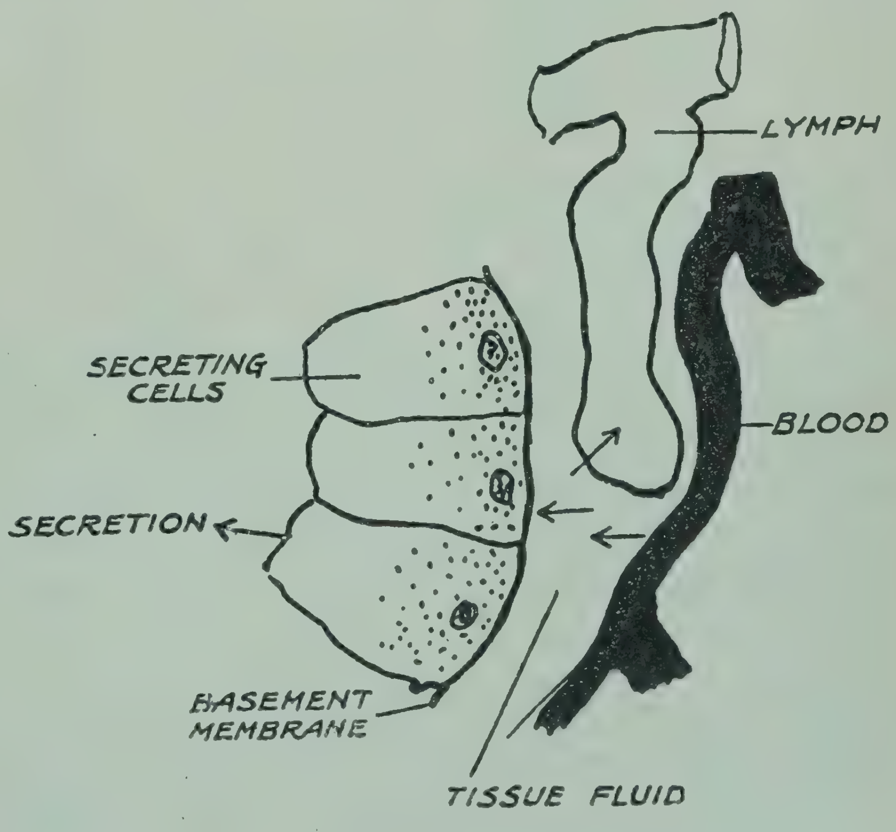

Fig. 469.

It is important, therefore, as Drinker has pointed out, always to regard the blood capillaries and the lymph system as serving together to " the same end—the maintenance of the internal environment at constant composition and volume."

---

* MacCallum. *Arch. f. Anat. u. Phys. (Anat. Abt.),* 1902, 273.
† Clark and Clark. *Amer. J. Anat.,* 1938, **62,** 59.

It is easy to obtain lymph for examination by putting a cannula into the thoracic duct, and collecting the fluid that drops from it. We may also tap in a similar way the lymphatics from the heart,* or lungs, or one of the large lymphatic trunks of the limbs †; but in the latter case we have to move the limb to induce a flow of lymph.

Properties of Lymph. Lymph obtained from the thoracic duct varies in composition and appearance. From a fasting animal the lymph is a transparent, slightly yellowish liquid. When obtained from an animal shortly after a fatty meal, it is milky from the presence of minute particles of fat absorbed from the alimentary canal, and, if the intestines be exposed, the small lymphatics are to be seen as white lines running from the intestine to the attached part of the mesentery. It is owing to this fact that these lymphatics have received the special name *lacteals*, the lymph in them, when milky, being called *chyle.*

On microscopic examination, the lymph presents lymphocytes similar to those of blood, which are, indeed, partly derived from the lymph. All the lymphatics pass at some point of their course through lymphatic glands, which add lymphocytes. Lymphocytes are also formed in all localities where we find adenoid tissue, such as the tonsils, air passages, Peyer's patches and solitary follicles, Malpighian bodies of the spleen, and thymus.

The lymph from the thoracic duct clots slowly after it has left the vessels, forming a colourless clot of fibrin. It contains about 6 per cent. of solids which are similar to those of the plasma, and are present in similar proportions except that it contains much less protein, as the following table shows :—

COMPARISON OF SERUM AND LYMPH OF DOG. (ARNOLD and MENDEL, *J. Biol. Chem.*, 1927, **72**, 189.)

	Serum g./100 c.c.	Lymph g./100 c.c.
Total solids . .	8·3	5·2
Chlorides . .	0·392	0·413
Calcium. . .	0·0104	0·0093
Phosphorus . .	0·0043	0·0036
Glucose . .	0·123	0·124
Non-protein N. .	0·0272	0·0270
Protein N. . .	0·90	0·57

Anything causing a change in composition of the blood, *e.g.* feeding with glucose, injection of insulin or parathyroid hormone, removal of the kidneys or parathyroids, etc., causes a comparable change in the composition of the lymph.‡ Liver lymph may contain more sugar than that from other parts if hepatic vein blood contains more sugar than portal vein blood.§

The Production of Lymph. The total volume of lymph in the body is no doubt variable from time to time, but is probably of about the same order as the blood volume. The volume of tissue fluid is probably similar under normal conditions, though much increased when tissues become œdematous. Investigation has shown that in the formation of tissue fluid and lymph the endothelial cells act passively, as colloidal membranes of variable permeability.

A comparison of the composition of serum, heart lymph and pericardial fluid shows that the last two resemble filtrates from the blood :—

† WHITE, FIELD and DRINKER. *Amer. J. Physiol.*, 1933, **103**, 34.

‡ HEIM, THOMSON and BARTTER. *Amer. J. Physiol.*, 1935, **113**, 548.

§ CLARK and WINTER. *J. Physiol.*, 1935, **83**, 49P.

SERUM, HEART LYMPH AND PERICARDIAL FLUID. (In round figures, from DRINKER *et al.*, 1940.)

Fluid	Total protein	Albumin/ globulin ratio	Chloride	Colloid osmotic pressure mm. H_2O	
			mg./100 c.c.		per g. protein
Serum . . .	5·95	1·01	416	234	38
Heart lymph . .	3·83	1·34	450	175	44
Pericardial fluid . .	1·63	1·14	434	59	43

The factors which are responsible for the transudation of tissue fluid may be divided into two classes—mechanical and chemical, the former depending largely on the pressure of the blood in, and the degree of active dilatation of, the vessels, and the latter chiefly on the metabolism of the cells outside the vessels.

The amount of tissue fluid formed in any given capillary area must be dependent on the capillary permeability, and on the difference of pressure between the blood in the vessels and the fluid in the tissue spaces. This latter pressure is normally extremely low (about 20 mm. H_2O),* so that we should expect that the exudation will rise and fall as the capillary pressure is increased or diminished. The chief factor is the permeability of the walls of the blood (and lymph) capillaries.† The capillary walls in the limbs and connective tissues present a considerable resistance to the filtration of lymph, and keep back the larger portion of the proteins of the blood plasma, but the intestinal capillaries are much more permeable, and in the liver we find the greatest permeability. The following table shows how variable the flow and protein content of the lymph is in different parts of the body :—

AVERAGE FLOW AND PROTEIN CONTENT OF LYMPH IN DOGS. (COURTICE, 1943.)

	Flow, c.c./hr.	Protein g./100 c.c.
Hind leg duct	1·5	1·5
Cervical duct	1·4	2·6
R. lymph duct	2·6	3·6
Thoracic duct	26·0	4·1
Blood plasma	—	5·4

As regards the interchanges of fluid and non-colloidal solutes between blood stream and tissue fluid, it seems clear that there is a sort of circulation of fluid constantly going on. The blood pressure in a capillary falls off sharply from its arterial to its venous end. Often it may be 30 to 40 mm. Hg. at the former and only 10 to 15 at the latter. At the higher pressure, which is above that of the colloidal osmotic pressure of the plasma, fluid will be passed out by ultrafiltration ; at the further end the pressure is below that of the colloid osmotic pressure of the plasma, and so at the venous end fluid will be reabsorbed into the blood stream.

If we regard the lymph as being completely separated from the tissue fluid by the delicate walls of the lymphatic capillaries, the lymph flow will similarly depend on the relation between pressure of tissue fluid and permeability of lymphatic capillary. It has been the usual practice to consider the permeability of blood and of lymph capillaries together. The justifiability of this may, however, be doubted, since there is reason to believe that the tissue fluid, even under normal conditions, and certainly under pathological ones, can vary considerably without there being any change in the rate of lymph formation.

The trivial lymph flow from a limb lymphatic is practically unaltered by changes in the arterial supply, although an increase may be obtained by active movement or by massage, or by ligaturing all the veins of the limb so as to cause a great rise of capillary pressure. It has been shown that when a person stands still in the erect posture, there is a loss of plasma, an increase in the red cell count, and a slow swelling of the legs. This indicates that fluid has passed out from the blood into the tissue spaces of the legs, the actual loss of blood volume being of the order of 300 or 400 c.c. in half an hour or less. On resuming the recumbent posture the process is reversed.

---

* WELLS *et al.* *J. Clin. Inv.*, 1938, **17**, 489.

† STARLING. *J. Physiol.*, 1894, **16**, 224.

The lymph flow from the intestines can be measured by collecting the lymph from the thoracic duct after tying off the lymphatics which leave the liver. It will be found that lowering of the capillary pressure in the intestines, by obstructing the thoracic aorta, stops the flow of lymph, whereas a rise of capillary pressure, such as that produced by ligature of the portal vein, causes a four or five fold increase of the lymph. The lymph from the intestines is relatively rich in proteins.

The effect of rise of capillary pressure on the lymph flow is still more striking in the case of the liver. If the inferior vena cava be obstructed just above the opening of the hepatic veins, there is a rise of pressure in the liver capillaries to three or four times the normal height, and a large increase in the lymph flow from the thoracic duct. The lymph may be increased eight to ten times in amount, and it contains more protein than before.*

It is possible to prepare artificial membranes, *e.g.* of collodion, which show similar gradations of permeability ; some so slightly permeable that no colloids can be forced through them (*cf.* ultrafiltration, p. 54), others allowing some colloids, *e.g.* serum albumin (of small size of particles), to pass, while retaining others, *e.g.* serum globulin, and some even allowing nearly all the colloids of the plasma to pass. When such a collodion membrane is used in an osmometer, with blood plasma inside and water or salt solution outside, the salts and other materials to which it is permeable will pass through, and the only osmotic pressure exerted will be that of the colloids which cannot permeate. Hence the higher the permeability of the membrane, the lower the effective osmotic pressure of the colloids, and the greater the amount of plasma constituents that will pass through. If the pressure inside the osmometer is raised above the osmotic pressure of the retained colloid, fluid and dissolved substances will pass out at a rate proportional to the raised pressure.

In the case of the limbs and connective tissues generally, the second factor, that of permeability, comes more into prominence. The osmotic interchanges between blood and cell, through the intermediation of the tissue fluid, are constantly going on in the normal life of the tissue, and are quite independent of the amount of fluid produced. Thus a gland cell may use up oxygen, calcium, or sugar, and create a deficit of these substances in the layer of tissue fluid immediately surrounding the cell. There is at once a disturbance of the equilibrium, and a flow of these substances from blood to tissue fluid is set up. Such changes can occur with great rapidity. We find, for instance, that if a very large amount (40 grammes) of glucose be injected into the circulation, osmotic equilibrium between blood and tissue fluid is established within half a minute of the termination of the injection. In this case, the rise of osmotic pressure caused by the injection of the sugar at once attracts water from the tissue fluid, and this in its turn from the tissue cells, while at the same time glucose is diffusing outwards from the blood, until finally the osmotic pressure inside and outside the vessels is the same. A process of this character would more usually work under normal circumstances in the reverse direction, and lead to a passage of fluid from blood to tissues and tissue spaces, and changes of this nature have often been believed to be associated with activity of the tissue cells. Every active contraction of a muscle, for instance, is attended by the breaking down of a few large molecules into a number of smaller ones, and this causes a rise of osmotic pressure in the muscle fibre and surrounding fluid, and therefore a passage of fluid from blood to tissue. It is certain, however, that much of the increased lymph flow from a limb during contraction of its muscles is due to the mechanical effect of the movement in accelerating lymph flow, so that the factors involved are complex.

---

* STARLING. *J. Physiol.*, 1895, **19**, 15.

The lymph flow from the heart shows a very close relationship to the amount of work the organ is doing: if that is increased the lymph flow is accelerated, and the same happens if the oxygen saturation of the circulating blood is reduced. The evidence of experiment on secreting glands is conflicting, for while several early workers claimed to have obtained an increase of lymph flow from the submaxillary gland when caused to secrete by chorda stimulation, others, more recently * have found no change in the lymph flow. This might be due to the fact that, although an increased amount of tissue fluid is exuded from the capillaries, the excess is all passed on into the secretion; against this explanation, however, is the further fact that if we paralyse the gland cells by means of atropine, the active flushing of the gland, which accompanies activity, produces little, if any, increase in the lymph flow from the gland.

When we speak of the permeability of the blood "capillaries" we should strictly include the smallest arterioles and venules with them. In muscle, where observations are easily made, the walls of the arterioles have been shown † to be slightly permeable, and those of the venules easily permeable, to molecules of dyestuffs which are probably larger than glucose molecules. In the capillaries proper, there is evidence that the permeability increases, as the capillary pressure declines, in passing from arteriole to venule. When we remember that the muscle capillary is a long one, the advantage of this graded permeability is evident, for if the vessel were equally permeable throughout its length, the tissue near the venous end of it would have less opportunity to receive nutrient material or get rid of its waste products, because all the advantage of first choice would lie with the tissue at the arterial end.

It is probable that the permeability of the endothelium is also increased when there is active dilatation of the capillaries, as happens when an organ becomes active. Further, the relative insusceptibility of the limb capillaries to pressure holds only for the absolutely normal capillary. Lowering of the oxygen pressure of the blood increases the lymph flow from almost any organ, *e.g.* heart, lung or limb. Any factor which leads to impaired nutrition of the vascular wall, such as the presence of poisons in the blood or in the surrounding tissues, scalding or freezing, increases its permeability. Under such conditions, the limb capillary reacts to changes of pressure like a liver capillary, the slightest increase of pressure causing an appreciable increase in the production of tissue fluid. As soon as the permeability of the capillary wall is increased to such an extent that the plasma proteins pass through, then the osmotic pressure of the plasma proteins ceases to be an effective force working against exudation, which then continues even at the lowest capillary pressures. This increased production may be too great to be carried off by the lymphatic channels, so that the exuded fluid stays in the tissue spaces, distending them, and causing the condition known as *œdema* or dropsy. In the lungs, *e.g.* after capillary damage by inhaled phosgene, the capillaries become freely permeable and œdema fluid of high protein content fills up the alveoli and causes death.

Lymphagogues.‡ Among the substances which have a direct action on the vessel wall are those (*e.g.* extract of mussels, commercial peptone, etc.) called by Heidenhain lymphagogues of the first class. These, on injection into the blood stream, cause an increased flow of lymph from the thoracic duct. This is probably due simply to their deleterious action on the capillary wall, chiefly of the liver capillaries. In fact, the injection or ingestion of these bodies often gives rise to a copious eruption of nettlerash due to an increased exudation of tissue fluid into the meshes of the cutis. Histamine, which is present in most tissue extracts, has a similar effect.

‡ Starling. *J. Physiol.*, 1894, **17**, 30.

Lymphagogue action of the second class may be produced by the injection of large amounts of crystalloids, such as sodium chloride, into the circulation. In this case the lymph becomes much more dilute. The explanation of the action of these bodies is that after the injection a condition of hydræmic plethora is brought about. This increase in the total volume of the blood has two consequences; first, the colloidal osmotic pressure of the plasma proteins is lowered owing to dilution, and second, there is an increased capillary pressure (Fig. 470, A). That the action of these bodies is purely mechanical is shown by the fact that, if the rise of capillary pressure be prevented by bleeding the animal immediately before the injection, the increase in the lymph flow is also prevented (Fig. 470, B).

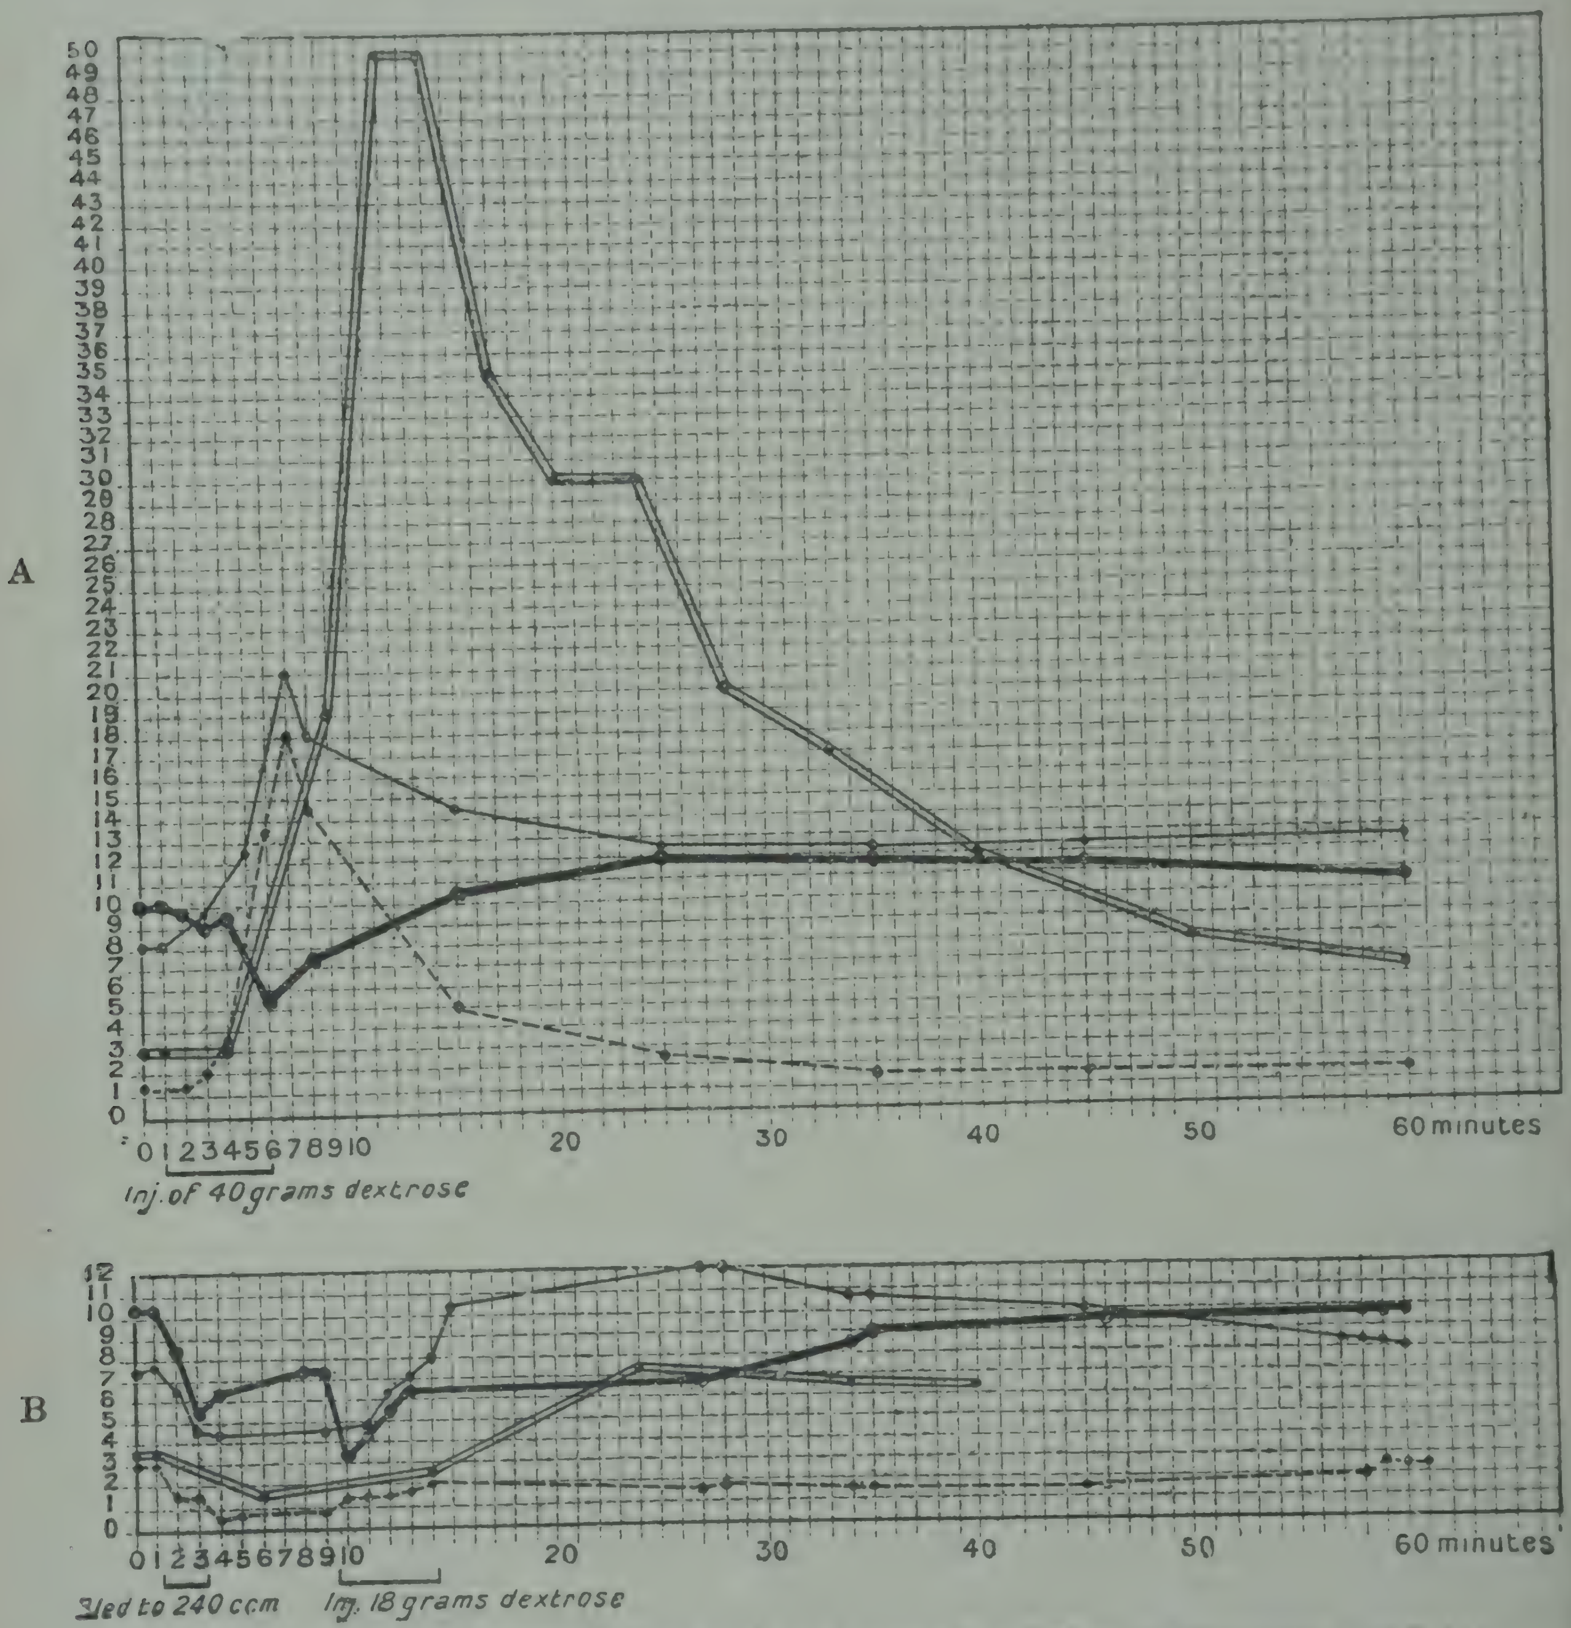

FIG. 470. Effect on Lymph Flow and on Arterial and Venous Pressures of Injection of Concentrated Solution of Glucose.

In B 240 c.c. blood was drawn from the animal before the injection. The double line = lymph flow in c.c. per ten minutes; thin line = portal vein; thick line = carotid artery; dotted line = inferior vena cava. (STARLING.)

Movement of Lymph. In the frog, the circulation of lymph is maintained by rhythmically contracting "lymph hearts." In the higher animals, the onward flow of lymph is effected partly by the pressure at which it is passed out into the lymph capillaries, and by pulsations of nearby arteries, but also to a large extent by the contractions of the skeletal muscles. In the smaller lymph radicles the pressure of lymph may attain 8 to 10 mm. of water. In the thoracic duct, at the point where it opens into the great veins of the neck, the pressure is obviously about the same as in these veins, that is to say, from — 4 to 0 mm. Hg, the negative pressure being occasioned by the aspiration of the thorax. This difference of pressure is sufficient to cause a certain amount of flow, though under normal circumstances no lymph at all flows from resting limbs. The only part of the body which gives a continuous stream of lymph during rest is the alimentary canal, the lymph of which passes into the lacteals, and thence makes its way through the thoracic duct. Movement, active or passive, of the limbs at once causes a flow of lymph from them.* Since the lymphatics are all provided with valves (Fig. 471), the effect of external pressure on them is to cause the lymph to flow in one direction only, viz. towards the thoracic duct and great veins. Hence we may look upon muscular exercise as the greatest factor in the circulation of lymph. The flow of lymph from the commencement of the thoracic duct in the abdominal cavity to the main part of it in the thoracic cavity is materially aided by the respiratory movements ; since, with every inspiration, the lacteals and abdominal part of the duct are subjected to a positive pressure, and the intrathoracic part of the duct to a negative pressure.

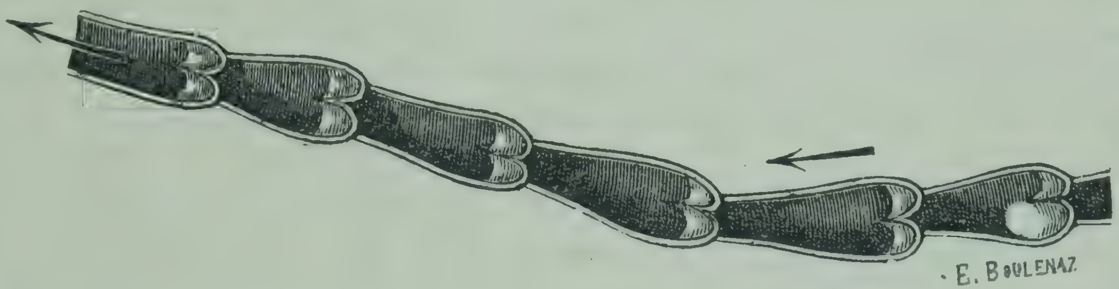

Fig. 471. A Lymphatic Vessel laid open to show Arrangement of the Valves. (Testut.)

Lymph Glands. Where a lymphatic gland is interpolated on the lymph path, a number of afferent lymph vessels enter it, and discharge the lymph into cortical lymph channels. After percolating through the gland the lymph is collected from the medullary part by a single efferent vessel ; the emergent lymph contains at least thirty times more lymphocytes than were present in the afferent stream. These latter few have escaped from the capillary blood.†

Lymphatic glands serve to collect particles and inactivate bacteria and toxins carried to them in the lymph stream (*e.g.* 99 per cent. of streptococci introduced into the lymph stream can be removed by passage through a lymph gland) : this is effected by the lymphocytes and monocytes in the gland, and it is often found that when tissues become infected with micro-organisms, the down-stream lymph glands become swollen and painful.

If a lymph gland is partially excised, the tissue regenerates, but after complete removal there is no re-formation of the gland. Owing to the ease with which new lymphatic vessels are formed, the removal of even a considerable number of lymphatic glands in an area is not usually followed by lymphatic obstruction.

Absorption from Lymph and Tissue Fluids.‡ On injecting certain coloured solutions (*e.g.* T.1824), into the connective tissues of a limb, and gently kneading the part, it is found that after a short time the fluid fills all the lymphatic channels running from the part, and we can in this way inject the lymphatics of the limb and trace their course on to the thoracic duct. If the limb is immobilised, the absorption does not occur. The same path is taken by micro-organisms as they spread in the body, even from fresh wounds, and by colloids and fine suspensions in general. Even the coarser particles of carmine or Indian ink which have been introduced in tattooing are slowly removed *viâ* the lymphatics, and deposited in lymph glands.

† Drinker and Yoffey. *Anat. Rec.*, 1939, **74**, 417.

‡ Starling and Tubby. *J. Physiol.*, 1894, **16**, 140; Starling. *J. Physiol.*, 1896, **19**, 898, **22**, *Proc.*, xxiv.

This process of lymphatic absorption is a slow one, unless aided by passive or active movements of the surrounding parts, and cannot therefore account for the rapid symptoms of poisoning which supervene within two or three minutes after the hypodermic injection of a solution of a soluble poison. The absorption of crystalloids is into the blood stream and not into the lymph, as is shown by the fact that the symptoms occur almost as quickly when all the tissues of an injected limb have been severed, with the exception of the main artery and vein. In the absorption of fluids from the pleural and peritoneal cavities, movements, such as those of respiration, have been supposed to play a part by aspirating fluids into the lymphatic capillaries. Yet, after injecting methylene blue or indigo carmine into the pleural cavity or subcutaneous tissues, the dye-stuff appears in the urine long before any trace of colour can be perceived in the lymph flowing from the thoracic duct.

Whether a substance introduced subcutaneously is absorbed into the blood stream direct, or into the lymph, is largely a question of its molecular size.* Thus, Russell viper venom, diphtheria toxin and tetanus toxin (mol. wt. $>$ 20,000), and tiger snake venom (mol. wt., 20,000) pass into the lymph, as do many colloidal dyes, while cobra venom (mol. wt. $<$ 5,000) and crystalloids generally, pass into the blood stream.

Definite, though slow, passage of fluid, of colloidal dyes, of toxins and even of bacteria has been shown to occur from the nasal passages into the cervical lymph, especially if passive movements of the head are made.

More difficulty is presented by the question of the mechanism of absorption, into the blood vessels, of the normal tissue fluids—such an absorption as we have seen to occur after loss of blood by hæmorrhage. It seems probable that this absorption depends on the small proportion of protein contained in the tissue fluid as compared with the blood plasma, and is due to the osmotic pressure of the protein. Thus, we may conceive that there is normally a balance in the capillaries between the processes of exudation and of absorption, the former being conditioned by the capillary blood pressure and the latter by the difference in protein content, and therefore of colloidal osmotic pressure, between the blood plasma and tissue fluid. A rise of capillary pressure will upset this balance in favour of transudation, and the blood will become more concentrated; whereas a fall of pressure will turn the scale in favour of absorption, and the volume of blood will be increased at the expense of the tissue fluids.

Serous Fluids. The pericardial and peritoneal fluids are apparently ultrafiltrates of plasma as regards their electrolyte content. The following shows the kind of relationship :—

AVERAGE FOR SERUM, PERICARDIAL FLUID AND PERITONEAL FLUID OF DOGS. (MAURER, WARREN and DRINKER.†)

	Serum	Pericardial Fluid	Peritoneal Fluid
Protein per cent. . .	5·93	1·82	2·56
Chloride mg./100 c.c. .	412	440	448
Ratio $\frac{\text{Cl}' \text{ serum}}{\text{Cl}' \text{ fluid}}$ . .	—	0·94	0·93

The albumin/globulin ratio, generally higher than in blood, is variable. The fluids clot on removal.

THE CEREBRO-SPINAL FLUID

Four membranes are interposed between the bony wall of the cranial cavity and the brain itself. From outside inwards, these are : (1) the periosteal layer of the dura ; (2) the meningeal layer of the dura ; (3) the arachnoid and (4) the pia. The cerebro-spinal fluid lies in the space between the arachnoid and the pia.

The dura consists of firm fibrous tissue ; its outer part represents the periosteum, and this is firmly attached to the interior of the cranium. Fibrous partitions are sent from the dura into the cavity of the cranium, thus supporting the chief parts of the brain. In the spinal canal, the bones have their own periosteum, and the meningeal dura, which is closely attached round the margins of the foramen magnum, forms a loose sheath round the spinal cord. Tubular prolongations are formed where each nerve-root emerges, and are continuous with the outer sheaths of the nerves. Where the venous sinuses occur, the two layers of the dura separate, so that the venous sinus lies between them. These sinuses are angular clefts, the chief of which lie along the attached margins of the falx cerebri and the tentorium cerebelli. The greater part of the blood which these contain drains into the internal jugular veins. In the spinal cord, these venous sinuses are replaced by plexuses of thin-walled veins, which are embedded in fat and lie on the outside of the dura. The arachnoid is a delicate, transparent membrane, covering the whole of the brain and spinal cord. Superficially it is covered by a layer of endothelial cells which bounds the sub-dural space. On its deep surface, it is connected with the pia mater by numerous fine fibres. It bridges over the inequalities in the surface of the brain, so that spaces are left which are filled with cerebro-spinal fluid. The arachnoid surrounds the cerebral and spinal nerves, and encloses them in loose sheaths as far as their points of exit from the skull or vertebral canal. On the upper surface of the brain it is very thin ; at the base it is thicker. The spinal part of the arachnoid is thin and delicate. It consists histologically of white fibrous and elastic tissue intimately blended, and contains blood vessels and a rich plexus of nerves. Wherever it comes in contact with cerebro-spinal fluid it is covered by flattened polygonal mesothelial cells.

The pia mater is a layer of connective tissue which serves to carry the blood supply to the whole surface of the brain. It closely follows all the irregularities of the latter, dipping down into the fissures and sulci of the brain. In the spinal canal, the pia sends out a series of processes, the ligamentum denticulatum. The outer extremities of these are attached to the dura mater, and help to sling the spinal cord in its dural sheath. By means of the rich blood supply conveyed by the pia mater, the brain is abundantly supplied with blood. From the circle of Willis, three main arteries on each side pass to supply separate regions of the brain.

There is a considerable space between the arachnoid and the pia covering the spinal cord, and since the cord ends at the first lumbar vertebra, whereas the dura and arachnoid extend to the second sacral vertebra, it is easy to puncture the theca and so to draw off cerebro-spinal fluid by means of a hollow needle. This simple operation, called *lumbar puncture,* is usually performed by piercing with the needle at the interval between the fourth and fifth lumbar vertebræ, and is of considerable value for diagnostic purposes as well as for the induction of " spinal anæsthesia," by the introduction of appropriate local anæsthetics into the thecal space.

THE SUB-ARACHNOID CISTERNÆ. The sub-arachnoid cavity, which is the space between the arachnoid and pia, contains the cerebro-spinal fluid and the larger blood vessels of the brain. It is traversed, as we have said, by spongy tissue consisting of delicate trabeculæ, which run from arachnoid to pia. In most parts of the cranial cavity, the space thus formed is small ; in certain parts near the base of the brain, however, the arachnoid is separated from the pia by wide intervals which communicate freely with one another and are named the sub-arachnoid cisternæ, *e.g.* the *cisterna magna,* below the cerebellum. The whole of these cavities, which contain the cerebro-spinal fluid, are lined by flattened mesothelial cells.

The Choroid Plexuses. These plexuses, which lie in the ventricles of the brain, consist of highly vascular tufts covered by ependymal cells. These peculiar masses of tissue apparently form a good deal of the cerebro-spinal fluid. Evidence of the secretory function of the choroid plexuses is partly of an histological, and partly of an experimental, nature. The cells are seen to contain granules, both eosinophil and basophil. Pilocarpine causes the protoplasm of the cell to become greatly increased in amount. The experimental evidence is that if, by blocking the foramen of Monro, one of the ventricles is prevented from getting rid of any fluid secreted into it, then hydrocephalus develops in that particular ventricle. Such a process does not take place if the choroid plexus be first removed from the ventricle.* Mechanical filtration no doubt contributes to the formation of C.S.F. Normally there is a constant flow of fluid from the lateral ventricles, so that it can be drawn off continuously by a catheter passed through the aqueduct of Sylvius into the third ventricle.†

It has been suggested that the rate of formation of cerebro-spinal fluid is accelerated by any circumstance which produces an increase of capillary pressure in the choroid plexuses. Yet occlusion of the great vein of Galen, which drains the choroid plexus, is not usually followed by hydrocephalus.‡ On the other hand, pressure may be exerted on the vein of Galen by reason of the vascular engorgement of a small body, the suprapineal arachnoid body,§ possibly under nervous control, and thereby the capillary pressure in the third and lateral ventricles, and the formation of C.S.F., may be increased.

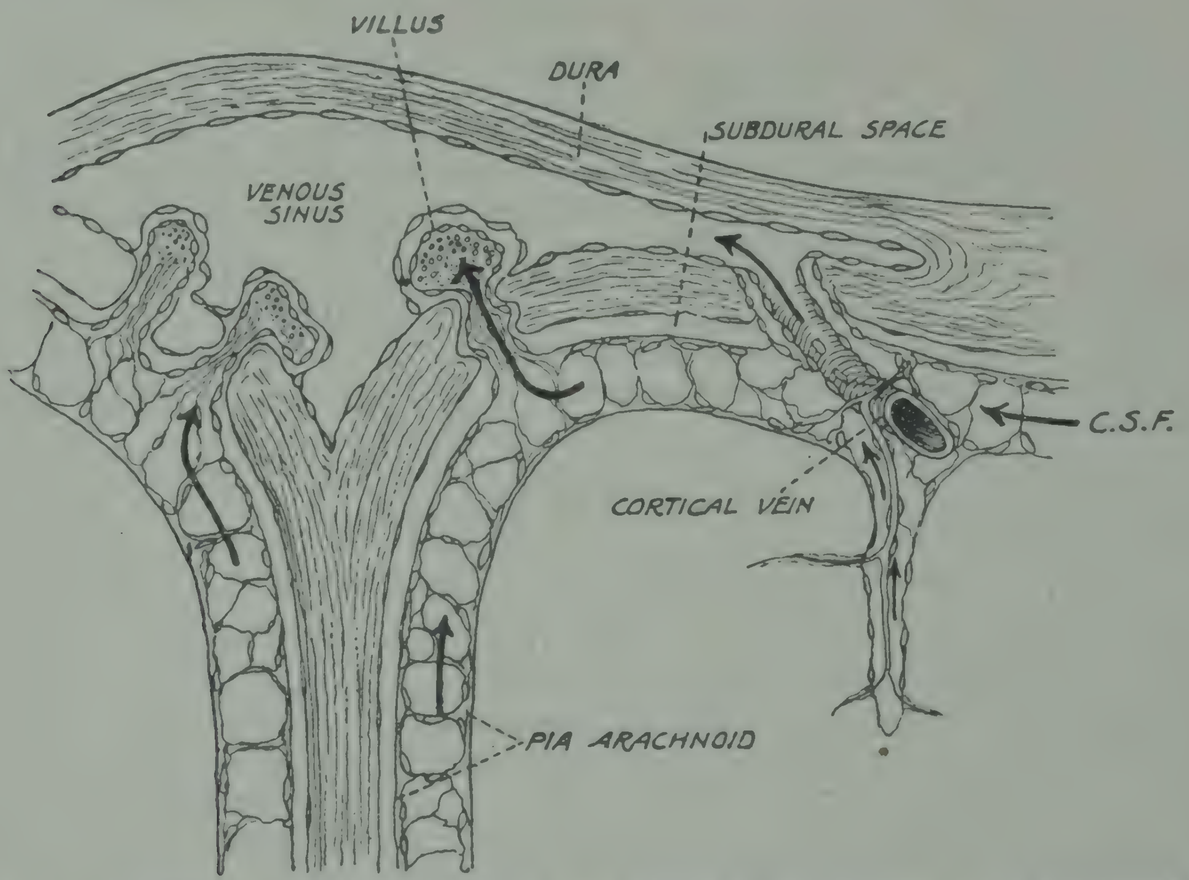

Fig. 472. Diagram of Relations of Sub-arachnoid Space to Arachnoid Villi, Cortical Veins, and Venous Sinus. (After Weed and Cushing.)

The Arachnoid Villi. These are minute processes of the arachnoid which project into the venous sinuses. Where these projections occur, the dura mater is interrupted. The processes themselves are lined by two layers of cells. Externally they are covered by the endothelium of the venous sinuses, and internally by the mesothelial cells of the arachnoid mater. They are present in most animals, as well as in men of all ages, are present in most of the cerebral sinuses, and are occasionally found penetrating the dura in other regions.

The Perivascular Spaces. Surrounding each of the blood vessels which penetrates into the surface of the central nervous system, is a sleeve formed of mesothelial cells. These tubes are called perivascular spaces. Thus a path is left clear for fluid to escape from the cell spaces inside the brain substance into the cerebro-spinal space. If these perivascular channels are followed inwards, they terminate in innumerable spaces, called perineuronal spaces, in which lie the nerve cells.

‡ Bedford. *Brain*, 1934, **57**, 1, 255.

§ Le Gros Clark. *B.M.J.*, 1940 (i), 476.

The relations of the perivascular spaces and arachnoid villi to the cerebro-spinal fluid and the blood are shown in Fig. 472.

The Cerebro-spinal Fluid. The chemical composition of this fluid is rather like that of lymph. Its specific gravity is about 1005. It contains salts, glucose and a little protein. Urea and creatinine are present in small amounts. Although at first sight the cerebro-spinal fluid might appear to be an ultra-filtrate or a dialysate of blood plasma, the balance of opinion seems to be that in its detailed composition it differs materially from those and must be regarded as a true secretion. Its total quantity in man is about 150 c.c. Its pressure inside the cranial cavity is about 100 mm. of water in recumbent subjects, but varies with posture ; usually it is definitely higher than the venous pressure in the torcula ; in the erect posture it may be below the atmospheric pressure. In disease, changes in the chemical composition and cells of the cerebro-spinal fluid may take place.

Circulation of Cerebro-spinal Fluid. This originates from two sources, the choroid plexuses in the ventricles, and the perivascular spaces found in relationship with the vessels, especially the arterial capillaries of the pia. It flows from the lateral ventricles by way of the foramen of Monro into the third ventricle, and thence, by the aqueduct of Sylvius, it reaches the fourth ventricle, from which it escapes, by way of the foramina of Majendie and Luschka, into the subarachnoid space. Having originated in this manner, the cerebro-spinal fluid passes slowly towards the convexity of the cerebrum to reach the arachnoid villi, through the walls of which it filters into the venous sinuses. That this is the normal direction taken by the circulation has been amply proved by Weed.* He injected into the lumbar subarachnoid space in animals a mixture of potassium ferrocyanide and ferric ammonium citrate, and, after an interval of several hours, fixed the entire brain in an acid fixative by which Prussian blue was precipitated wherever the mixture had travelled. The coloured precipitate was found all along the subarachnoid space and thence through the arachnoidal villi into the venous sinuses. There is no reason to suppose that the drainage is anything more than a filtration of the cerebro-spinal fluid from the subarachnoid space, where its pressure is higher, into the venous sinus, where its pressure is lower.

Under certain circumstances, it is possible to reverse the normal direction of flow. Instead of cerebro-spinal fluid being produced in the peri-vascular spaces, as is normally the case, in cerebral anæmia the spaces may be widely dilated and absorption of cerebro-spinal fluid may take place there, presumably into the capillaries and veins. Hence, if the ferrocyanide mixture be injected under these conditions, staining of the perivascular spaces, and even of the perineuronal spaces, results. A similar result follows after the intravenous injection of hypertonic salt solutions,† by which water is rapidly abstracted from the brain tissue as well as from the cerebro-spinal fluid, by way of the perivascular spaces. Owing to the rapid osmotic removal of water, the brain also shrinks appreciably, a fact which has been utilised in the performance of surgical operations on the brain, parts of which become much more readily accessible after a preliminary injection of strong salt solution. The total volume of cerebro-spinal fluid is augmented to keep pace with the shrinkage of the brain.

That there is some drainage of the cerebro-spinal fluid into lymphatics is suggested by the fact that if a colloidal dye is injected into the subdural space, dye very soon appears in the cervical lymph ducts.

CHAPTER XXXVIII

THE DEFENCE OF THE ORGANISM AGAINST INFECTION

THE CELLULAR MECHANISMS OF DEFENCE

INVASION of a higher animal or plant by some lower organism is fraught with danger to the host. There are four types of lower organism against which defence is needed, viz. *viruses* (*e.g.* measles, small-pox), *bacteria* (*e.g.* tetanus, diphtheria), *moulds* (*e.g.* ringworm), and *protozoa* (*e.g.* malaria, amœbic dysentery).

The prevention of infection is of course the function of the epithelial covering, either of the skin, or of the surface of the gut. Protection here may be of a physical or chemical character. The cells may secrete a horny or chitinous layer, which presents a mechanical obstruction to the entry of bacteria. They may secrete mucin, which entangles invading micro-organisms, or they may secrete substances which actually kill such organisms. Thus, infection of the eyes is prevented by the presence, in the tears, of an enzyme, *lysozyme* * which is extremely potent in destroying most airborne organisms ; the same enzyme is also present in the mucus of the respiratory tracts, uterine cervix, etc., in skin, and indeed in most tissues.

When a micro-organism has obtained entrance through a wound, the task of dealing with the invader becomes the office of a special type of cell called a *phagocyte*, and the whole process by which particulate foreign material, or the animal's own dead tissues are got rid of, is spoken of as *phagocytosis*. It may be studied in its simplest form by injuring some tissue which is free from blood vessels. Thus, the tail fin of an embryonic axolotl may be cauterised with silver nitrate ; a certain number of cells are destroyed, and the dead tissue thereupon is treated as a foreign body. As a result, the wandering cells or histiocytes (macrophages) move from the surrounding tissues towards the seat of the injury, and the day after the injury has been inflicted, a collection of these macrophages can be seen, many of which contain débris of the destroyed tissue, which they have taken up. The cells finally wander away from the part, and the destruction is made good by the proliferation of the fibroblasts and of the epithelium immediately adjoining the injury.

Inflammation. It is evident that the accumulation of cells for the defence of the organism against invading microbes will be much more effective if the blood vessels participate in the process, so that, by their means, the phagocytic resources of all parts of the body can be drawn upon to ward off a localised attack. The process of phagocytosis thus, in the higher animals, becomes merged into the more complex series of phenomena to which the term "*inflammation*" has been applied. This process can be studied by observing the effects of slight injury to some vascular transparent part of the body, *e.g.* the frog's tongue or mesentery, or the web of the frog's foot. For this purpose a small piece of the skin of the frog's web may be snipped off with fine curved scissors, the section being sufficiently deep to remove the skin without causing hæmorrhage. The first effect noticed in the immediate neighbourhood of the injury is a dilatation of the vessels, especially of the venules, and an acceleration of the blood flow. In the course of an hour, the capillaries also become dilated, and many capillary channels, previously invisible, are now occupied with blood. In some instances, in higher animals, new capillaries have been observed, under the microscope, to grow out from other capillaries, towards the area of inflammation. Through the dilated capillaries there is a rapid blood stream, the corpuscles occupying the axis of the vessel, so that there is a periaxial layer of plasma. A little later, this acceleration gives place to a slowing of the blood stream, and simultaneously the leucocytes of the blood are seen to be adherent to the capillary wall. Apparently the latter becomes what we may call "sticky," the effect of the stickiness being to increase the resistance to the passage of the blood through the vessel, and also to cause the adhesion of the leucocytes to the wall. As the current becomes still slower, the distinction between axial and peripheral streams disappears. The corpuscles are now closely packed together, the white corpuscles being predominant at the margins of the capillary, where they form a lining to the vessel (Fig. 473). The next stage is the emigration of the leucocytes. These may be observed to thrust a process through the vessel wall (according to Arnold this process of emigration always occurs through the stigmata, *i.e.* the points where the endothelial cells come in contact—Fig. 474). The prolongation enlarges on the outer side of the vessel, while the portion of the leucocyte within the vessel becomes smaller, so that finally the whole leucocyte flows through, and lies in the tissue spaces outside the capillary.

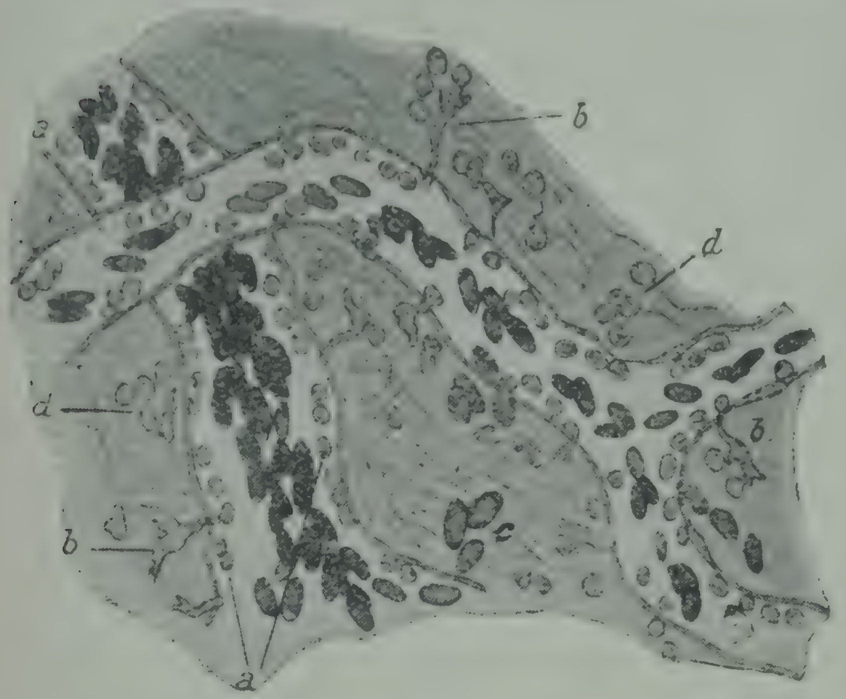

FIG. 473. Inflamed Mesentery of Frog, to show margination of leucocytes in the inflamed capillaries, *a*; migration of leucocytes, *b*; escape of red corpuscles, *c*; accumulation of leucocytes outside the capillaries, *d*.
(From ADAMI after RIBBERT.)

In the course of five or six hours, all the capillaries and small veins in the neighbourhood of the injury may show a crowd of polymorphonuclear leucocytes along their outer surfaces. In addition, there is a migration of certain tissue cells, viz. fibroblasts and histiocytes, to the affected place; later, there is often a further emigration from the blood of histiocytes and of lymphocytes. Of these various cells, the polymorphonuclear leucocytes and the histiocytes are phagocytic, and help to remove invading particles or organisms, and also later to remove the tissue injured by the primary lesion. As soon as this is effected, repair of the injured tissue occurs by a proliferation of the fibroblasts and the epithelium, while the leucocytes are destroyed by macrophages.

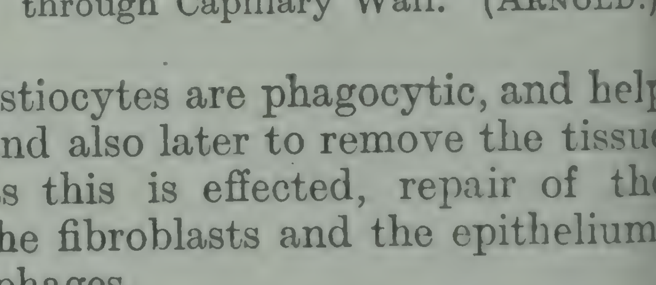

FIG. 474. Emigration of Leucocytes through Capillary Wall. (ARNOLD.)

Inflammation in warm-blooded animals always gives rise to dilatation of vessels and increased vascularity of the part, to alteration of the vessel wall and therefore to increased effusion of fluid. There are warmth and redness of the part from the vascular dilatation, swelling from the effusion of tissue fluid, and very often, as a result of the injury or the swelling and the consequent involvement of sensory nerves, pain. The four cardinal symptoms of inflammation, namely, *rubor*, *calor*, *turgor* and *dolor*, which have been described for generations as typical of this condition, naturally leave out of account the phenomenon of phagocytosis round the seat of injury with the objects of removing injured tissue, of destroying micro-organisms, of protecting the body from general infection, and of preparing the way for reintegration of tissue.

The essential phagocytic character of the inflammatory process is clearly shown if the primary lesion be attended with infection. Thus, if a small quantity of a culture of staphylococcus be injected into the subcutaneous tissue of the rabbit, the vessels surrounding the point of injection may, within four hours, be found densely filled with corpuscles. In ten hours' time the leucocytes are present in large numbers outside the vessels, while the injected cocci have spread for some distance along the lymphatic spaces and, while still partly free, have been to a large extent ingested by the leucocytes. In twenty hours' time the connective tissue fibrils at the point of injection are found to be widely separated by the aggregation of phagocytes. In forty-eight hours' time a well-defined abscess is produced. At the centre of this, all traces of previous connective tissue have disappeared and its place has been taken by *pus*, *i.e.* a mass of leucocytes, many of them dead and in a state of degeneration, mingled with staphylococci, partly within, partly outside the cells. The margin of the abscess is formed by connective tissue infiltrated with living macrophages. A certain number of cocci are to be seen free in the tissue outside this layer, but in the course of a day or two these free cocci disappear, and there is thus a continuous layer of phagocytes surrounding the abscess cavity, and preventing any further invasion of the body as a whole from the seat of infection. The abscess subsequently discharges on to the exterior by a process of necrosis of the overlying skin, and regeneration of tissue takes place in the same manner as after the more trivial injury.

We have abundant evidence to show that the essential factor in this aggregation of leucocytes is their chemical sensibility, and that the phenomenon is simply one of *chemotaxis*. A capillary glass tube containing a suspension of dead micrococci, or peptone, if introduced into the anterior chamber of the eye or into the subcutaneous tissue, is found after a short time to be full of leucocytes. The positive chemotactic influence exerted by any given species of pathogenic bacterium is roughly inversely proportional to its virulence. A culture lacking in virulence may cause a very pronounced aggregation of leucocytes which speedily destroy the micro-organism, whereas if a culture of a more virulent variety of the same microbe be injected, there may be all the signs of inflammation, swelling, and large effusion of fluid, though the tissues may contain very few leucocytes. Under the circumstances, the micro-organism rapidly proliferates and spreads from the seat of the lesion, giving rise finally to general infection. Usually, however, when bacteria enter the blood stream, they are rapidly removed by fixed histiocytes of liver and spleen, by polymorphonuclear cells in the blood, and by macrophages in the lungs.

The increase in capillary permeability and the chemotactic action on leucocytes appear to be due to the presence of a crystalloid substance formed in the tissues, and to which Menkin has given the name *leukotaxin;* it is probably a polypeptide.* It can be extracted from inflammatory exudate from which the cells have been removed. Such an exudate can be obtained from the peritoneal cavity after injection into it of turpentine. Injection of leukotaxin reproduces many of the phenomena of inflammation, *e.g.* increased permeability of capillaries, and migration of polymorphs, and, later, of macrophages. The local effect on capillaries can be strikingly shown by giving an intracutaneous injection on the rabbit's abdomen, followed by an intravenous injection of trypan blue. Around the site of leukotaxin injection the skin speedily turns blue, but remains unchanged round the site of a control injection of saline.

There is no doubt that, in all active inflammations, the polymorphonuclear leucocyte is the form which is attracted first, and in largest numbers, to the seat of injury. It is the characteristic cell from which pus is formed, and is actively phagocytic. It has nothing to do with the regeneration of the destroyed tissue. The eosinophile corpuscle is also present at an early stage around the inflammatory focus, but is never present in numbers at all comparable with those of the polymorphonuclear leucocyte. It is especially abundant in chronic inflammations of certain tissues, such as the skin, but is rarely seen to ingest bacteria, and therefore cannot be spoken of as phagocytic. The lymphocytes predominate in certain chronic inflammations, especially in those caused by the tubercle bacillus. They do not ingest bacteria. The histogenous wandering cells (macrophages) appear in the inflammatory area at a later period than the polymorphonuclear and eosinophile cells. They are actively phagocytic and motile. As a rule, their phagocytic properties are exerted, not on bacteria, but on other cells and cell *débris*. After an acute inflammation, their chief office is to clear away the remains of the polymorphonuclear leucocytes and dead tissues, so as to prepare the way for subsequent regeneration. The fibroblasts are connective tissue cells, and it is held by some investigators that they can be converted into macrophages, and *vice versâ*. It is, however, difficult to be certain whether the wandering and the fixed connective tissue corpuscles are of identical or of different origin. In the process of repair, the fibroblasts are converted into fibrous, or scar, tissue. We thus see that several types of the wandering cells of mesodermal origin, which take part in inflammation, do not destroy invading organisms by the process of ingestion. Yet the part played by such cells in the defence of the organism is no less important than that of the actively phagocytic cells.

* Cullumbine and Rydon. *Br. J. Exp. Path.*, 1946, 27, 33.

Leucocytes are able to destroy bacteria, not only by the process of intracellular digestion, but also by the excretion, into the surrounding body-fluids, of substances which have a deleterious influence on bacteria. Thus, normal blood serum is found to have a strong destructive influence on most species of bacteria, whether pathogenic or not. Since this property is not shared to anything like the same extent by the blood plasma, it may be ascribed to changes in the leucocytes in the process of clotting and the consequent liberation of bactericidal substances.

Many species of pathogenic bacteria cannot infect the animal as a whole. These, nevertheless, may multiply on the surface of the body, or in an abscess cavity, and lead to the death of the host, in consequence of the production by the bacteria of soluble *toxins*, which are absorbed into the blood stream. Examples of such micro-organisms are those which are associated with tetanus and diphtheria. There must be other mechanisms at the disposal of the body for the neutralisation of these toxins. The protection of the body against destruction by bacterial toxins involves in fact a whole series of chemical mechanisms, of equal importance with the phagocytic mechanism.

THE CHEMICAL MECHANISMS OF DEFENCE

Infection and Immunity. All infectious diseases are caused by the agency of micro-organisms. The greater number of these are bacteria or viruses, a certain number must be classed with the yeasts, while others are protozoal in character.

In the protozoal diseases, *e.g.*, malaria, the micro-organisms exist for the greater part as intracellular parasites. One attack of the disease does not as a rule confer immunity, and the treatment has to be sought along the lines of medication by drugs, which will either directly destroy the infecting agent, or enable the tissue to combat it.

The infections due to the viruses are in many ways similar to those induced by bacteria, but in this case the causative " organism " is a substance which can pass through the pores of the finest filter, and is invisible under the microscope. Viruses are proteins of enzyme-like properties ; some have been crystallised, and shown to possess spherical or rod-like molecules, visible by electron microscopy : they cannot be cultivated except in living tissues,[*] whereas the bacterial micro-organisms can usually be cultivated on artificia media outside the body.

---

[*] STEINHARD and LAMBERT. *J. Infect. Dis.*, 1914, **14**, 87 ; MAITLAND and MAITLAND *Lancet*, 1928 ii., 596.

It is especially in the class of diseases due to bacteria, that the organism has developed chemical mechanisms of defence. The diseases due to bacteria include diphtheria, tetanus, tubercle, anthrax, typhoid and many others. In these diseases we have to deal with a number of phenomena more or less common to all. The infection in each case is due to the actual transference of the specific organism from one animal to another. After the micro-organism has attained entrance into the system there is a period of incubation before the disease is manifest. When this occurs, the specific microbe is to be found in large quantities either in the blood or in the tissues of the body. The disease is generally characterised by fever and often by local lesions, such as the intestinal ulcers of typhoid, or the glandular swellings of bubonic plague. The micro-organisms may develop in the animal until its death, or the disease may terminate in recovery and the total disappearance of the microbes from the body. Some animals or individuals are naturally immune to particular diseases, *e.g.* dogs to typhoid, and this is called *natural congenital immunity*. In other cases, it is found that, after recovery, the patient cannot be reinfected by the bacterium which was the cause of the disease, and this condition, called *natural acquired immunity*, may last as long as the patient lives.

Toxins. One class, of which the diphtheria and tetanus bacilli are examples, secrete into the surrounding culture-fluid substances, which, when injected into animals, act as virulent poisons. The other class of bacteria do not form such extracellular toxins, but in their case it is found that, if the bodies of the bacilli be broken up, the injection of the contents of the bacteria is attended with poisonous effects. The bacteria may be thus classified according as they produce *extracellular* or *intracellular toxins.*

We may first deal with the manner in which the body reacts to the exotoxins. If a culture of diphtheria or tetanus bacilli be filtered, the clear filtrate free from bacilli is found to exercise as poisonous results as if the culture of the living bacilli had itself been employed. The toxins contained in these fluids are extremely potent. Thus five-millionths of a gramme of dried tetanus toxin is a fatal dose for a mouse, and 0·00023 g. would kill a man; the pure toxins, which have never been isolated, must be much more powerful. The toxin is an unstable body, and is destroyed by heating to 65° C. The nature of toxins is not known, though they are probably proteins. Similar toxins are widely distributed. Thus they form the active constituent of snake venom and of the poison of scorpions and spiders. They also occur in the seeds of castor oil and of jequirity, the toxins of which are proteins, known respectively as *ricin* and *abrin.* There is a great variability in the reaction of different animals to these toxins. To the poison of tetanus, the rabbit is, weight for weight, two thousand times, and the hen twenty thousand times, more resistant than the guinea-pig. A certain time is necessary after the introduction of the toxin before its effects are displayed. There is a striking difference in this respect between the action of these complex bodies and the action of crystalloid drugs, such as strychnine. This time cannot be reduced beyond a certain limit, however much toxin be injected. Thus, a lethal dose of diphtheria toxin kills a guinea-pig in fifteen hours. If ninety thousand lethal doses be injected into a guinea-pig, it is not possible to reduce the time of survival below twelve hours. Another characteristic of these toxins is the specificity of their action. One kind of toxin may act chiefly on the central nervous system, another on the peripheral nerves, another on the red blood corpuscles. Associated with this specific action is the actual combination which occurs between the toxin and the organ on which it exerts its effect. Thus, tetanus toxin has a specific affinity for the central nervous system, and may be removed from a solution by shaking the latter with an emulsion of the brain of a susceptible animal, such as a guinea-pig, but not with one of the brain of an animal of a non-susceptible species.

Antitoxins. In spite of the excessively lethal character of these toxins, it is possible to render an animal immune to their action. If a dose of diphtheria or tetanus toxin which is smaller than the fatal dose be injected into an animal, the latter shows signs of injury, from which it recovers. When recovery is complete, it is found that three or four times the fatal dose may be injected without producing any evil effects ; and this process of injection of toxin may be repeated in continually increasing doses, until the animal may finally be able to withstand a dose one hundred thousand times as large as that which would have been fatal to it in the first instance. This is a condition called *active artificial immunity*, and it is found that the blood serum of the immunised animal has the power of neutralising the toxin. Thus, if blood serum from a horse which has been treated with large doses of diphtheria toxin be mixed with an equal quantity of the toxin itself, the mixture may be injected into susceptible animals without the production of any effect. It is possible in this way to get a serum, 1 c.c. of which will neutralise many fatal doses of the toxin ; further, this antitoxic serum may be injected into a susceptible animal and then confers *passive artificial immunity* on the latter, or it may be injected into a diseased animal and so used as a curative agent. *Antitoxins* thus play a great part in therapeutics, especially of tetanus and diphtheria. In the case of tetanus, the toxin appears to be absorbed by the motor end plates, from which it diffuses along the motor axons to reach the ventral horn cells of the cord. By the time that it has arrived at the central nervous system, and the spasms typical of tetanus have broken out, the toxin is already so firmly bound to the reacting tissue that the injection of antitoxin into the blood stream has little or no effect on the course of the disorder. The use of the tetanus antitoxin is, therefore, chiefly as a prophylactic agent.

If we define a unit of toxin as that amount which possesses a certain power, *e.g.* which will kill a guinea-pig in so many days, or will cause the complete hæmolysis of 1 c.c. of blood in two and a half hours, we can find the amount of anti-body which is just sufficient to neutralise this effect, and this amount of anti-body can be regarded also as one unit. If, instead of one unit of each, we take 100 units, the neutralisation is effected in the same way. The process is found, however, to be more complex when we take 100 units of toxin, or lysin, and attempt to neutralise them by the fractional addition of antitoxin. In the case of a strong acid and strong alkali, we know that if 100 c.c. of alkali are just sufficient to neutralise 100 c.c. of acid, the addition of 50 c.c. of alkali will leave half the acid unneutralised. If we try the same experiment in the case of mixtures of toxin and antitoxin, it will be found that the addition of 50 units of antitoxin will neutralise much more than half of the toxin, and the same applies to other bodies of this class. Further, 1 c.c. of antilysin exactly neutralises 1 c.c. of lysin ; but these two substances will no longer be in equilibrium when the whole is diluted up to 10 c.c. with water.

The interaction, therefore, resembles adsorption. The exact adsorption which takes place must be a function of the chemical configuration of the substance forming the surface, since otherwise it would be impossible to account for the extremely specific character of the interaction between toxins and their corresponding antitoxins. It probably depends upon the operation of such forces as electronic van der Waal's attraction, Coulomb attraction, electrical dipoles or multipoles, formation of hydrogen bonds, and other forces dealt with by physical chemistry. In any case, the antitoxin does not *destroy* the toxin, since it is possible, from an inert mixture of toxin and antitoxin, to separate toxin and anti-body once more.

THE SIDE-CHAIN THEORY. How are we to account for the production, as a result of the injection of toxins into the body, of antitoxin far transcending the amount of toxin injected ? In all the speculations on the mode of production and action of antitoxins an important part has been played by a conception put forward by Ehrlich in 1885. According to this conception, which is spoken of as the " side-chain theory," each unit of living matter consists of a centrally placed portion with a number of side chains attached to it. To these side chains, or *receptors*, various nutritive or other substances may be linked, provided their chemical configuration is of the right kind. Ehrlich regarded the toxins as possessing two side chains, one of which, by its stereomeric configuration, is peculiarly adapted to fit on to the side chains of the protoplasm which the toxin attacks, and this group is known as the *haptophore* group ; and another side chain, the *toxophore* group, which is responsible, when the toxin is once anchored, for the destructive changes wrought by the toxin on the cell of the body (Fig. 475, 2). The antitoxins are supposed to act by uniting with the haptophore group, and so preventing the susceptible protoplasm from doing so and suffering their injurious effects.

The formation of antitoxins is accounted for on this hypothesis in the following manner When a receptor of the cell is occupied by becoming attached to the haptophore group o the toxin, this side chain, is, so to speak, shut out from the normal activities of the cell. A defect is thus produced in the cell, to which the latter endeavours to adapt itself by the production of other side chains of the same character (Fig. 475, 3, 4). It may be regarded as a general rule in living tissues, that a reaction tends to be an over-reaction, so that the compensation by the cell should more than make good the defect produced by the attachment of the toxin. We thus get, not one, but a number of side chains produced, of the same character as that occupied by the toxin molecule, and therefore able also to act as receptors for the haptophore group of the toxin. These new receptor side chains, being produced in excess, were supposed by Ehrlich to be thrown off from the cell and to circulate in the body fluids (Fig. 475, 4). The fragments thus set free have a specific power of uniting with the toxin, and it is this excess of side chains, thrown off from the cell, which represents the antitoxin molecules found circulating in the blood after the injection of toxins. It will be noted that this theory, though chemical in form, is really purely biological. It does not explain the phenomena by reference to the known laws of chemistry, but is a manner of re-naming the biological phenomena, which facilitates their description and discussion and enables us to classify the very complex phenomena of immunity, though only in an imperfect fashion.

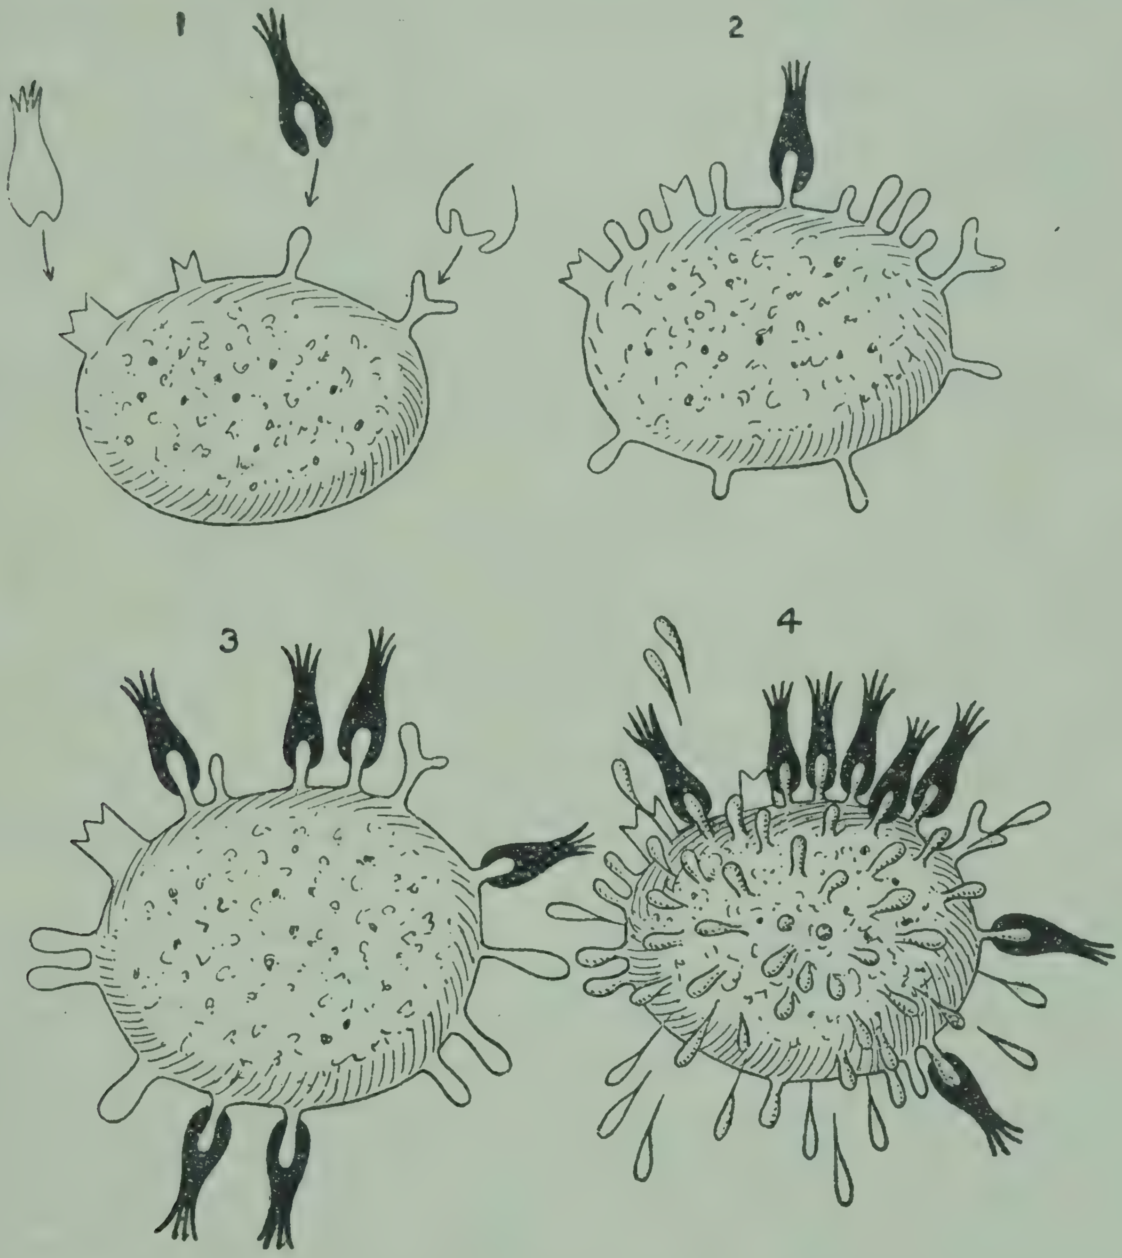

FIG. 475. Schematic Representation of Formation of Antitoxin as Side Chains of Protoplasmic Molecule. The black bodies are the toxin molecules which fit by their haptophore end on to the side chains of the cell. (EHRLICH.)

A more modern version of the hypothesis is that the antibodies are not formed in all cells of the body, but that the reticulo-endothelial cells, which are known to be active in taking up various antigenic materials, react by producing antibodies.

Antigens. The property of giving rise to anti-bodies on injection into an animal is not confined to toxins ; a large number of substances, all of them containing proteins, have the same property. All such substances are classed together as *antigens*, and are highly specific. Some proteins, *e.g.* insulin, gelatin, cannot act as antigens. Bacteria, alive or dead (and thus including endotoxins), or any animal or vegetable cells, venoms, viruses, or pure proteins derived from any of them, can act as antigens, provided they are foreign to the species of animal into which they are injected. (An exception is the protein of the crystalline lens, which can act as an antigen even for the same species.) They all give rise to the production of *specific anti-bodies*. Thus, human serum injected into a rabbit produces in a few days in the rabbit's serum a substance which will give a precipitate when mixed with human serum even in minute traces. This *precipitin* formation is specific, so that it may be used as a test to find the species of any unknown specimen of serum.

The antigenic properties of proteins may be artificially altered by the introduction of new groups: *e.g.* insulin and gelatin become antigenic when coupled with glucosidotyrosine; the resulting antibodies, however, do not react with the same antigen, but with the globulin analogue, glucosidotyrosyl-globulin.*

In a similar way, using an extract of dead bacteria, or a protein, as antigen, a specific precipitin for the bacterial extract or for the particular protein, as the case may be, develops in the blood.

A *vaccine* is such a collection of killed bacteria or virus, and is often injected into patients to stimulate the production of anti-bodies by their own tissues.

When live foreign cells, *e.g.* bacteria or red cells, have been injected, there is developed an anti-body which causes these cells, when added to the serum, to gather together or agglutinate. Typhoid fever can be diagnosed by the fact that the patient's serum causes agglutination of the bacteria from a pure typhoid culture (Widal test). The anti-body concerned is called an *agglutinin*.

The amount of an antibody formed after a single injection of an antigen varies with the quantity of antigen given, though not in direct proportion. After the injection, the antibody begins to appear in a few days, reaches a maximum about the fifteenth day, and then declines, with diminishing speed, over a period of months or years. Second doses of antigen cause earlier and larger antibody formation.

The nature of these specific anti-bodies, and the cause of their high specificity to the antigens which give rise to them, are not exactly known. They appear to be specialised serum γ-globulins, possessing specific groups which enable them to unite with the corresponding antigens. With regard to the antigens of bacteria, recent work has indicated that, while some of the specificity is attributable to proteins, the most specific immunological reactions are often associated with the presence of highly specialised polysaccharides.† These are, in fact, the "haptenes" postulated by Ehrlich. No antigenic properties are possessed by the specific polysaccharides when pure; to show such properties, a protein foreign to the reacting animal (*e.g.* one from the bacterial substance) must also be present.

Cytolysins. Normal goat's serum may be mixed with the red blood corpuscles of the sheep without any injury to the latter. If, however, washed sheep's erythrocytes be injected at intervals of a few days into a goat, the goat's serum is found to have acquired the power of rapidly agglutinating, and then of dissolving, the red blood corpuscles. A specific *hæmolysin* is said to have been produced. This hæmolytic power can be tested by mixing the serum and the washed blood corpuscles together and allowing the mixture to stand in a narrow tube. The corpuscles rapidly sink to the bottom, leaving the colourless serum above, unless hæmolysis has occurred, in which case the serum will be red.

If the hæmolytic serum be heated to 60° C., it is found to have lost its power of dissolving sheep's corpuscles. This power is at once restored if to the heated serum be added any normal blood serum, even of the sheep itself. It seems, therefore, that two substances are involved in the hæmolysis, namely, (*a*) a substance present in most normal sera, and believed to be formed by the leucocytes; it is destroyed at a temperature of 60° C. and has been called the *complement;* and (*b*) a substance which is only present in the serum as a result of the previous injection of some species of red blood corpuscle, which is resistant to the action of heat, and is called the *amboceptor*.

Apparently the amboceptor becomes attached to the red cell first, and then the complement is linked on to this and hæmolysis ensues. Thus, if a rabbit is sensitised against human red cells, and some of its serum taken and heated to 60° C., it will not now hæmolyse human red cells, because the complement has been destroyed by heat. If the human cells added to it are now removed by centrifugalisation, the addition of complement to them,

---

* CLUTTON, HARINGTON and YUILL. *Bioch. J.*, 1938, **32**, 1111.

† THOMSEN. "Antigens in the Light of Recent Investigations," 1931. (Copenhagen, Levin and Munksgaard.)

e.g. normal guinea-pig serum, causes immediate hæmolysis, whereas if complement is added to the supernatant serum removed from the red cells, no hæmolysis occurs on adding fresh human cells, because the amboceptor has all been removed by those first added.

The function of the amboceptor thus seems to be to enable the complement already present in normal serum to act upon the red blood corpuscles. We may regard the amboceptor, therefore, as having two haptophore groups, one of which anchors on to the red blood corpuscle, while the other attaches itself to the complement (Fig. 476, 7). The amboceptor *plus* the complement thus comes to resemble the toxin molecule, having a free haptophore group at one end and a toxophore group (the complement) at the other end. The reaction to the injection of the red blood corpuscles consists in the formation of the amboceptor, which is essentially the anti-body of the red blood corpuscle (Fig. 476, 8).

Similar specific anti-bodies, capable of effecting the dissolution of cells or organisms, may be produced by the injection of various species of bacteria, or of animal cells, such as leucocytes, spermatozoa, liver cells, etc., and there can be no doubt that bacteriolytic substances play a considerable part in acquired immunity.

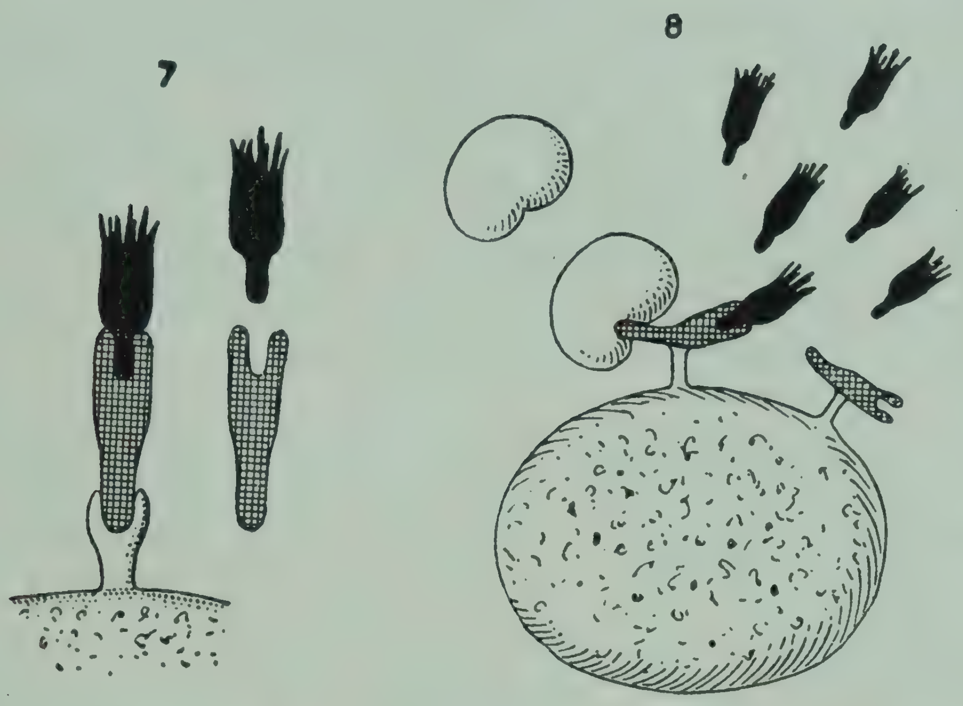

FIG. 476. Diagrams to show the relation of Amboceptor and Complement to Red Corpuscles (7) and to the Animal Cell (8). (EHRLICH.)

A mixture of red cells and specific hæmolytic amboceptor (heated immune serum) can be used as a test for the presence or absence of complement. If complement is added, hæmolysis occurs, as shown above. Based on this fact, and on the further fact that complement is fixed by the amboceptor in presence of its specific antigen, is the important *complement-fixation test* for the identification of either antigens or amboceptors. An important test related to this is the *Wassermann reaction* for syphilis; the patient's serum (= amboceptors ?) is heated to 55° C., mixed with certain lipoids (= antigens ?), and then some guinea-pig serum (complement) added. After a time, heated anti-sheep serum from a rabbit, and washed sheep corpuscles, are added, to test whether complement has been fixed or not. Hæmolysis indicates no fixation, and therefore a negative result of the test; absence of hæmolysis, a positive result.

Opsonins. In some cases the anti-bodies produced by the injection of living or dead micro-organisms do not bring about actual destruction of the bacteria, but alter them in such a way as to make them more susceptible to the action of the phagocytes. If washed white blood corpuscles be mixed with cocci, such as those found in an ordinary boil, they are found to take up the micro-organisms in considerable numbers. The numbers taken up are much increased in the presence of serum derived from an individual who has received repeated vaccine injections of the dead micrococci in question. To the substances in the serum, which thus prepare the micrococci for ingestion by the phagocytes, Wright gave the name of opsonins. The opsonic index of the leucocytes of any individual, in reference to a given species of microbe, is determined by observing the number of the microbes taken up by the leucocytes after treatment with the serum of the individual, and then comparing it with the number taken up by the same leucocytes when the bacteria have been treated with the serum of an average individual.

We thus see that immunity, whether innate or acquired, is extremely complex in character and may depend on one or more of many factors. The immunity of an animal to any given infection may be determined by the absence from his body of receptor groups for the toxin excreted by the microbe responsible for the infection, or by the fact that the receptor groups, though present, are confined to tissues on which the toxophore group can have no influence. Thus, *e.g.* an attachment of the tetanus toxin to a connective tissue cell would be without effect on the health of the body. Again, immunity may be due to the efficacy of the phagocytes, either of the fluids or of the connective tissues, in ingesting and destroying the micro-organisms, and this, as we have seen, may again be dependent on the presence in, or absence from, the body fluids of substances which, while not destroying the micro-organisms, render them more accessible to the action of the phagocytes. In those cases where the infecting organism secretes a specific toxin, the main line of defence, and the main factor in the production of immunity, is the formation of specific antitoxins to the poison in question. Finally, there may be produced, as a result of the excess of micro-organisms, substances such as the amboceptors, which render the micro-organisms susceptible to destruction by the complements or cytases normally present in the circulating fluids, and possibly themselves derived from the activity or destruction of the leucocytes and other phagocytes of the body.

In this short description we have been able to touch only upon the most salient features of the immunity problem. The question enters strictly into physiology, since, as we have seen, it involves adaptations on the part of the organism to changes in itself or in its environment.

Anaphylaxis (*v.* also p. 51). If an animal be given injections of a foreign protein, it is found that, after ten or more days, a small dose of the same antigen causes a very severe reaction, or death. This, which appears like the opposite to immunity, is called anaphylaxis. Death occurs owing to profound shock, which manifests itself differently in different species; thus in the guinea-pig death is due to asphyxia from constriction of the bronchioles. In the dog, death is due to engorgement of the liver from constriction of branches of the hepatic veins. These differences are explained by the differences in the abundance and distribution of plain muscle in different species, for in all cases generalised contraction of plain muscle is the outstanding feature of anaphylactic shock; Dale has shown that the plain muscle of a sensitised animal gives a powerful contraction when a trace of the antigen is added, even if the tissue has been previously washed free of all blood. The reaction is, therefore, due to a direct action of the antigen on the tissues, and there is much evidence in favour of the belief that the substances passed out as "precipitins" into the plasma are at a later stage absorbed by the tissue cells, and so sensitise these to the antigen. Thus, the anaphylactic sensibility is found to wax as the precipitin content of the serum wanes. In anaphylactic shock the blood coagulability is reduced or abolished; this is due to the liberation of heparin from the mast cells of the liver.[*]

The close similarity between the anaphylactic responses of different tissues in various species of animals, and the responses of those particular tissues to histamine, led to the suggestion that the phenomena of anaphylaxis were due to the liberation of histamine into the blood, and its subsequent distribution all over the body. The fact that histamine can be shown to be produced in the isolated tissues of sensitised guinea-pigs [†] gives support to the idea, but the anaphylactic response of isolated tissues discovered by Dale indicates that the histamine is locally produced. Lewis observed that the local anaphylactic response in the human skin was similar to the response to other skin injuries, and it now seems probable that the phenomena are due to the liberation, within the cells, of a histamine-like substance, in consequence of the injury produced by the union of anti-body and antigen.

Anaphylactic shock may be met with in medical practice, as when a second dose of a serum is given after a long interval. The name has also been loosely used to describe many different shock-like conditions, some of which are probably due to a direct toxic action on the vascular system, and in which there are no phenomena of antigenic sensitisation. The anaphylactic reaction is highly specific, and the antigens are invariably proteins. Benadryl, $(C_6H_5)_2CH—O—CH_2—CH_2—N(CH_3)_2$ (HCl)., competes with histamine, and is used as a drug to combat anaphylactic and allergic phenomenon.

CHAPTER XXXIX

RESPIRATION

I. THE MECHANICS OF THE RESPIRATORY MOVEMENTS

In multicellular animals tissue respiration is carried out between the internal medium, *e.g.* blood, and the individual cells ; and the use of the special organ of respiration is to bring the circulating internal medium in intimate relation, over a large area, with the surrounding air or water. In these animals we can distinguish two processes—viz. (1) the interchange of gases between the tissue cells and the surrounding fluid, " internal respiration " ; (2) the interchange of gases between the circulating fluid and the external medium, " external respiration." In most water animals the respiratory organ, the gills, presents a large surface, well supplied with blood, over which a continual stream of water is kept up.

In all air-breathing vertebrates the organs of external respiration, the lungs, contain numerous air sacs. The renewal of the air in the air sacs is effected by the movements of respiration, while a rapid circulation of blood is carried out through a fine meshwork of capillaries just underneath the surface of the sacs.

The lungs in their development grow out from the fore part of the alimentary canal into the front part of the pleural cavity. The surrounding body walls become strengthened by the formation of the ribs, so that the lungs are suspended in a bony cage-work, the thorax. Their outer surface is covered with a serous membrane, the *pleura*, which is reflected on to the wall of the thorax from the roots of the lungs, and completely lines the cavity in which they lie. The surface of the pleura facing the pleural cavity is lined with a continuous layer of flattened mesothelial cells, and is kept moist by the lymph-like pleural fluid. Thus, being attached to the thorax only where the bronchi and great vessels enter, the lungs are able to glide easily over the inner surface of the thorax, with which under normal circumstances they are in intimate contact.

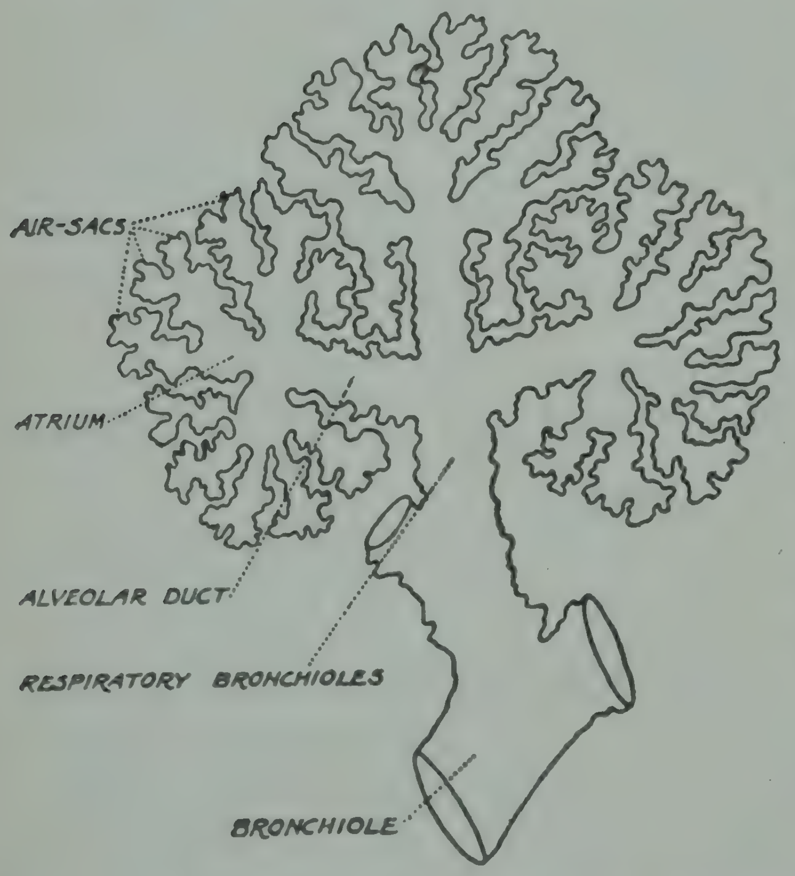

Fig. 477. Diagram of the Air-chambers derived from a Bronchiole. (After Miller.)

The trachea divides below into the two main *bronchi*, and these subdivide into primary and secondary bronchi, etc., each branch becoming smaller, although the total area of their cross-section is together greater than that of the parent tube. The terminal ramifications of the conducting airway, called *bronchioles*, open into *respiratory bronchioles*, and these branch again into *alveolar ducts*.

Confusion has arisen in the use of the terms " atria " and " infundibula," which, in any case, have no particular physiological significance ; it is proposed therefore, to omit these, and to regard the alveolar ducts as forming a branching network of tubes, opening into *alveolar sacs* or air sacs, in the walls of which are situated minute sacculations, the *alveoli*. A few alveoli also open from the walls of the ducts and respiratory bronchioles (Fig. 477).

The larger tubes are kept patent by incomplete rings of cartilage which ar reduced to irregular plates in the smaller tubes and disappear in the bronchioles The walls contain fibrous and elastic tissue throughout, while in the conductin tubes there is a muscular layer which increases down to the terminal bronchioles, where it is thickest in proportion to the other layers. Thence it continues, with the elastic tissue, to invest the respiratory portions of the lung, though much reduced in quantity, being broken up by the alveoli which are evaginated through its meshes.

The lining epithelium is ciliated and columnar in the larger tubes, changing to cubical in the respiratory bronchiole, beyond which it becomes flattened to the " pavement " type which lines the alveoli.

The walls of the airway are supplied with *arterial blood* by the *bronchial arteries*, and the respiratory parts of the lung receive venous blood from the pulmonary arteries.

The alveoli are the special respiratory parts of the lung. Their thin walls are composed of connective tissue containing a large number of elastic fibres, and are covered internally by a single layer of extremely thin, large, flattened epithelial cells. The alveoli are closely packed together, so that, in a section of the lung, an alveolus is seen to be in contact with others on all sides. The alveoli are not blind sacs, but communicate freely with adjoining alveoli by means of " vents " or stomata in their walls.* These probably serve to equalise air pressures in different alveoli, and to enable the alveoli still to be filled if the duct is occluded.

Immediately outside the pavement epithelium ramify blood-capillaries derived from the pulmonary artery. These form a close network, and the venous blood in them is in proximity to air on two sides, being separated from the air in the alveoli only by the thin endothelial cells of the capillary wall and the flattened cells lining the alveoli. It is customary to speak of this barrier between air and blood as the *alveolar membrane*, and it is through this membrane that the gaseous interchange occurs.

THE NASAL PASSAGES. The complex nasal passages are covered with a very vascular mucous membrane, by which the incoming air is warmed, and since the mucosa is endowed with mucous glands, the air is also moistened and freed from dust.

It is common knowledge that the nasal passages vary considerably from time to time as regards the ease with which they allow air to enter. Apart from a condition of œdema of the mucosa due to infection, the patency of the nasal passages is subject to change by reason of the variable engorgement of its submucous blood vessels.† The degree of patency may be estimated by blowing a constant stream of air into a nostril, and measuring the pressure of the entering stream ; if the passage is constricted, the pressure is raised, and *vice versâ*.‡ Spraying of the nasal mucosa with adrenaline constricts the vessels and lowers the resistance to air entry ; histamine has the reverse action. Exposure of the body to heat, or to infra-red rays causes closure, while short waves, or skin-cooling, opens the passages. The explanation of the phenomenon is disputed, but it appears to be due to a reflex from the skin. The following table shows the effect of various conditions on the cross-section of the nasal passage, as measured by the rhinomanometric method mentioned above, on a large number of subjects.

AVERAGE CROSS-SECTION IN MM^2 OF NASAL PASSAGES, AT PRESSURE OF 40 CM. WATER (VAN DISHOECK)

Initial cross-section	Electric fire for 10 minutes	Histamine 1 : 1000	Adrenaline 1 : 1000
20·8	16·8	10·2	25·1

The effects of stuffy rooms with central heating bears out these observations.

Respiratory Movements. A constant renewal of the air in the lungs is secured by movements of the thorax; this constitutes normal breathing. With inspiration the cavity of the thorax is enlarged, and the lungs swell up to fill the increased space. The capacity of the air passages of the lungs being thus increased, air is sucked in through the trachea. Inspiration is immediately followed by expiration, which causes diminution of the capacity of the thorax and expulsion of air. Expiration normally lasts 1·3 to 1·4 times the length of inspiration. Expiration is followed, normally without a pause, by inspiration. The number of respirations in the resting adult is commonly about 17 or 18 a minute. This is, however, much influenced by various conditions of the body and also by age. Thus a newborn child breathes about 14 times a minute, a child of five about 26 times, a man of twenty-five about 16, and of fifty about 18. The frequency is increased by any muscular effort, even that of standing. These movements are much affected by psychical activity; they are to a certain extent under the control of the will, although they can occur in an animal deprived of its cerebrum, and are normally carried out without any special act of volition. We can breathe fast or slowly at pleasure, and can even cease breathing for a time. It is impossible, however, to prolong this respiratory standstill for much more than a minute; the need of breathing becomes imperative, and against our will we are forced to breathe.

With every inspiration, the cavity of the thorax is enlarged in all dimensions, from above downwards by the contraction of the diaphragm, and in its transverse diameters by the movements of the ribs. Quiet breathing is almost entirely diaphragmatic.*

The Diaphragm consists of a central tendon which forms an arched double cupola, to the circumference of which are attached muscle fibres. The diaphragmatic muscles present two main divisions, namely, (1) the spinal or crural part, the fibres of which arise from the upper three or four lumbar vertebræ and from the arcuate ligaments, and are inserted into the posterior margin of the central tendon; and (2) the sterno-costal part, which arises by a series of digitations from the cartilages and adjoining bony parts of the lower six ribs and from the back of the ensiform process. These latter fibres pass backwards as they ascend. In the cavity of the larger dome on the right side lies the liver, while the smaller dome on the left side is occupied by the spleen and stomach (Fig. 478). These viscera, in the normal condition, are pressed against the under surface of the diaphragm by the elasticity of the abdominal walls. The central part of the diaphragm is thus pressed up into the chest, partly by the intra-abdominal pressure, and partly by the elastic traction of the extended lungs. The upper surface of the central tendon is united to the pericardium. This part, during expiration, is the highest part of the middle portion of the diaphragm. In expiration, the lateral muscular zone of the diaphragm lies in contact with the lower part of the thoracic wall (Fig. 478). During inspiration, the muscle fibres contract and draw the central tendon downwards, so that the lower surface of the lungs descends. The enlargement of the lungs at the lower part of the thorax is aided by the abduction of the floating ribs, produced by the contraction of the *quadratus lumborum* and *deep costal* muscles. In this contraction the diaphragm presses on the contents of the abdomen, so that the abdomen swells out with each inspiratory movement. The middle of the central tendon, where the heart lies, moves less than the two domes, and the part where the vena cava passes through the tendon is practically stationary during normal respiration. In deep inspiration, however, both this part as well as the rest of the pericardial attachment is forcibly depressed towards the abdomen. In quiet breathing, when observed by X-rays, the mean descent of the right dome in inspiration has been found to be about 12·5 mm., and of the left dome 12 mm. We may say, roughly, that the average descent of the diaphragm during normal respiration is about half an inch. The viscera and the intra-

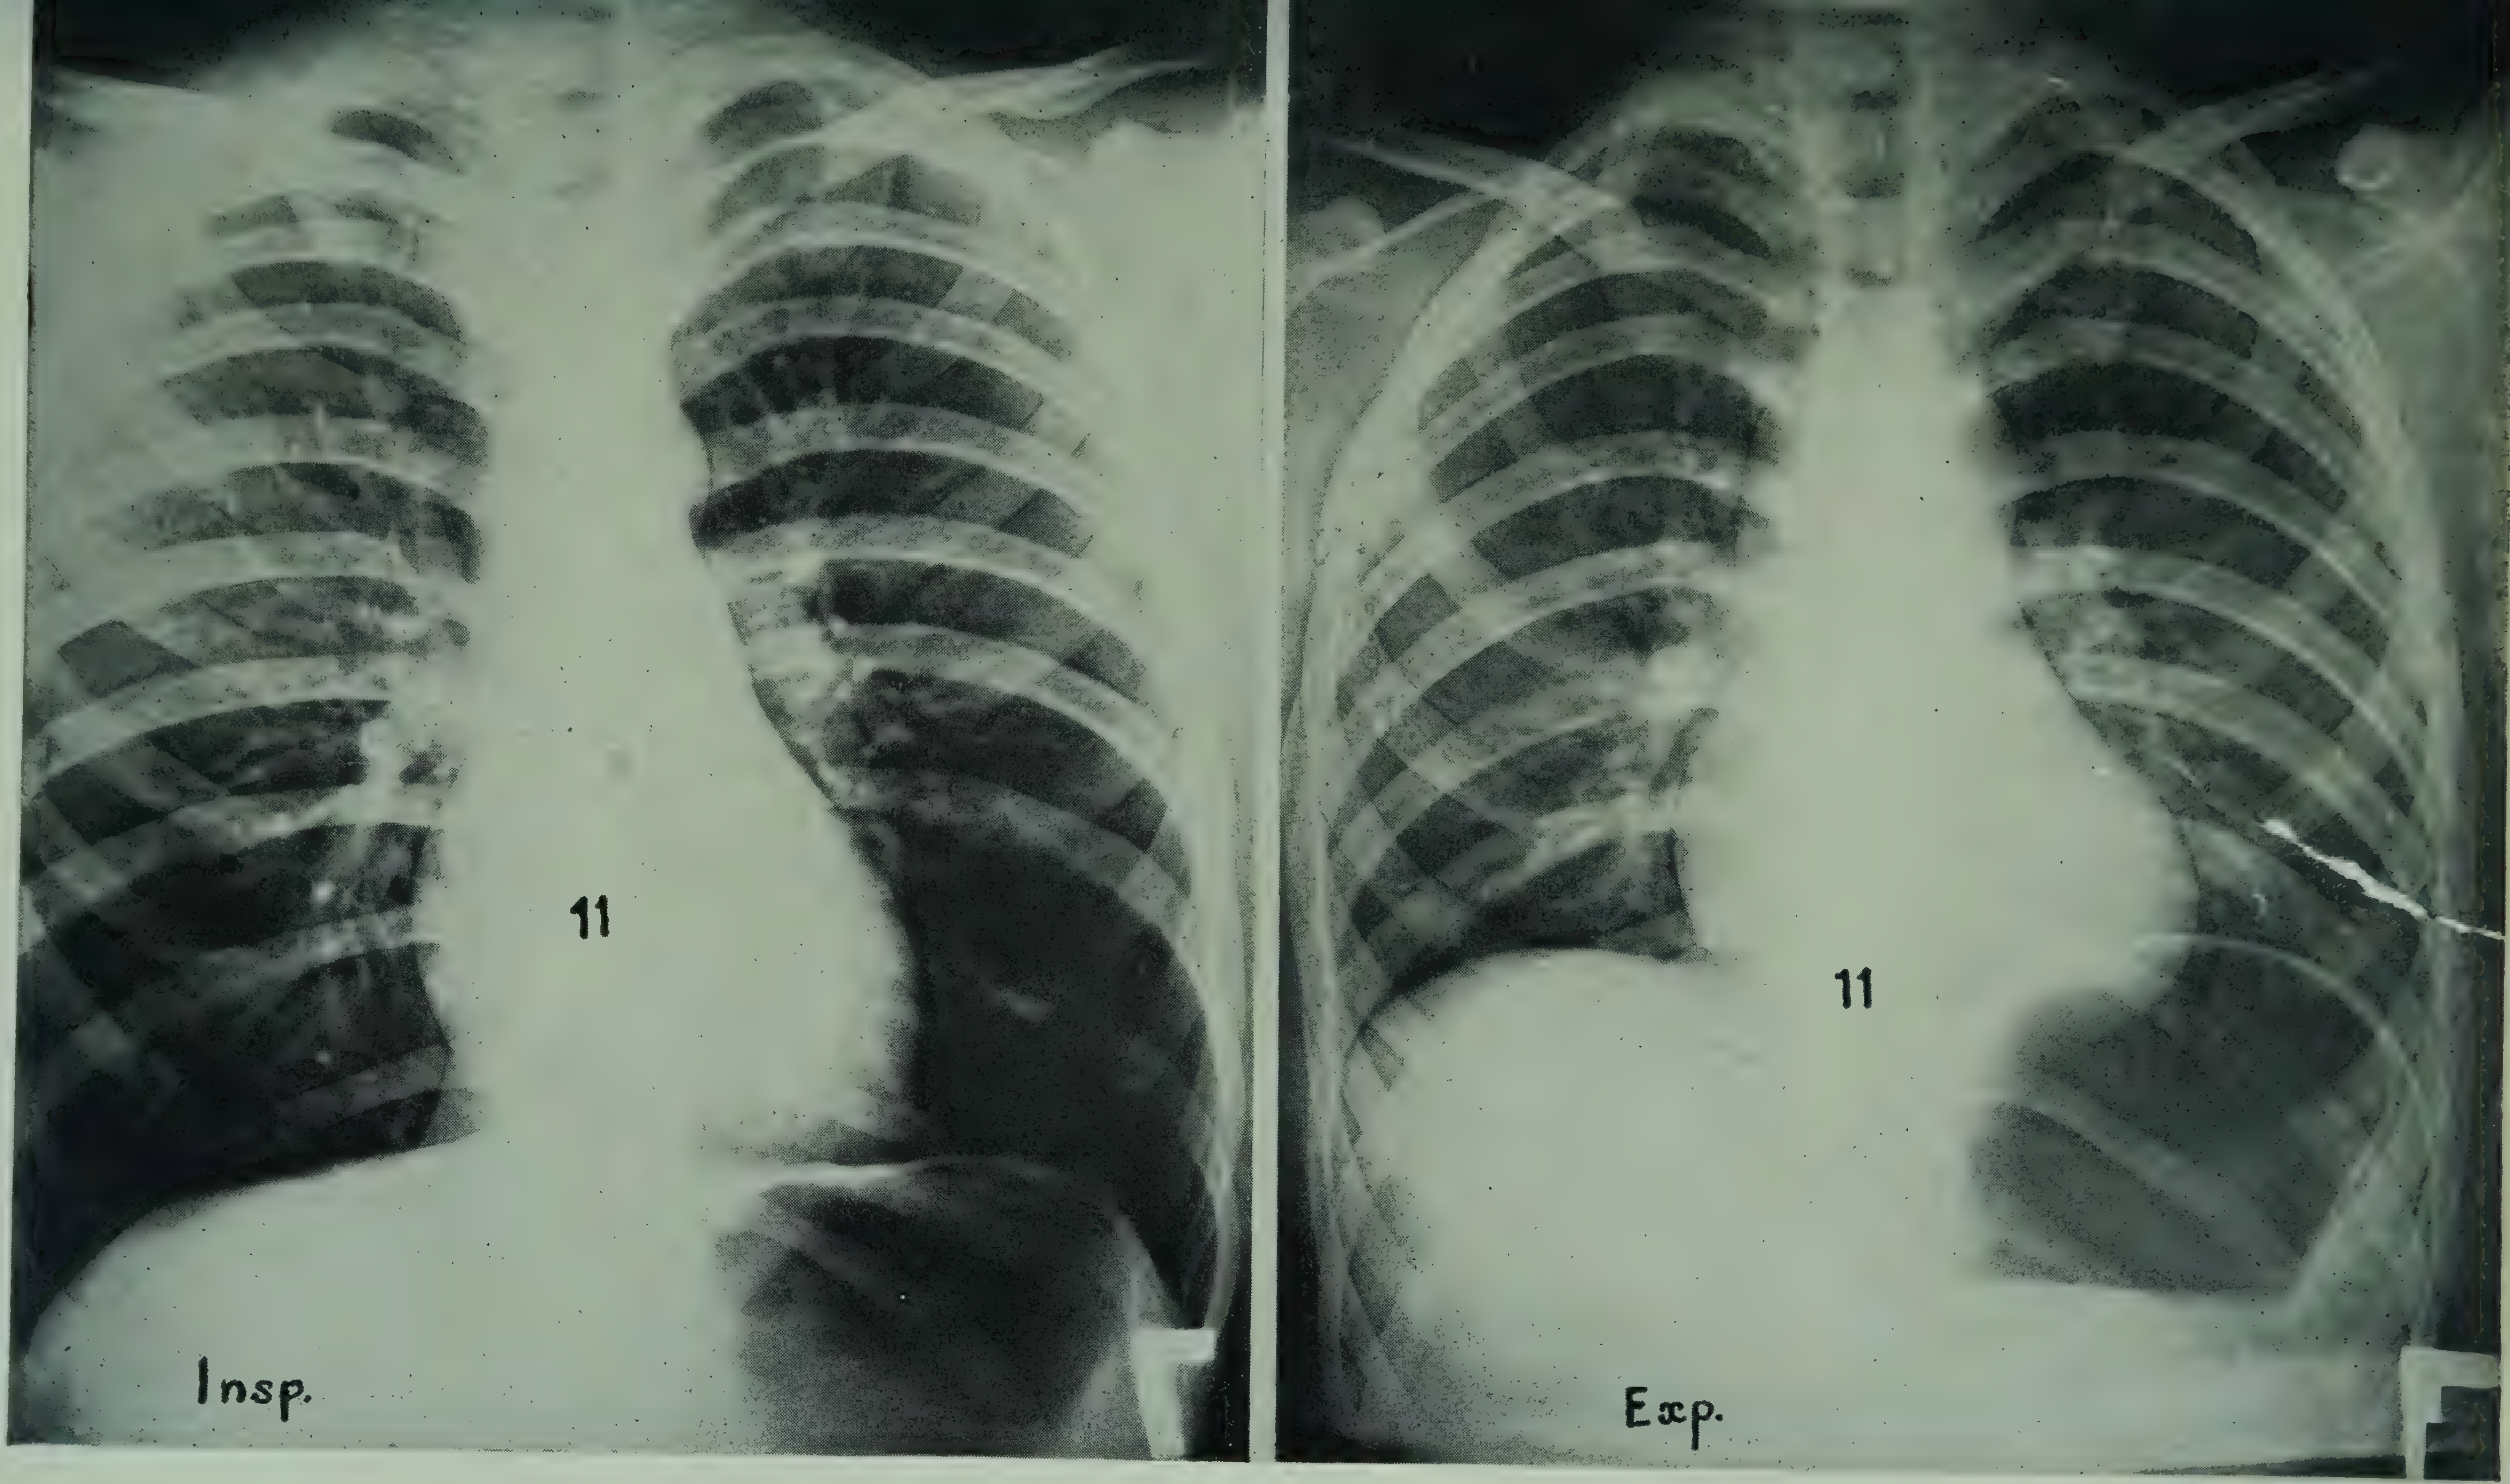

FIG. 478. Postero-anterior radiographs (negatives) of the thorax of a youth aged 18, taken at 6 feet distance. The level of the 11th thoracic vertebra is indicated as a landmark. In full inspiration note the darkness (*i.e.* transparency) of the lower half of the lung-fields, the width of the intercostal spaces and the outline of the heart, diaphragm, root of lung, and the gas-filled fundus of the stomach. In full expiration note the lessened opacity of lower half of the lung-fields, the obliquity of the ribs, the altered position of the heart, root of lungs and diaphragm, and the expansion of the gas in the stomach fundus. (Radiograph specially made by DR. JAMES F. BRAILSFORD.)

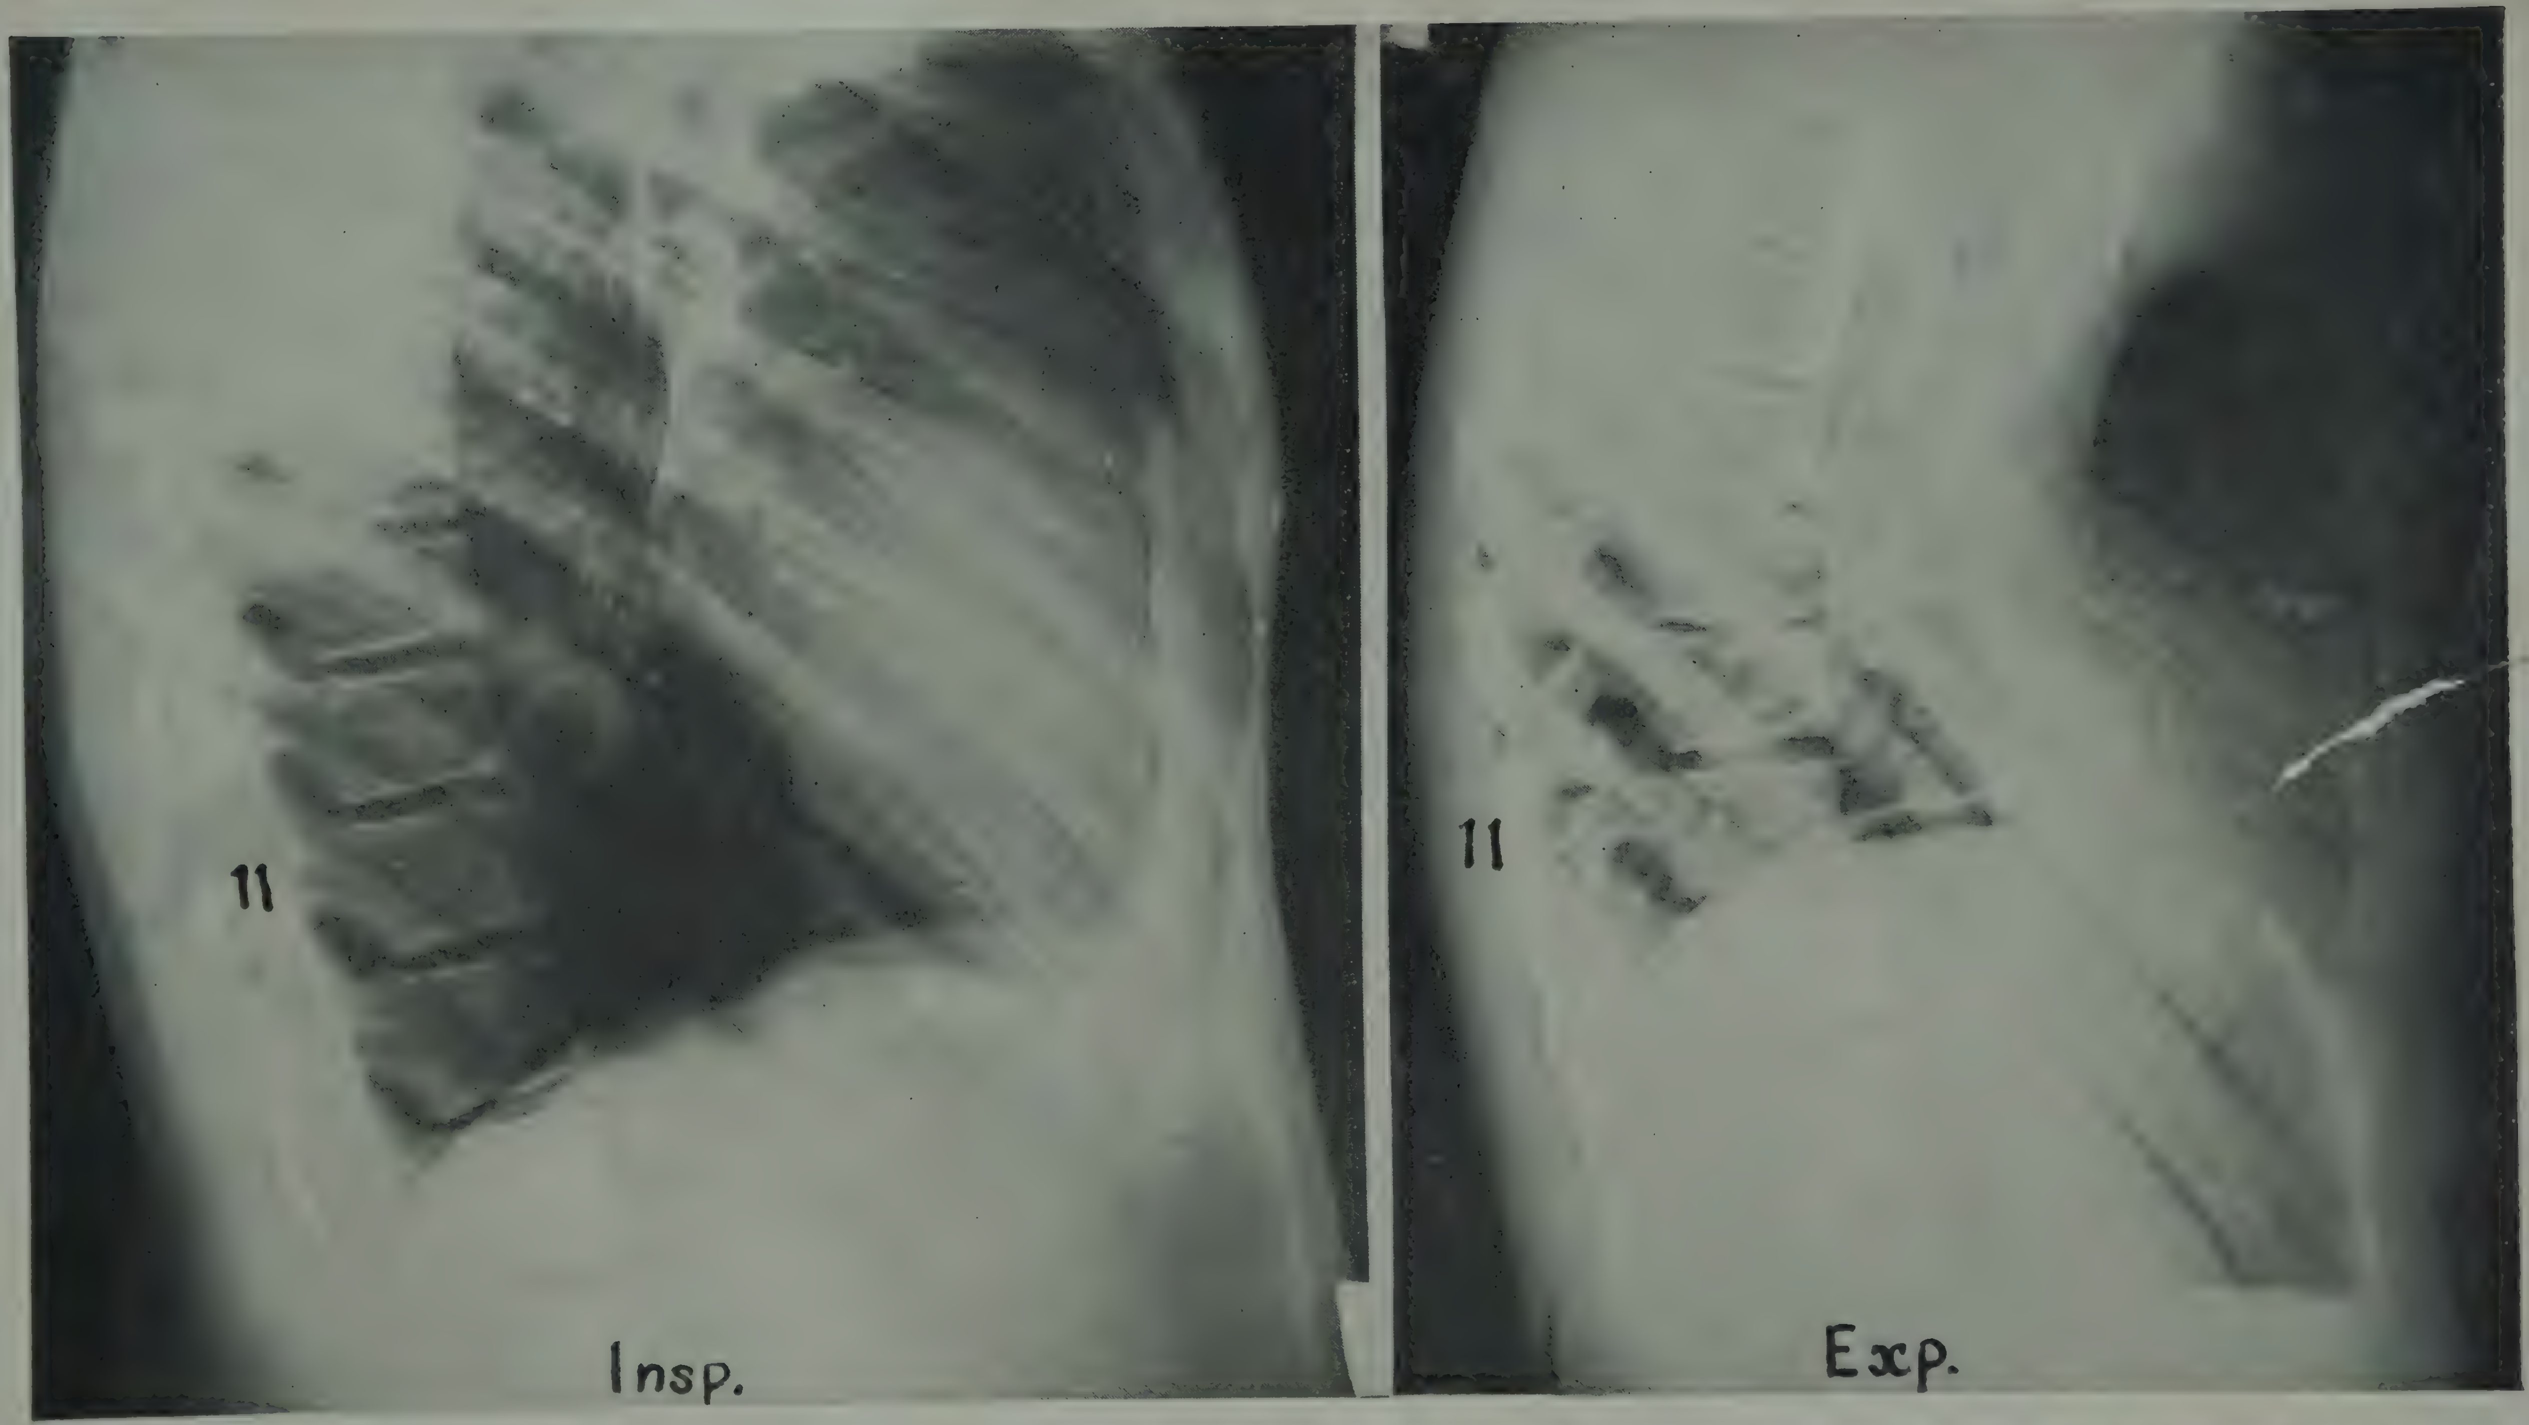

FIG. 479. Lateral radiograph of the chest of the same subject as the preceding figure. Note particularly the reduced obliquity of the ribs and the darkness of the lower lung-fields in full inspiration. (Radiograph specially made by DR. JAMES F. BRAILSFORD.)

abdominal pressure play an important part in determining the movement of the diaphragm, and especially in preserving the abduction of the lower ribs and so furnishing a fixed point for the muscular fibres of the diaphragm. If the contents of the abdomen are removed from a living animal, the ribs are drawn inwards every time the diaphragm contracts. In children with weak chest walls, and with respiratory obstruction, we may often see a depression round the lower part of the chest, which corresponds to the line at which the diaphragm leaves the chest wall, so that the distending force of the abdominal pressure on the bony walls of the thorax abruptly gives place to the pull of the distended lung. The contraction of the diaphragm may be regarded as a rhythmic fluctuation of tonus ; in quiet breathing, at all events, only some of the fibres, and not always the same ones, "contract," which explains the absence of fatigue.

Rib Movements. The enlargement in the other diameters is effected by an elevation of the ribs (Figs. 478 and 479). Each pair of corresponding ribs forms a ring directed obliquely from behind downwards and forwards. With each inspiratory movement the ribs are raised and the horizontal distance between sternum and spinal column is therefore increased. Moreover, the ribs from the first to the seventh increase in length from above downwards, so that when they are raised, the sixth rib, for instance, occupies the situation previously taken by the fifth, and the transverse diameters of the thorax at this level become greater. With each inspiration, there is also a rotation of the ribs. In the expiratory condition their outer surfaces are directed not only outwards but also downwards. As they are raised by the inspiratory movements, they rotate on an axis directed through the fore and hind ends of the rib, so that their outer surfaces are turned directly outwards. In this way a certain enlargement of the thoracic cavity is produced. As the thorax is raised, there is always some twisting of the rib cartilages.

The chief muscles raising the ribs in inspiration are the external intercostals ; their action will be explained later. The serrati postici and scaleni also contribute. It is probable that an important part is played by the extension of the spinal column. This movement, which is specially marked at the upper part of the thorax, causes an increase in all three diameters of this cavity.

The muscles mentioned are the only ones normally engaged in carrying out inspiration. When, from any cause, the inspiratory efforts become more forcible, a large number of accessory muscles are brought into play. These are : the scaleni, sterno-mastoid, trapezius, pectoral muscles, rhomboids, and the serratus anticus.

The force exerted by the inspiratory muscles is nearly all spent in overcoming the elastic resistance of the lungs and costal cartilages. A free access of air is provided for by contractions of certain accessory muscles of respiration. Thus there is rhythmical separation and approximation of the vocal cords, synchronous respectively with inspiration and expiration (Fig. 315, p. 467). When inspiration is laboured, the alæ nasi are dilated by the action of the dilator nasi. This movement, which is constant in many animals, becomes very marked in children suffering from certain types of respiratory trouble.

Expiration. In expiration, the processes are reversed, and the cavity of the thorax is diminished in all three dimensions. Normal expiration is chiefly effected passively. When the inspiratory muscles cease to contract, the stretched lungs contract by virtue of the elastic tissue they contain, and the thorax itself sinks by its own weight, and by the elastic reaction of the stretched costal cartilages.

In a position of rest, however, the elasticity of the thorax is opposed to that of the lungs and would, therefore, tend to produce inspiration. This would make inspiration easier at its onset, and would also present an impediment to expiration, towards the end of which there is need for active muscular contractions. Hence, contraction of the expiratory muscles reciprocates with that of the inpsiratory muscles. In fact, Sherrington's results on the co-ordination of muscular movements would lead us to expect inhibition of the tone, *e.g.* of the abdominal muscles, during inspiration, and active augmentation during expiration. Where the tone of the muscle is entirely lost, *e.g.* in visceroptosis, the diaphragm is thrown out of action, breathing being carried out chiefly by an elevation of the upper part of the thorax. Under normal circumstances, the internal intercostal muscles also contract with each expiration. When the nerves to external and internal intercostal muscles are led off to recording oscillographs, showers of nerve impulses are seen to pass down these, to the external intercostals in inspiration and to the internal intercostals in expiration.* When the breathing is deepened the impulses are seen to be more frequent.

In forced expiration, other muscles may take part—such as the serratus posticus inferior and the muscles forming the wall of the abdomen, *i.e.* the rectus, obliquus, and transversus abdominis muscles.

Although the action of the intercostal muscles has been a subject of debate and cannot even yet be regarded as definitely settled, physiological experiments serve on the whole to confirm the view first put forward by Hamberger, and based on a consideration of the direction of the fibres. The external intercostals pass from one rib to the next below, downwards and forwards. Hence, if a pair of ribs be isolated from the rest of the chest wall, leaving the vertebral and costal attachments intact, contraction of these muscles will cause both ribs to rise.† This result will be evident from a consideration of Fig. 480, where *ab* is a fibre of the external intercostal muscles passing from the rib *vs* to be attached to the rib *v′s′* at *b*. When *ab* contracts, the tension it exerts on its two attachments can be resolved into two components *ac* acting downwards and *bd* acting upwards. *bd*, however, acts at the end of the long lever *bv′*, whereas *ac* acts at the end of the short lever *av*. Hence the raising effect will overcome the depressing effect, and both ribs will rise.

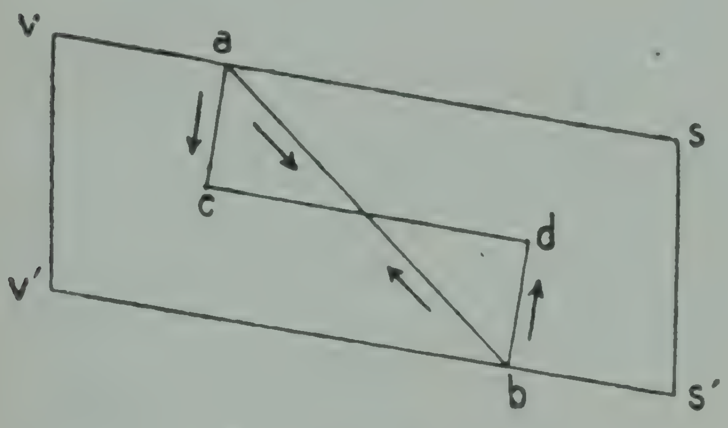

Fig. 480.

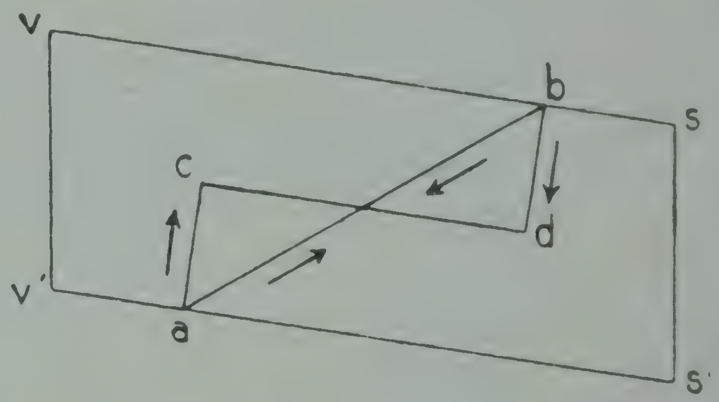

Fig. 481.

The fibres of the internal intercostals run in the opposite direction to the external muscles, and from a consideration of Fig. 481 it is evident that their effect will be to depress any pair of ribs, thus acting as expiratory muscles.

Owing to the fact that the costal cartilages make an angle with the bony ribs, the fibres of prolongation of the internal intercostals, *musculi intercartilaginei,* have the same relation to their attachments that the external intercostals have to the bony ribs. Their action, therefore, must be to raise the cartilages and flatten out the angle between the cartilaginous and bony ribs, so that they must act with the external intercostals as inspiratory muscles.

Lung Movements. As the lungs are inflated their position changes in relation to the thoracic wall. All parts are not equally distensible in the normal position of the lungs. There are three areas which are in contact with the nearly stationary parts of the thoracic wall and cannot therefore be directly expanded. These are (1) the mediastinal surface in contact with the pericardium and structures of the mediastinum ; (2) the dorsal surface in contact with the spinal column and with the spinal segments of the ribs ; (3) the apical surface lying in contact with the deep cervical fascia at the root of the neck. The expansion of these portions of the lung is in a downward direction and is indirectly caused by the movement of the diaphragm. The roots of the lungs move, with inspiration, slightly forwards and downwards. With inspiration there is also an increase in length and width of all the air-tubes, even of the trachea and large bronchi, but especially of the smaller ones. The actual alveoli are probably little, if at all, stretched at inspiration, but merely become flatter and wider. At expiration, all these changes are reversed.

Methods for Study of Respiratory Movements. In man, the enlargement of the chest and the accompanying movements of the diaphragm, ribs, heart, root of lungs, etc., can partly be seen on visual, or better on X-ray examination ; records of the expansion of the chest or abdomen can be obtained by the use of stethographs, of which there are many patterns, mostly on the air-transmission principle (Fig. 482).

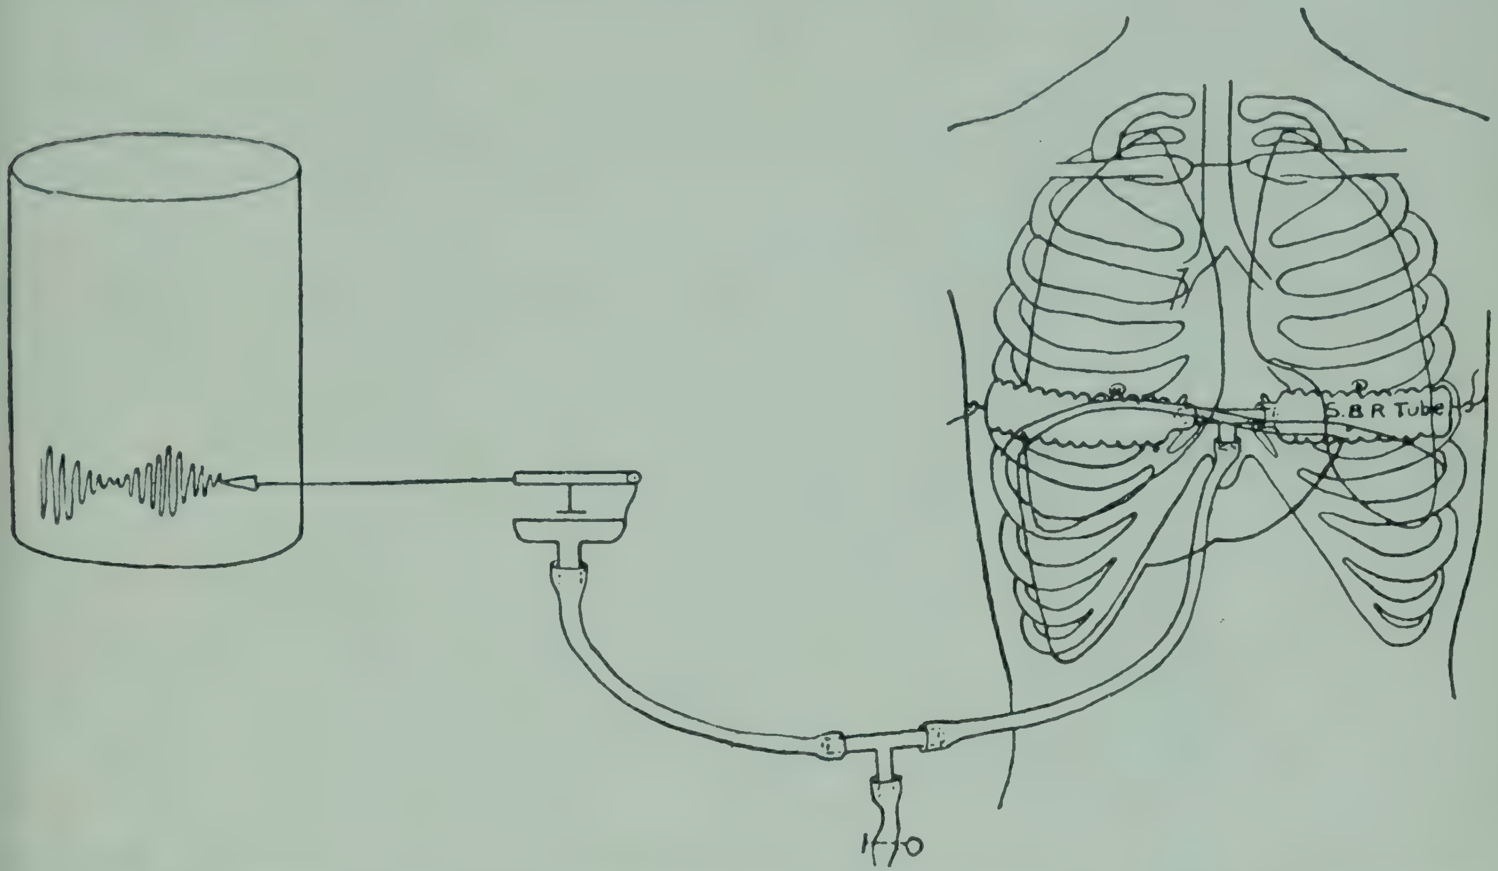

Fig. 482. A convenient form of stethograph. The portion placed round the chest consists of corrugated (" Gorman ") tubing, which opens out like a concertina on inspiration. (Harris's " Experimental Physiology.")

In animals a record may be made of movements of portions of the diaphragm, of the sternum or ribs, or of the larynx. A convenient method is to insert a small rubber balloon filled with air or water beneath the diaphragm and connect it with a water manometer or volume recorder. Yet another method is to record the intrapleural pressure changes,* or the pressure changes in the trachea. The volumes of air breathed in or out may be measured by a gas-meter or spirometer through which the man or animal breathes by means of appropriately arranged valves.† A method giving quantitative records is to place the man, or animal, in an airtight box, from which the head protrudes, the neck passing through an airtight collar : the interior of the box is connected to a volume recorder.‡ Other quantitative methods can be used, but cannot be described here.§

The extent and boundaries of the lungs can be ascertained in the living subject by means of *percussion*. On tapping a finger laid on the chest, a sound is emitted, which varies with the nature of the subjacent tissues. If this is lung tissue filled with air, a clear resonant tone is obtained ; where it is solid tissue, such as the heart, or a lung consolidated with inflammatory products, or the liver, a dull sound is obtained. It is easy to show that the resonant area of the chest increases with each inspiration. The apices of the lungs extend about one inch above the clavicle anteriorly, and reach as high as the seventh spinous process behind. During moderate expiration the lower margin of the lungs extends, in front, from the upper border of the sixth rib at its insertion to the sternum, and runs obliquely downwards to the level of the tenth rib at the back of the chest. During the deepest inspiration the lungs descend, in front, to the seventh intercostal space, and behind, to the eleventh rib, while during deepest possible expiration, the lower margins of the lungs are elevated almost as much as they descend during inspiration. In the front of the chest a triangular space can always be marked out over the heart, where the note obtained on percussion is dull. This space is bounded on the right by the left border of the sternum and extends out as far as the cardiac apex, being bounded above by the fourth costo-sternal articulation and below by the sixth costal cartilage.

Breath Sounds. If the ear be applied to the chest wall, either directly or through the medium of a stethoscope, each inspiration is found to be accompanied by a fine rustling sound, the "vesicular murmur." It is thought to be caused by the sudden dilatation of the air vesicles during inspiration, or perhaps by the current of air passing from the terminal bronchioles into the wider respiratory bronchioles. It is important to remember that this sound is heard only during inspiration, and over healthy lungs. On listening over the larger air passages, *i.e.* the larynx, trachea, and bronchi, we hear a much louder sound which accompanies both expiration and inspiration, and may be compared to a sharp whispered *hah*. This is known as the "bronchial murmur." It can be heard also at the back of the chest between the scapulæ at the level of the fourth dorsal vertebra, where the trachea bifurcates. In all other parts of the chest the healthy lung prevents the propagation of this sound to the chest wall. If, however, the lung is solid, as occurs in pneumonia, it conducts the sound easily from the large air tubes to the chest wall. Bronchial breathing at any part of the chest, other than that immediately over the air tubes, is therefore a sign of consolidation or cavitation of the lung. Absence of breath sounds at any part of the chest implies, either that air is not entering that part of the lung, or that the lung is separated from the chest wall, *e.g.* by effused fluid, which does not conduct the sound to the surface.

Intrathoracic and Intra-abdominal Pressures. Even at the end of normal expiration the healthy adult lungs are in a stretched condition. This is shown by the fact that if an opening be made into the pleural cavity, air rushes into the opening (*pneumothorax*)* and the lungs collapse, driving a certain amount of air out through the trachea. Since the lungs are always tending to collapse, it is evident that they must exert a pull on the thoracic wall. The pressure in the pleural cavity, between the two layers of the pleura, is called the "intra-pleural pressure." Owing to the pull of the lungs it is below the pressure of the surrounding atmosphere and is sometimes, though inaccurately, called a "negative pressure" in consequence. It is often imagined, though quite wrongly, that the existence of this "negative pressure" is in some way essential to the performance of inspiration, in which act it becomes still more "negative." Actually, of course, the pleura covering the surface of the lungs is in contact, except for a film of pleural fluid, with the pleural layer lining the chest wall, so that the "pleural cavity," in the normal chest, is almost non-existent, and in any case does not contain air. The so-called "negative pressure" is again often, and once more wrongly, stated to be what keeps the two layers of the pleura in contact. So far from being the cause, it is, in fact, an effect, firstly of this contact, secondly of the normally stretched condition of the lungs. The effect of the contact between the two pleural surfaces is that, in order to separate them, the film of liquid by which they are wetted must be broken. To do this requires considerable force, a film of water at body temperature being able to sustain a tension of 3,600 mm. Hg/sq. cm. without rupture.† Everyone knows that what makes a dry rubber sucker adhere is not suction within but pressure of air from without; remove this air pressure and the sucker fails to stick. But a wet sucker would still adhere unless pulled sufficiently to break the fluid film. The lungs, therefore, cling to the chest wall because they fill all the available space of the thorax. If, in so doing, they are stretched, there will be a tendency, proportional to the stretch, for the lungs to collapse, and this will cause the so-called negative pressure. If the atmospheric pressure inside the lung $= P$, and the elastic recoil of the lungs $= p$, then the two layers of pleura will be held together by the force $P - p + S$, the "negative pressure" of course also being $= p$, and exerted on the whole contents of the thorax, and S being the initial force required to break the liquid film. In the expiratory position the intrapleural pressure is 3 to 5 mm. Hg below the atmospheric; in normal inspiration the difference is about 5 to 10 mm. below atmospheric. If the lungs are fully distended by a deep inspiration the elastic forces are brought more into play, and the negative pressure in the pleura may amount to 30 mm. But it must be clearly understood that if the lung tissue had no elastic recoil, so that there was no "negative pressure," the act of inspiration would not be affected in any way. But respiration becomes impossible directly free openings are made into the pleural cavities on both sides of the chest. With each inspiratory movement, air rushes in through these openings, so that the thoracic movements can no longer exert any influence on the volume of the lungs.

---

* Graham. Alterations of Intrapleural Pressure and their Significance. Harvey Lectures, XIX, 1924, 123. Lippincott.

† Burns. *J. Physiol.*, 1940, **98**, 26P.

The negative pressure in the thorax is diminished by any factor decreasing the elasticity of the lung tissue. Thus, in an old man, where the elastic tissue is degenerated and the alveoli are enlarged, giving rise to the condition known as *emphysema*, the lungs may collapse only slightly, or not at all, on opening the chest. The lungs do not collapse on making an opening in the chest of a new-born mammal; but this is owing to the fact that they completely fill the thorax in the expiratory position, and it is only later that, with the growth of the ribs, the thorax gets, so to speak, too large for the lungs, which are therefore stretched to fill it.

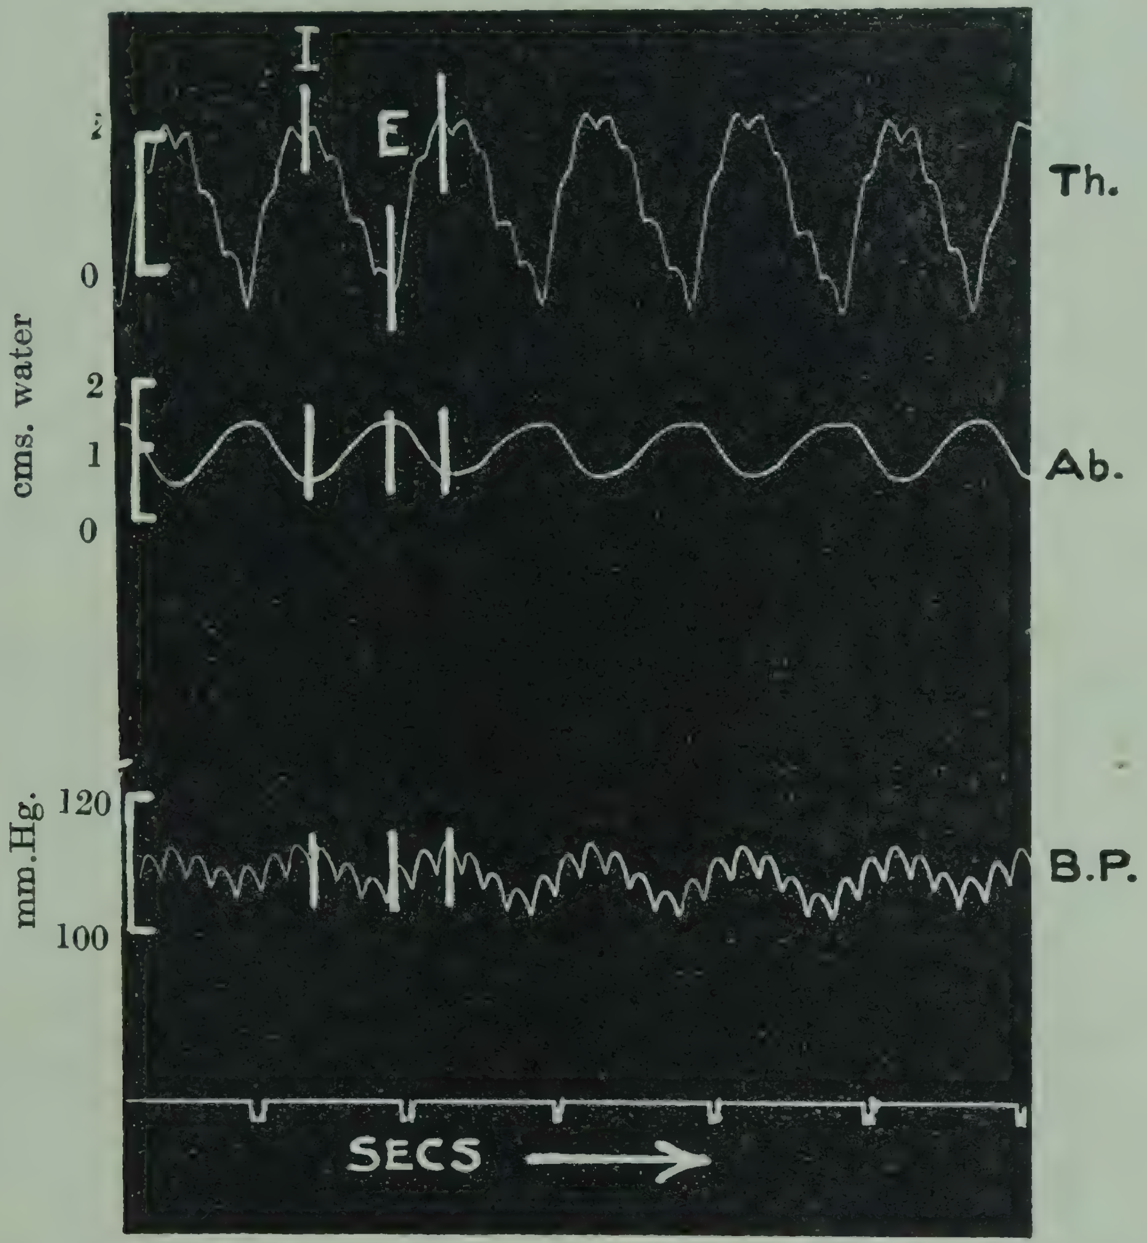

Fig. 483. Fluctuations of intrathoracic (Th) and intra-abdominal (Ab.) pressure (in terms of cm. water) and of arterial blood pressure (in mm. Hg) of an anæsthetised cat breathing quietly. I = inspiration begins. E = expiration begins. (H. P. Gilding.)

The pressure in the abdominal cavity is of course raised when the diaphragm descends during inspiration, so that the pressure fluctuations in the thoracic and abdominal cavities are reciprocal in direction (Fig. 483). Whether the actual pressure at any point in the abdominal cavity is above or below that of the outside air will obviously depend greatly upon the position considered, the posture of the body, the tension on the abdominal walls, etc., but in any cases with normal breathing, the pressure in the abdomen will rise, as that in the thorax falls, during inspiration, and *vice versâ*. This is a fact of the greatest importance in several directions.

If a manometer be connected with one of the nostrils, so as to register the pressure in the air cavities, it is found that there is a negative pressure of

— 1 mm. Hg with inspiration, and a positive pressure of 2 or 3 mm. with expiration. With forced inspiration, the pressure may amount to — 57 mm. Hg, and with forced expiration there may be a pressure of + 87 mm., the latter mainly due to action of the abdominal muscles.

Pulmonary Ventilation. When breathing quietly, a man takes in and gives out at each breath about 500 c.c. of air, measured dry and at 0° C. If measured moist and at the temperature of the body, viz. 37° C., the volume would be about 600 c.c. This amount is known as the *tidal air*. By means of a forcible inspiratory effort, it is possible to take in about 2,000 c.c. more (*complemental air*). At the end of a normal expiration a forcible contraction of the expiratory muscles will drive out about 1,300 c.c. more (*reserve or supplemental air*). These three amounts together constitute the "*vital capacity*" of an individual. This total may be determined by means of the spirometer, a small gasometer with a gauge by which the amount of air in it can be at once read off. The person to be tested fills his lungs as full as possible, and then expires to the utmost into the spirometer. Individual variations in vital capacity are great (2·5—5·5 l.), and depend to a considerable extent on physical build. Of the total lung volume, the vital capacity of British subjects averages about 71 per cent., supplemental 25 per cent., functional residual air 54 per cent., residual air 29 per cent.* The *functional residual air* is supplemental plus residual air (Fig. 484). The pulmonary ventilation and vital

capacity are greatest when standing, and least when lying in the prone position, the difference in V.C. being about 300 to 500 c.c. The loss of vital capacity when lying down is due to upward displacement of the diaphragm by the abdominal viscera, and also, according to Hamilton and Morgan,* to the fact that blood accumulates in the lungs. In cardiac disorders with weakness of the left ventricle, patients often are unable to lie down because of the pulmonary congestion and breathlessness which ensue (orthopnœa).

Increased depth of breathing is called *hyperpnœa.* When for any reason the pulmonary ventilation approximates to the volume of the vital capacity, the breathing becomes laboured, and is called *dyspnœa.* Voluntary hyperpnœa is called *forced breathing.*

Under no circumstances can expiration quite empty the lungs of air. At the end of the most forcible expiration the alveoli and all the air tubes still contain air. The air left in the lungs after the most vigorous expiration is known as the *residual air.* As a result of actual determinations, we may assume the residual air in the lungs as something between 1,000 and 1,700 c.c., generally about 1,600 c.c. It is not reduced in the recumbent posture.

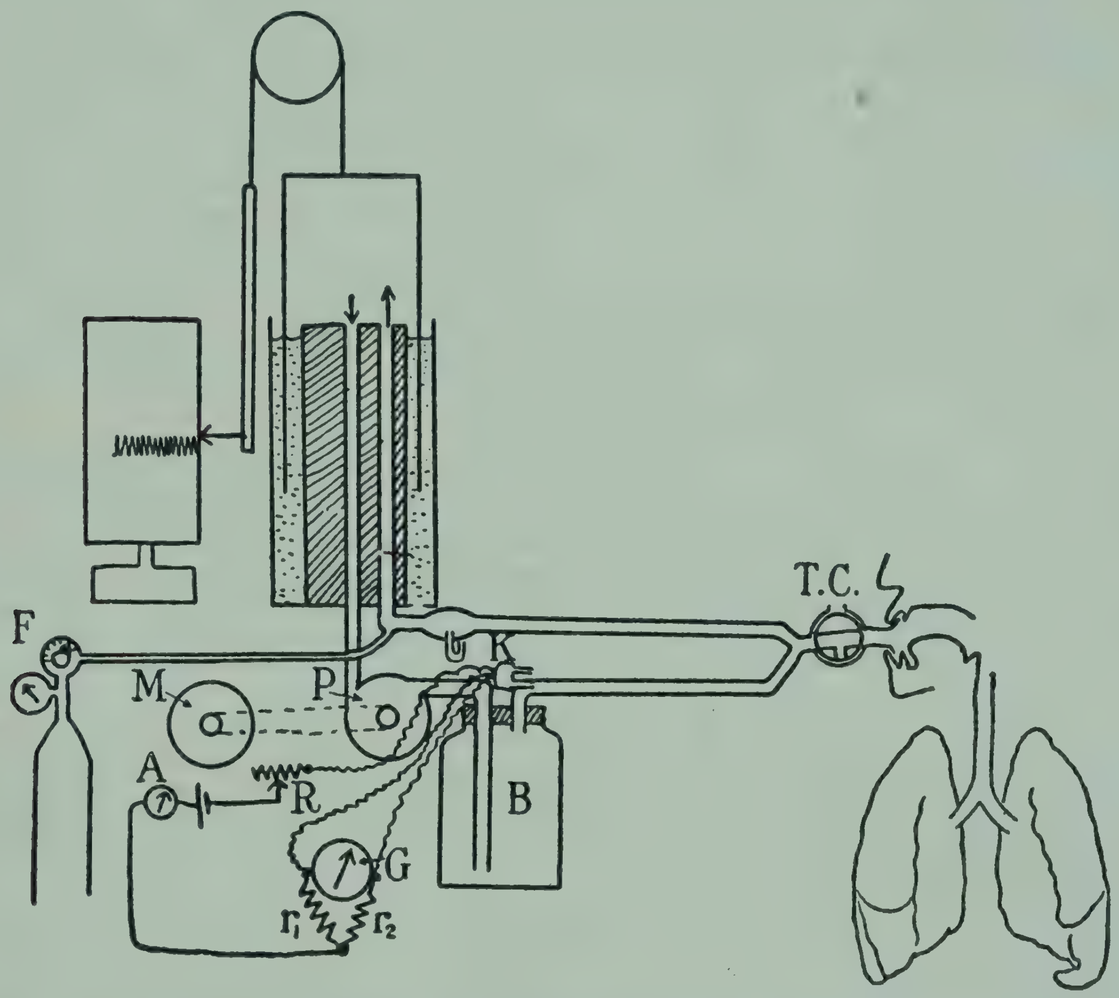

Fig. 485. Spirometer arranged to determine lung volume. P., the circulating pump ; B, bottle with absorbent for CO_2 ; volume kept constant by running in O_2 from F. at same rate as usage ; K, a katharometer connected to ammeter A and galvanometer G, for ensuring constant composition of mixture. (Herrald and McMichael, *Proc. R. S.*, 1939, **126B**, 491.)

The various lung volumes can be accurately determined by the use of a recording spirometer as follows : †

(1) The subject is connected to the spirometer arranged as in Fig. 485 and a record of the rate of oxygen consumption is taken in the usual way. During this time records are also made of *vital capacity, complemental air* and *supplemental air.* The subject is now disconnected.

(2) It now remains to determine *functional residual air.* The principle of the method is to let the patient breathe from an atmosphere of *known volume* and of *known composition,* but differing from that of the air by being greatly enriched with oxygen. The composition of the mixture is kept constant by adding oxygen at the same rate as the subject uses it. The CO_2 is absorbed. In seven minutes the N_2 is evenly distributed, the patient is disconnected and the mixture analysed for O_2 and N_2.

---

* Hamilton and Morgan. *Amer. J. Physiol.*, 1932, **99**, 526.

† Herrald and McMichael. *Proc. R. S.*, 1939, **126B**, 491.

A calculation shows the functional residual air. Thus, suppose the patient's lungs at the start contained x l. of air which = 0·791 x l. of N_2, and suppose the spirometer contains to begin with 2 l. of air (= 2 × 0·791 l. N) plus 3 l. of O_2. The volume is the same at the end because oxygen is added as used, and all that has happened is that the lung gases and spirometer gases have been mixed together. Suppose there is 50 per cent. of N_2 in the final mixture; the functional residual air is x l.

Then we have

$$\begin{aligned} 2 \times 0{\cdot}791 + 0{\cdot}791\,x &= 0{\cdot}50\,(x + 5) \\ 0{\cdot}291\,x &= 0{\cdot}918 \\ \therefore \quad x &= 3{\cdot}16 \text{ l.} \end{aligned}$$

(3) If the supplemental air was found to be, say, 1·56 l., the *residual air* would be 3·16 − 1·56 l. = 1·6 l.

Of the 500 c.c. of tidal air taken in at each inspiration, only a certain part reaches the alveoli, part being required to fill the air tubes, trachea, bronchi, and bronchioles which lead to the air cells. The volume of these air tubes is called the "*dead space*," and is normally taken as about 140 c.c., so that, of the 500 c.c., about 360 c.c. actually reach the alveoli. For the same reason, the expired air represents the air from the alveoli (360 c.c.), diluted with 140 c.c. of dead space air which has remained in the air tubes and undergone very little change, other than the elevation of temperature and saturation with aqueous vapour. There is no doubt, however, that it is incorrect to regard the volume of the dead space as constant, since not only do the branches of the bronchial tree show at inspiration an increase, and at expiration a decrease, in all dimensions, but the volume of the physiological dead space no doubt varies with alterations in the state of the bronchial musculature and various other factors. It is, for instance, increased in exercise.*

The velocity with which the air enters and leaves the respiratory tract may be investigated by photographing the displacement of a fine quartz fibre placed in the path of the moving air. It shows that the maximum speed of movement of the air is at the commencement of inspiration and expiration, and the minimum speed just before the end of each phase.

KEITH (1909). The Mechanism of Respiration in Man. (L. HILL's "Further Advances in Physiology.") London. (Arnold.)

Artificial Respiration. Under various conditions the respiratory movements may cease, and it is then necessary, in order to save life, to cause air to enter the lungs by some artificial means. This may be accomplished in various ways by which air is forced or drawn into the lungs, and forced or drawn out of them, at suitable intervals. The most easily controllable method of doing either is by means of suitable air-pumps, but when these cannot be used, quiet efficient ventilation can be obtained by simple means, as described below.

Inflation Methods. These methods are most commonly applied to anæsthetised animals. In the simplest method, a suitable tracheal cannula is tied into the trachea, and warm moist air is delivered to the tube rhythmically from a pump. The tracheal cannula has a side tube which can be partially closed by a screw clamp; as each blast of air is delivered, some excess escapes by the side tube, and the rest of it inflates the lung; between the blasts the lungs collapse and the air expelled escapes by the side tube. When ventilation is being carried out with gases other than atmospheric air, this method is wasteful. In such cases it is better to use a more elaborate pump, such as the one designed by Starling ("Ideal" pump). In this the side tube is closed by a mechanical device while the pump is delivering, so that the whole of the air delivered is kept in the closed system of lungs plus tubes; at the end of the stroke the side tube is opened and the lungs collapse. In a third type of pump, the trachea is connected to a double pump which alternately forces air into the trachea from one barrel and draws it out again into the other one. The last two methods both allow of respiration being carried out with any desired gas mixture. With suitable modifications in the way of masks instead of tracheal cannulæ, similar devices have been applied for use on the human subject. It was found by Yandell Henderson, Drinker and others that the administration, by some such method, of oxygen containing 5 per cent. carbon dioxide is most valuable in the resuscitation of persons apparently drowned or suffering from coal gas poisoning, and various apparatus for the purpose have been introduced.

---

* DOUGLAS and HALDANE. *J. Physiol.*, 1912, **45**, 235.

Continuous Insufflation. If a flexible tube of small diameter be passed down the trachea as far as its bifurcation, it is possible to maintain life without any movement of the chest at all, by injecting a constant stream of oxygen, with or without 5 per cent. CO_2, by way of the tube, so that the lungs are slightly distended. This has enabled operations to be carried out on patients with opened thorax.

*Chamber Method.** In this method the subject is placed with his body in a chamber and the head outside, the neck passing through an airtight collar in the wall. The chamber is airtight, and when air is sucked out of it by a rhythmically operated pump, the subject's chest is expanded and air is drawn into his lungs ; the reverse happens when air enters the chamber again.

The Bragg-Paul Pulsator † is a simple mechanical device which can be operated by a motor, or by water-pressure for indefinitely long periods.‡ It consists of a rubber air-bag wrapped round the chest and rhythmically inflated and deflated.

Emergency Methods. In animals rhythmic compression of the chest is often sufficient. In man, several adequate methods are available.§ That described by Schäfer,|| is generally adopted for the resuscitation of asphyxiated persons. The subject is placed in the prone position, with the head slightly to one side ; the mouth is cleared and the tongue pulled well forward. The operator, kneeling either at the side, or astride, of the subject, places the palms of his hands flat on the subject's trunk, just over or below the lowest ribs and then by leaning forward presses *gently* forwards and upwards so as to exert pressure there, for, say, two seconds (Fig. 486). He then leans back a little to release the pressure for two seconds and then again repeats the forward movement, and so on. In this way air is forced out of the chest when pressure is applied, because the diaphragm is pushed up ; when the pressure is released, the elastic recoil draws air into the chest. It is easy by this method, *with which every person of adult age should be familiar*, to maintain normal ventilation in an unconscious subject for long periods without undue fatigue on the part of the operator.

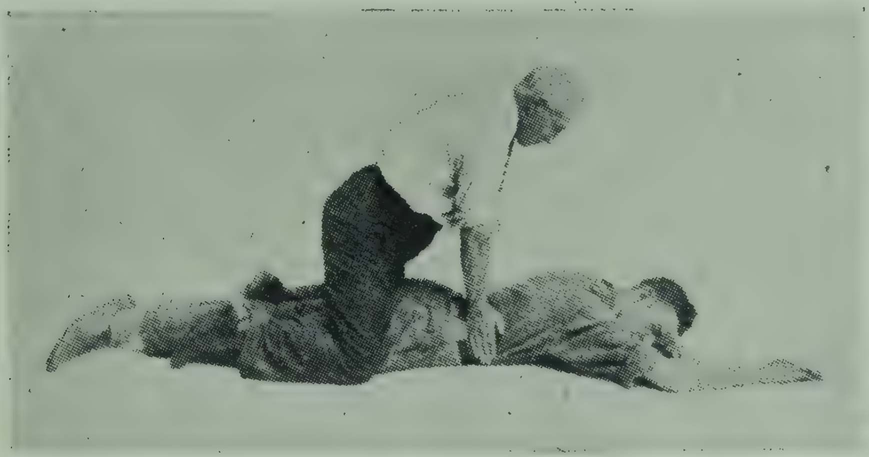

FIG. 486. Schäfer's method of artificial respiration. (DRINKER.)

With patients under operation, and lying in the supine position, this method cannot readily be used ; but quite good results can be obtained by similarly applying intermittent pressure on the epigastrium, by which means also the diaphragm is made to ascend. *Pressure on the upper ribs is almost useless.* In both of these methods it is advantageous, where possible, to let the subject inhale, from a suitable mask, a mixture of oxygen and 5 per cent. carbon dioxide.

Another simple method which can be carried out for long periods is the rocking method of Eve.¶ The patient is placed in the prone position on a

stretcher, which is rocked on a pivot, like a see-saw, 45 degrees up and down 12 to 15 times a minute. When the head is downwards the weight of the abdominal viscera pushes the diaphragm up, and in the feet-down position the diaphragm descends. The tidal air by this method is slightly greater than in Schäfer's method,* viz. 450 to 600 c.c./min.: it also favours venous return to the heart, and hence the cardiac output is improved.

THE BRONCHIAL MUSCULATURE

All the air tubes have in their walls a middle layer of plain muscle. When the lung is normally distended, this muscle is neither circular nor longitudinal, but forms an oblique network, which by its constriction narrows the lumen and decreases the length of the tube at the same time. The muscle only appears circular and compact when microscopically examined in the collapsed state (Macklin). The guinea-pig is perhaps the only animal in which the bronchial muscle is definitely circular and also compact,† and in this animal the thickest muscle is in the secondary *bronchi* (just after they arise from the primary); this is the site of occlusion which causes death from asphyxia in anaphylaxis in the guinea-pig. Immediately internal to the muscle coat lies a prominent layer of longitudinally coursing branched elastic fibres, and from this elastic lamina fibres extend amongst the muscle fibres and form, as in the arteries, gut, spleen, etc., an intimate "tissue partnership." In expiration, contraction of this "myo-elastic" system plays an important part in decreasing the size of the whole lung, and in addition decreases the capacity of the dead space by shortening and narrowing the airway. Contraction of the bronchial muscle has the following effects: (1) a constriction of the bronchi and bronchioles; (2) a diminution of the air space of the lung, and therefore of the volume of the lung; (3) an increased resistance to the passage of the air into, and out of, the alveoli.

† MILLER. *Amer. Rev. Tub.*, 1921, **5**, 689.

Changes in the condition of contraction of the bronchial muscle may be studied in various ways. In one method, artificial respiration is carried out, a constant volume of air being blown in at each respiration—excess escaping by side-tube, while alterations in pressure due to the varying resistance of the bronchioles may be recorded from a tracheal side tube (Fig. 487, T.P.). Any diminution in the calibre of the bronchioles must increase the resistance to the incoming current of air, and so cause a rise of pressure in the tracheal tube. By a second method, artificial respiration at a constant pressure is made use of, and alterations in lung volume at each pump stroke may be recorded by enclosing the lung in a plethysmograph * (Fig. 487). In a third method, the lungs may be excised and the air tubes perfused from the trachea with a suitable warm saline solution, while the pulmonary circulation is also similarly perfused. The bronchial perfusion fluid flows away through scarifications made on the lung surface, while the resistance is measured by a tracheal side tube and suitable manometer.† The action of drugs or inorganic ions may conveniently be studied by this method. By all these methods it has been shown that stimulation of the peripheral end of the vagus or presence of acetyl choline causes constriction of the bronchioles (Fig. 487) which is paralysed by atropine, while inhibitor fibres supply the bronchial muscle from the sympathetic nervous system ‡ (Fig. 488). The action of adrenaline also causes dilatation of the bronchi. Histamine causes intense constriction of bronchi through its direct action on the muscle,§ and this, like all reactions of plain (and other) muscle, is diminished by reduction of the calcium content of the fluid in which it is bathed.||

In man the bronchi have been studied with the aid of the bronchoscope,[*] and by X-rays after the injection of radio-opaque substances ("lipiodol") into the bronchial tree.[†] By both these methods the bronchi have been shown to have a rhythm synchronous with and similar to that of the vocal cords (p. 467), dilating in inspiration and constricting in expiration. The cause of this rhythm is not known. In part it is no doubt passive, and represents a general alternate expansion and contraction of the whole of the lung in consequence of the respiratory movements. But many believe it to be also, in part, active. In so far as this is the case it may be regarded as a part of the normal respiratory movement, caused by the discharge of nervous impulses from the respiratory centre; we may suppose that, at each inspiration, the broncho-constrictor impulses passing down the vagi are inhibited and that broncho-dilator impulses are sent down the sympathetic fibres to the lungs; at expiration the reverse happens.

Peristaltic movements have also been described in the bronchi and are markedly brought into play on the introduction of foreign bodies (Reinberg). (Spontaneous rhythmic waves have been observed in the bronchi of the chick embryo by Lewis.[‡]) These represent a protective mechanism of the lung, which thus raises unwelcome fluid to those parts of the airway (primary and secondary bronchi) where the cough reflex can be originated, by which it is finally expelled.

In asthma, the excessive tonus of the bronchial muscle will cause obstruction to the passage of air in and out of the lung, expiration becoming more difficult than inspiration, probably owing to the rhythm mentioned above. Whether this hypertonus depends on chemical factors or not is at present unknown, but it is clear that nervous elements can be superimposed to add to the difficulties of the already complicated clinical picture.

2. THE CHEMISTRY OF RESPIRATION

Expired Air. The tissues of a man of 70 kg. body weight consume, on an average during working hours, about 400 c.c. oxygen per minute. This oxygen is used for the oxidation of various materials in the body, and the tissues, in consequence, produce 300 to 350 c.c. of carbon dioxide. The oxygen required by the tissues is taken from the blood, and the carbon dioxide formed is, in return, passed out into the blood. Hence, the venous blood contains less oxygen but more CO_2 than arterial blood. In its passage through the lungs, the blood is again arterialized, oxygen passing into it and CO_2 out, owing to an exchange with the air in the alveoli. This air is continually renewed by breathing, and hence the expired air contains less oxygen, and more carbon dioxide than that which is inspired. Its composition is not constant, however.

Expired air can be collected for analysis or measurement by the use of the Douglas bag[§] (Fig. 489). The subject breathes through the valves, which are so arranged that air from the outer atmosphere enters at inspiration, and is drawn into the lungs, while at expiration the expired air passes through the other valve, and into the bag, which is of about 100 l. capacity, and made of an impermeable fabric. Samples of the air can be drawn off from the bag for analysis, and the volume of expired air collected in a given time measured by expressing the contents of the bag through a gas meter.

Analysis of the air is made by the use of Haldane's gas analysis apparatus, of which descriptions will be found in practical handbooks.[||] The principle is that a measured volume of the gas is taken, the CO_2 absorbed by KOH solution, and the shrinkage of volume measured; then the oxygen is absorbed by alkaline pyrogallate, and the volume loss again measured: the residual volume is nitrogen. The whole analysis is conducted at constant temperature and pressure, and with the gas saturated with water vapour. Since only the relative volumes of the components are required, the results are the same as if the gas were dry, and at N.T.P. ; addition of water vapour, or rise of temperature, or fall of pressure, causes expansion of all components equally.

[§] Douglas. *J. Physiol.*, 1911, **42**, *Proc.* xvii.

[||] *E.g.* Douglas and Priestley (1948). Human Physiology. Oxford: Clarendon Press.

The expired air of normal resting persons at sea-level contains about 3·0 to 4·5 per cent. of carbon dioxide, and 16·0 to 17·5 per cent. of oxygen. As a very rough average, it compares as follows with the inspired air :

	Inspired Air	Expired Air
Oxygen	20·95 vols. per cent.	16·4 vols. per cent.
Nitrogen (including argon)	79·01 ,, ,,	79·5 ,, ,,
Carbon dioxide	0·04 ,, ,,	4·1 ,, ,,

The inspired air contains a variable amount of aqueous vapour and has a variable temperature. Expired air, as expelled, has a temperature, in our climate, of about 35·5° C. and is about 90 per cent. saturated with aqueous vapour at that temperature, *i.e.* its aqueous vapour tension, as expired, is about 39 mm. Hg. In the alveoli we may assume the air to have a temperature of 37° C. and a tension of aqueous vapour of 45 mm. Hg. Thus when a man is breathing air at a pressure of 760 mm. Hg., the pressure of the mixture of permanent gases in the alveoli of his lungs will be only 760—45, *i.e.* 715 mm. Hg.*

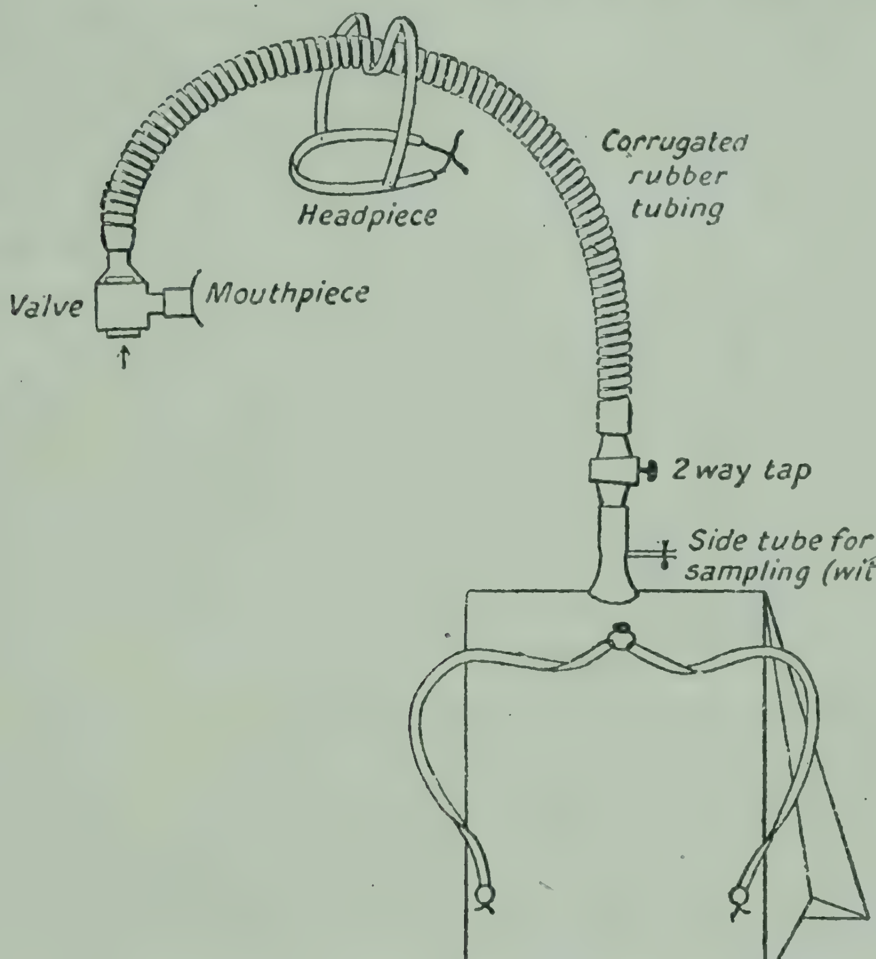

Fig. 489. Douglas' bag, with valves for collection of expired air.

Calculation from these data and from the volume expired shows that, whereas about 250 c.c. of oxygen are used up per minute by a normal resting man, only about 215 c.c. of carbon dioxide are added to the expired air in the same time, while the total *volume* of nitrogen leaving the lungs is the same as that taken in. In the analyses, the nitrogen *percentage* is seen to be higher in the expired air. This is because the volume at N.T.P. of air expired is less than that inspired, owing to the disappearance of a certain amount of oxygen, without the production of a corresponding amount of carbon dioxide, so that the *relative* amount of nitrogen is slightly increased. The reason for this disappearance of oxygen is that when fats and proteins are being consumed, some of it is used for the combustion of hydrogen and for the partial oxidation of nitrogen, as well as in burning carbon. The ratio of the volumes $\frac{\mathrm{CO_2}}{\mathrm{O_2}}$ which are exchanged in a given time, and which is called the *respiratory quotient*, is normally about 0·85, but varies according to the nature of the materials subjected to combustion in the body and to other conditions.

---

* It is generally assumed that the tension of aqueous vapour in alveolar air is 47 mm., *i.e.* that it is in equilibrium with *water* at 37° C. Direct experiment by Christie and Loomis (*J. Physiol.*, 1932, **77**, 35) gives a tension of aqueous vapour of only about 45 mm. Hg in quiet breathing, and still less during hyperpnœa.

Alveolar Air. As already explained, only about 360 c.c. of the 500 c.c. of air drawn in at an average breath reach the alveoli, the other 140 c.c. being dead space air. Hence, the alveolar air must contain more carbon dioxide and less oxygen than the mixed expired air, which consists of alveolar air *plus* the unchanged dead space air, which precedes it on expiration.

At the end of an expiration, the dead space has been swept out by, and remains filled with, alveolar air. Based on this fact, a sample of alveolar air may be obtained for analysis in the following way (Haldane and Priestley).* A piece of indiarubber tubing is taken, of about 1 inch diameter and 4 feet long. Into one end (Fig. 490) is fitted a mouthpiece, near to which is a gas sampling-tube, which is provided with three-way taps at both ends. Before an experiment the sampling-tube is completely evacuated. The subject of the experiment, after breathing *normally* a few times, puts his mouth to the tube at the end of a normal inspiration, expires quickly and deeply, and closes the mouthpiece with his tongue. The tap of the sampling-tube is then turned, and the air near the mouthpiece, which is that last expelled from the lungs, rushes into it. The tap of the tube is then turned off, and the gas sample removed for analysis. A similar sample is then taken, in which the subject expires deeply at the end of a normal expiration. This sample will contain slightly more $\mathrm{CO_2}$ and less $\mathrm{O_2}$ than that obtained at the end of inspiration. The mean of the two samples is taken as the average composition of the subject's alveolar air.

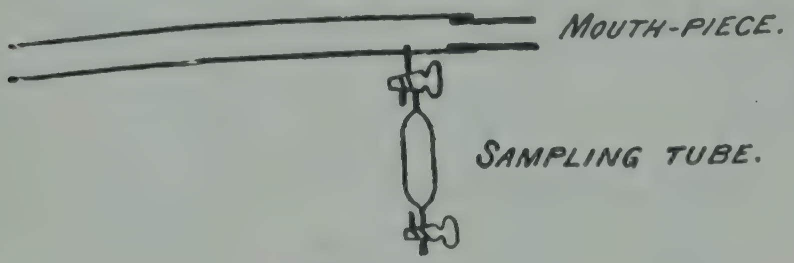

FIG. 490.

The composition of the alveolar air in a resting subject at normal atmospheric pressure is nearly constant, though showing variations from one individual to another. It also varies with posture ; the $\mathrm{CO_2}$ content may be 0·3 to 0·4 per cent. higher when supine than when standing erect, apparently because there is less blood and more air in the lungs when standing.† We may take the average composition for adult men at 760 mm. pressure, to be as follows :—

MEAN COMPOSITION OF ALVEOLAR AIR. (Adult Men.)

	Volumes per cent. (dry	Pressure mm. Hg (moist)
Carbon dioxide	5·50	39
Oxygen	13·80	99
Nitrogen	80·70	577
Water vapour	0·00	45
	100·00	760

It is often better to express the data regarding respiratory airs in terms of partial pressures, as in the last column of this table, than in terms of percentage composition. From Dalton's law we know that the total pressure exerted by a mixture of gases is equal to the sum of the separate pressures which each gas would exert if it alone occupied the whole volume. Aqueous vapour must be considered as one of the gases in alveolar air, and its partial pressure at 37° C. (= 45 mm.) allowed as a part of the total (*i.e.* barometric) pressure. The following example will explain the calculation :—

---

* HALDANE and PRIESTLEY. *J. Physiol.*, 1904, **32**, 225.

† MACKAY. *J. Physiol.*, 1943, **102**, 228.

Suppose that a sample of alveolar air had the composition (dry), CO_2 = 5·6 per cent. ; O_2 = 13·7 per cent. ; N_2 = 80·7 per cent. by volume, and that the barometer was at the time at 755 mm. Hg.

Then, since aqueous vapour = 45 mm. Hg, the remaining gases together contribute 710 mm. Hg, and of this

$$CO_2 = \frac{5\cdot 6}{100} \times 710 = 39 \text{ mm. Hg.}$$

$$O_2 = \frac{13\cdot 7}{100} \times 710 = 98 \text{ mm. Hg.}$$

$$N_2 = \text{the remainder (or } \frac{80\cdot 7}{100} \times 710) = 573 \text{ mm. Hg.}$$

These are the pressures exerted by each gas on any surface boundary.

The range for CO_2 pressures is about 32 to 45 mm. for men. In children and women the pressure of carbon dioxide is on the average a little less, and the oxygen a little more.

The difference between the composition of expired air and alveolar air is determined by the dilution of the alveolar air with that contained in the dead space. Hence, with shallow breathing there will be a large difference, but this will decrease with increased depth of respiration. Thus, if the alveolar air contained 6 per cent. CO_2 and the dead space amounted to 150 c.c., the expired air would contain only 3 per cent. CO_2 when the person was taking in only 300 c.c. at each respiration. If, however, he was breathing slowly and deeply, so as to raise the tidal air to 1,500 c.c., only one-tenth of this would be represented by the dead space, and the expired air would contain nine-tenths as much CO_2 as the alveolar air, *i.e.* 5·4 per cent.

The dead space can be determined by measuring the volume and estimating the composition of the air in an average expiration, and by finding the composition of the alveolar air. Then dead space

$$= \frac{\text{Tidal air vol.} \times (CO_2 \text{ per cent. in alveolar air} - CO_2 \text{ per cent. in expired air})}{CO_2 \text{ per cent. in alveolar air}}$$

The changes in the composition of alveolar air with each breath are by no means so great as those produced in the tidal air, since the latter forms only a small proportion of the total air in the lung alveoli. Thus, at the end of a normal expiration, the alveoli still contain 2,500 c.c. of gases. In inspiration 360 c.c. atmospheric air are taken into this space and mixed with the 2,500 c.c. already there. The " ventilation coefficient " in quiet breathing is therefore only one-seventh, and the change in the oxygen and carbon dioxide content of the alveolar air produced by this access of 360 c.c., will amount to less than one-half per cent. This is illustrated by the following figures from Haldane and Priestley,* giving the alveolar content in carbon dioxide at the end of inspiration and at the end of expiration respectively.

ALVEOLAR CO_2 PER CENT.

Individual	Alveolar CO_2 at end of inspiration. (Mean of twelve observations) per cent.	Alveolar CO_2 at end of expiration per cent.	Mean
J. S. H.	5·54	5·70	5·62
J. G. P.	6·17	6·39	6·28

We can thus speak of an average composition of alveolar air, which, in spite of the constant ventilation, remains almost constant in composition.

---

* HALDANE and PRIESTLEY. *J. Physiol.*, 1904, **32**, 222.

THE RESPIRATORY FUNCTION OF THE BLOOD

The Blood Gases. It was shown by Magnus, in 1837,* that the blood passing to the lungs contained more carbon dioxide and less oxygen than that passing away from the lungs. This proved that combustion does not occur in the lungs, as Lavoisier had suggested,† but that the blood acts simply as a carrier of the oxygen from the lungs to the tissues, and of the carbon dioxide from the tissues to the lungs. We thus learnt to distinguish between external and internal respiratory processes. If any further proof is required that it is the tissues themselves which utilise oxygen and produce carbon dioxide, we may refer to the fact that any surviving tissue, quite free from blood, can be shown by the use of the microrespirometer (p. 146), to absorb oxygen and give out carbon dioxide. A consideration of the process of external respiration necessitates an investigation of the manner in which gases are held by the blood and of the factors which are responsible for the transfer of oxygen and carbon dioxide from alveolar air to blood, and from blood to alveolar air.

If blood be exposed to a vacuum, preferably at body temperature, the whole of its contained gases are given off. In this manner, about 60—70 c.c. of mixed gases may be obtained from 100 c.c. of blood; they consist of oxygen, carbon dioxide and nitrogen (with argon in insignificant quantities). The nitrogen forms only about 1 volume per cent. in both arterial and venous blood. The amounts of oxygen and carbon dioxide in these two kinds of blood differ, however, within wide limits. The following Table ‡ represents the average composition of the gases obtained from arterial and venous bloods in man:

From 100 vols.	May be obtained		
	Of oxygen	Of carbon dioxide	Of nitrogen
Of arterial blood .	19·0 ± 0·49 vols. .	49·9 ± 0·51 vols. .	0·9 vols.
Of venous blood .	10·6 ± 0·36 ,, .	57·8 ± 0·35 ,, .	,, ,,

Measured at 760 mm. and 0° C.

Simple evacuation, though a standard method, is very laborious, and demands relatively large amounts of blood. The modern methods (p. 498), enable accurate determinations to be made on 0·5 to 2·0 c.c. of blood.

Laws of Solubility of Gases in Liquids. If a gas is in simple solution, the amount of it dissolved varies directly with its partial pressure. When only one gas is present, the whole pressure is due to that one gas. Thus, if water dissolves a certain quantity of a gas at a given temperature and pressure, it will take up twice as much if the pressure of the gas be doubled. The absorption coefficient of a liquid for a gas at a given temperature is the number of cubic centimetres of gas, measured at N.T.P., which will be taken up at the particular temperature by 1 c.c. of the liquid when the gas is at a pressure of 760 mm. Hg. The absorption coefficient diminishes with rise of temperature. The following table represents the absorption coefficients for some important gases in water at various temperatures:

Temperature	Oxygen	Carbon dioxide	Carbon monoxide	Nitrogen §
0	0·0489	1·713	0·0354	0·0239
10	0·0380	1·194	0·0282	0·0196
20	0·0310	0·878	0·0232	0·0164
30	0·0262	0·665	0·0200	0·0138
40	0·0231	0·530	0·0178	0·0118

From this table we see that 100 c.c. of water at 0° C. will absorb 4·89 c.c oxygen at one atmosphere pressure. If the pressure is reduced to one half a atmosphere, the volume of gas absorbed, when measured at N.T.P., will be 2·45 volumes. On a graph, of which the ordinates represent the amount of gas dissolved, and the abscissæ the different pressures of the gas, we shall get a straight line. The amount absorbed depends on the partial pressure of the particular gas considered, and is not altered by the presence of other gases at the same time. The normal pressure of the whole atmosphere is 760 mm. Since the atmosphere consists roughly of four parts of nitrogen with one part of oxygen, the atmospheric pressure is due, as to one-fifth to the oxygen, and as to four-fifths to the nitrogen. If we shake up water at 0° C. with the atmospheric air at the ordinary pressure, 100 c.c. of water will absorb 4·89 c.c. × $\frac{1}{5}$ of oxygen, and of nitrogen 2·39 c.c. × $\frac{4}{5}$. We may therefore extend our statement as to the solubility of gases in liquids, and say that *the amount of gas which a liquid will dissolve is directly proportional to the partial pressure of the gas* (Henry's law).

‡ After data from Looney and Jellinek. *Am. J. Physiol.*, 1937, **118**, 225.

§ Atmospheric "nitrogen" contains 1·185 per cent. argon, and this mixture is slightl less soluble than pure nitrogen, *e.g.* 0·0134 at 30° C.

When water is saturated with a gas at a given pressure, a state of equilibrium exists between the gas dissolved and the gas in contact with the liquid. At equilibrium, the number of molecules of the gas entering the liquid in unit time must equal the number of molecules of the gas leaving it. If we remove the liquid after saturation, say, at one atmosphere, to a vessel where it is in contact with the same gas at a pressure of half an atmosphere, the liquid will give off gas until the amount left in solution is diminished to one-half. The gas dissolved in a liquid thus exerts a pressure or *tension* tending to make it escape from the liquid. The only way in which we can measure this tension is by finding what pressure of that gas is in equilibrium with the liquid. Thus, if we take some water containing carbon dioxide in solution, divide it into two parts, and shake up one part with a gaseous mixture containing 4 per cent. of carbon dioxide and the other part with a mixture containing 5 per cent. of carbon dioxide, and find that the solution loses gas to the former and takes up carbon dioxide from the latter, we may conclude that the tension of carbon dioxide in the original liquid was something between 4 and 5 per cent. of an atmosphere. It is by similar means that the tensions of gases in the blood are measured, the instruments for this purpose receiving the name of *aerotonometers*.

The solvent power of water for gases is diminished if the water contains solid substances in solution. The absorption coefficient of blood plasma for gases is 97·5 per cent. of that for pure water, and of blood 92 per cent., that of the blood corpuscles being as low as 81 per cent. owing to their smaller content of free water. We may thus compute the absorption coefficient (for *physical* solution) of blood plasma, blood and blood corpuscles for oxygen, nitrogen and carbon dioxide.

	Oxygen		Nitrogen		Carbon dioxide	
	15°	38°	15°	38°	15°	38°
Blood plasma . .	0·033	0·023	0·017	0·012	0·994	0·541
Blood	0·031	0·022	0·016	0·011	0·937	0·511
Blood corpuscles .	0·025	0·019	0·014	0·010	0·825	0·450

THE CARRIAGE OF OXYGEN BY THE BLOOD

The Oxygen Dissociation Curve. From the above Table we see that 100 volumes of blood at 38° C. would contain 2·2 vols. of oxygen *in solution*, if the blood had been brought into equilibrium with oxygen at a pressure of one atmosphere. The blood in the lungs is, however, exposed to air which contains only about one-sixth of its volume of oxygen, so that the total amount of oxygen present in physical solution in arterial blood cannot be more than about 0·36 vols.

---

[*] Van Slyke and his collaborators have estimated the solubility co-efficient of CO_2 in blood plasma at 38° C. as 0·510 instead of 0·541 as given by Bohr.

per cent. But, as a matter of fact, blood saturated with air contains about twenty volumes per cent. of oxygen, so that most of the oxygen cannot be in merely physical solution, but must be in some form of reversible combination with some of the constituents of the blood ; and, in fact, practically the whole is contained in the red blood corpuscles, in combination with hæmoglobin, the plasma containing no more than can be accounted for by simple solution. This is further proved by the fact that we can displace the oxygen (O_2) from the oxyhæmoglobin by equal volumes of CO or NO.

The relation between the partial pressure of oxygen and the proportion of oxyhæmoglobin present (or "percentage saturation") when equilibrium is reached under varying conditions, can be investigated in the following way :

A cylindrical glass vessel of about 300 c.c. capacity is filled with a gaseous mixture of known composition, containing oxygen. Into it are introduced 2 or 3 c.c. of blood or of hæmoglobin solution. It is then immersed in a horizontal position in a water bath at a constant temperature, and slowly revolved. In this way the blood is continually spread in a thin layer over the sides of the vessel. At the end of half an hour it will have attained equilibrium with the gaseous mixture, and a sample may be drawn off for determination of its percentage oxygen saturation. A sample of the gas is also analysed to find the final partial pressure of its components. The results, plotted as in Fig. 491, where abscissæ are pressures of oxygen in mm. Hg, and ordinates are percentage saturations, form what is called the "*dissociation curve*" of the blood (or of the oxyhæmoglobin). It tells us what percentage of the hæmoglobin is saturated with oxygen at each partial pressure of that gas.

It will be noted that, as the partial pressure of oxygen is lowered, little oxygen is given off until the partial pressure of the oxygen is diminished to about 30 mm. Hg (Fig. 491). At this point a rapid evolution of oxygen begins, and continues at falling pressure until, at 0 mm. pressure, all the oxyhæmoglobin is converted into hæmoglobin. The same observation may be made in the reverse direction, *i.e.* if a solution of reduced hæmoglobin be exposed to gradually increasing pressures of oxygen, it will be found that the greatest absorption takes place between 0 and 30 mm. Hg. After this point, the oxygen is more and more slowly absorbed until it asymptotically reaches the point of complete saturation.

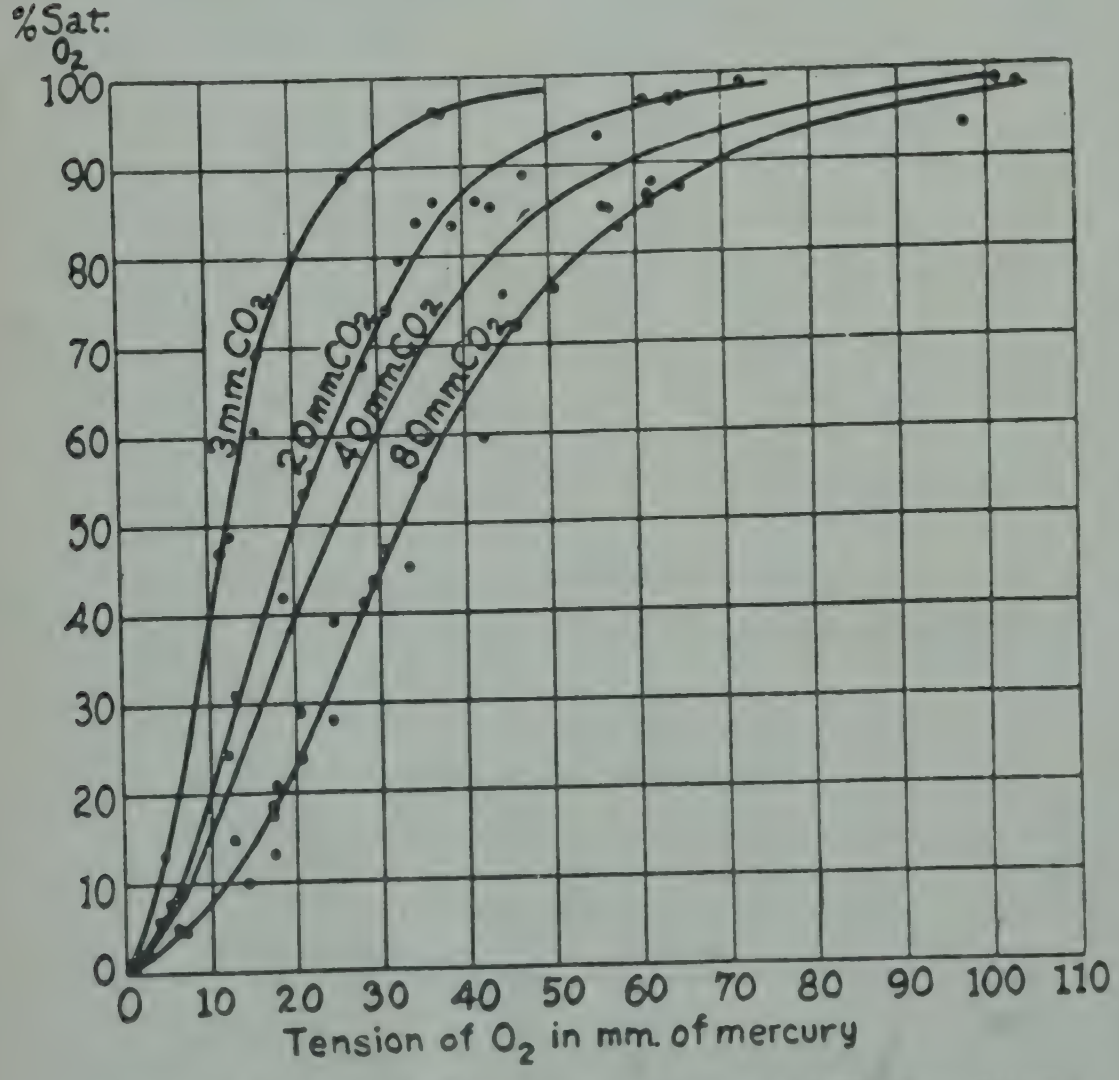

FIG. 491. Oxygen Dissociation Curves of Human Blood, exposed to pressure of 3, 20, 40 and 80 mm. of CO_2. (BOCK, FIELD and ADAIR. *J. Biol. Chem.*, 1924, **59,** 366.)

The dissociation curve approximately fits the equation (Hill's equation [*]) :—

$$\frac{y}{100} = \frac{Kx^{2.5}}{1 + Kx^{2.5}}$$

---

[*] A. V. HILL. *J. Physiol.*, 1910, **40,** *Proc.* iv. ; W. E. L. BROWN and A. V. HILL. *Proc. R. S.*, 1923, **94B,** 297.

where x = oxygen pressure, y = per cent. saturation of the Hb, and K the dissociation constant. Hence if one point is actually determined, the rest of the curve can be approximately calculated. The theoretical significance of the curve is doubtful.* The fact that the curve is not a rectangular hyperbola, though somewhat similar to one, is important. The S-shaped part which it shows at the lower oxygen pressures means that with falling oxygen pressures the hæmoglobin gives up its oxygen more easily than the rectangular hyperbola would require. It is stated to be due to the formation of intermediary compounds of hæmoglobin with oxygen.

The dissociation curve of oxyhæmoglobin is largely altered by slight variations in the fluid in which the hæmoglobin is dissolved. The most important of these conditions are (1) the saline content of the fluid (as, *e.g.* in blood), (2) the reaction of the fluid, (3) the source of the hæmoglobin, *i.e.* the age and species of the animal from which it was prepared.

The effect of change of hydrogen-ion concentration, or so-called "Bohr effect," is important. In Fig. 491 is represented the influence of varying tensions of carbon dioxide on the dissociation curve. It will be seen that the higher the CO_2 tension in the blood, the less firmly is its oxygen held. In other words, carbon dioxide, or other acid, tends to expel oxygen from the blood. The normal tension of CO_2 in arterial blood is about 40 mm. Hg. At 150 mm. oxygen pressure the blood is practically saturated with oxygen, whatever (within physiological limits) the pressure of the carbon dioxide; but at lower pressures of oxygen, the pressure of carbon dioxide makes a considerable difference to the oxygen saturation. Thus, at an oxygen pressure of 20 mm. Hg the amount of oxyhæmoglobin formed is 80 per cent. when the carbon dioxide pressure is 3 mm., whereas at a pressure of carbon dioxide of 40 mm. the degree of saturation of the hæmoglobin is only 40 per cent. In consequence of this fact, in the tissues where the carbon dioxide tension is high, the oxyhæmoglobin will be dissociated with greater ease, so that oxygen will readily be set free where it is most wanted.

A change in the opposite direction is produced when part of the hæmoglobin is converted into carboxy-hæmoglobin or methæmoglobin,† the curve of dissociation being moved to the left and having its S-inflection reduced, *i.e.* the oxygen is more difficult to remove from the hæmoglobin.

Another important factor which affects the oxyhæmoglobin dissociation curve is, of course, the temperature at which equilibrium is effected. Rise of temperature, like rise of H-ion concentration, flattens out the curve, *i.e.* rise of temperature facilitates the removal of oxygen from oxyhæmoglobin.‡

Uptake of Oxygen by the Blood. The foregoing considerations relate to the state of equilibrium between hæmoglobin and oxygen, but give no information as to the speed with which that state is reached. In passing from alveolar air to oxyhæmoglobin, the following phases must be considered in the transport of oxygen, and all must take time :—

1. Passage through the alveolar membrane.
2. Passage into the blood plasma.
3. Passage through the erythrocyte envelope.
4. Diffusion into the erythrocyte cytoplasm.
5. Combination with hæmoglobin.

All phases together are expressed in the so-called diffusion constant (*v.* p. 740), but here we are concerned with phases 2 to 5.

Phase 5, the velocity of the reaction $Hb + O_2 \rightarrow HbO_2$ is so high ($k = 132$) that it may be regarded for physiological purposes as instantaneous : the speed of the reverse reaction of reduction, though less, is also high ($k = 17{\cdot}5$).§

An idea of the velocities concerned in phases 2 to 5 collectively can be obtained by measuring the speed of uptake (and conversely, of the yielding-up) of oxygen by the blood. The velocity of the exchanges is probably about one-tenth of that for phase 5 alone, but will clearly depend on the extent of surface of blood exposed to the gas phase, and if this is not large the speed will be still less. Fig. 492 illustrates these velocities under comparable, but artificial, conditions for uptake and release of oxygen (and of CO_2): in the better conditions in the body these speeds would no doubt be considerably greater.

Uptake of Oxygen in the Lungs. We are now in a position to understand how the oxygen is taken up by the blood, as it circulates round the pulmonary alveoli. Arterial blood, such as that which fills the pulmonary veins and the systemic arteries, is very nearly (viz. about 98 per cent.) saturated with oxygen (*e.g.* it contains about 19·5 volumes out of a possible 20 volumes per cent.). Venous blood, as passed to the lung, is about 66 per cent. saturated (*i.e.* it contains about 13 volumes of oxygen per cent.). The oxygen tensions are about 97 mm. for arterial blood, and 40 mm. for venous blood, *i.e.* at a tension of 97 mm. the blood is nearly saturated. The pressure of oxygen in the alveoli is normally about the same, being usually about 98 mm. Hence the venous blood brought to the alveoli, being only separated from the alveolar air by the thin alveolar membrane, and, aided by the Bohr effect caused by the release of CO_2 from the blood, will rapidly take up oxygen from it, and will speedily approach the point of saturation. In its rapid transit through the lungs, however, final equilibrium may not be reached, because, as shown in Fig. 492, the rate of uptake of oxygen slows down as saturation is neared. Also, the arterial blood is never quite in equilibrium with alveolar air, because some venous blood from bronchial veins drains into the pulmonary veins. (In some pathological cases also, part of the pulmonary circulation leads through collapsed or otherwise non-ventilated alveoli. In such cases even breathing pure oxygen fails to give full saturation of the arterial blood.)

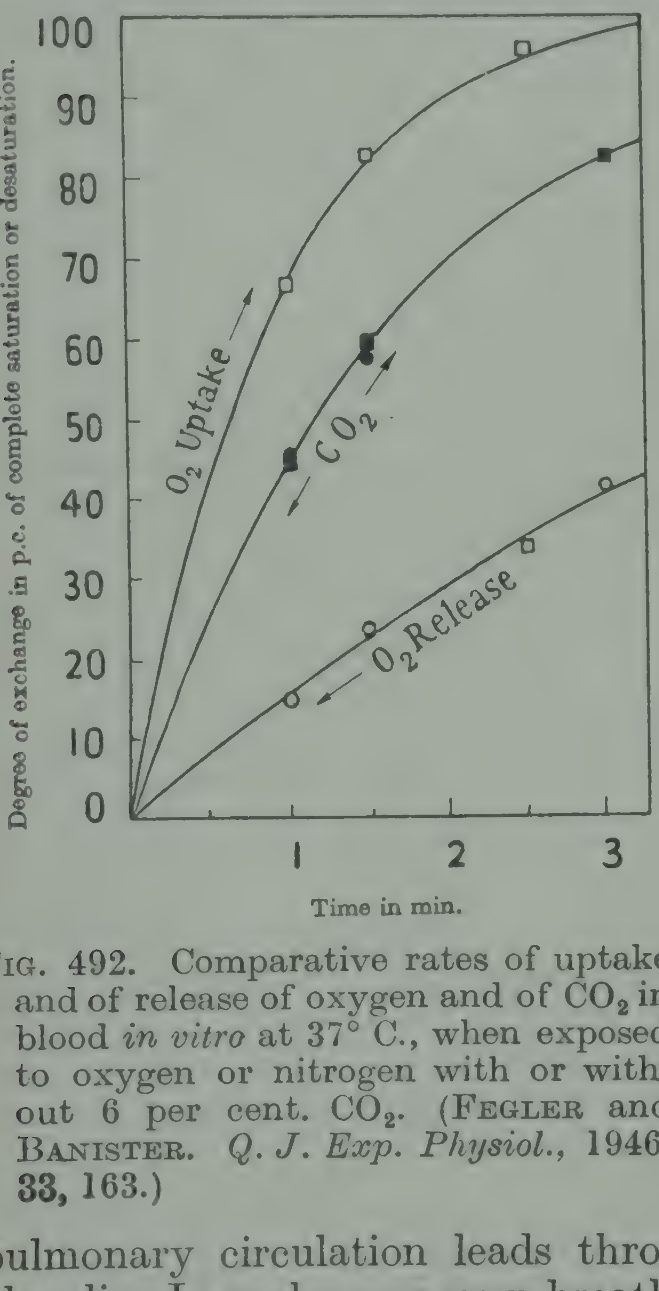

FIG. 492. Comparative rates of uptake and of release of oxygen and of CO_2 in blood *in vitro* at 37° C., when exposed to oxygen or nitrogen with or without 6 per cent. CO_2. (FEGLER and BANISTER. *Q. J. Exp. Physiol.*, 1946, **33,** 163.)

Passage of Oxygen to Tissues. The blood, thus laden with oxygen, is sent from the left side of the heart to all parts of the body. It must be remembered that in the tissues, as in the lungs, the hæmoglobin does not exchange its oxygen directly. In both cases, the interchange is effected through the intermediation of capillary wall and of the plasma and, in the tissues, of the tissue fluid as well. Since the tissue elements are constantly using up oxygen, they absorb any oxygen that is present in the surrounding fluid. There is, in consequence, a descending slope of oxygen tensions from red blood corpuscle through plasma, vessel wall, tissue fluid and tissue element and (assuming that all the media are permeable to it) the oxygen is bound to follow this gradient. The cell draws from the tissue fluid, and the tissue fluid from the plasma, so that the oxygen tension in the plasma sinks. The immediate result is an evolution of oxygen from the oxyhæmoglobin and the oxygen set free is taken up by the plasma, to be in turn passed on to the tissue fluid and cells.

THE CARRIAGE OF CARBON DIOXIDE BY THE BLOOD

Carbon dioxide is soluble in water, and therefore in blood, which at 38° C., when exposed to a pressure of 40 mm. CO_2, *i.e.* about that of arterial blood, would hold, in a state of *physical* solution, about 2·7 volumes of CO_2 per 100 c.c. of blood. But blood, as drawn from the body, may contain as much as 60 volumes per cent. of carbon dioxide, held in such a state as to be removable in a vacuum, and we have now to inquire why it is that blood is capable of holding such large amounts of carbon dioxide. A further fact is that this carbon dioxide can also be expelled from it by the addition of strong acids. This suggests at once that the carbon dioxide is held in the blood as a bicarbonate or carbonate, from which union it is expelled by acid, or when the blood is exposed to a vacuum. It should further be noted that, after all possible carbon dioxide has been drawn from blood by exposure to a vacuum, no more can be driven off on addition of a strong acid. One method of expulsion is as good as the other, so far as the total yield of CO_2 from whole blood is concerned.

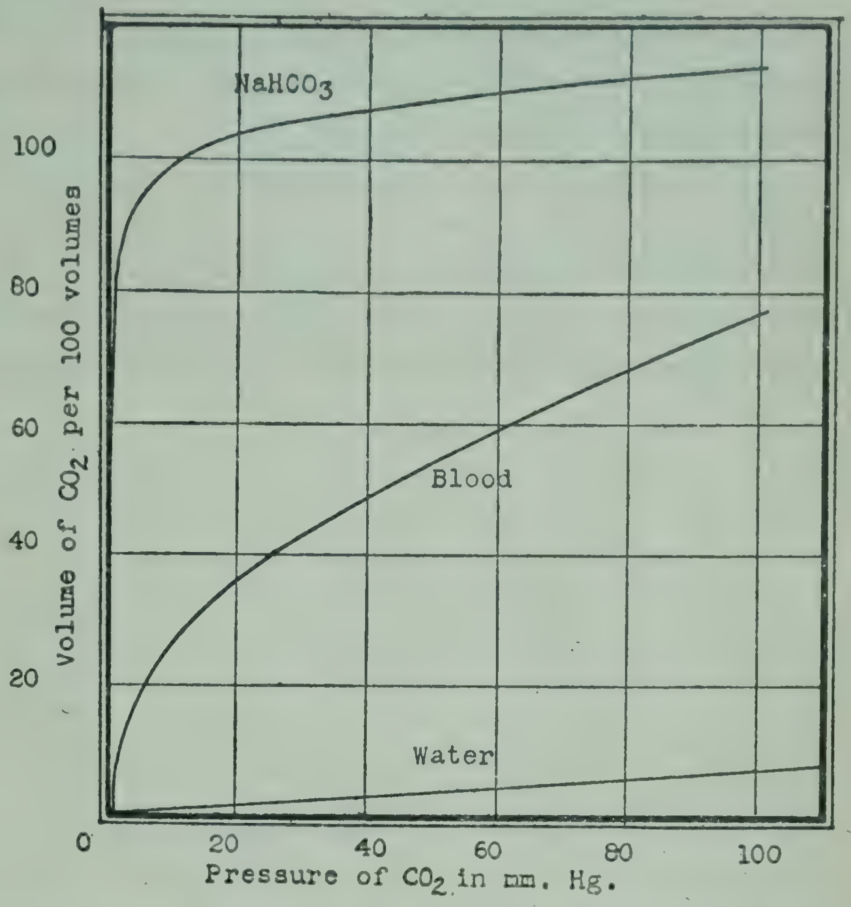

FIG. 493. Comparison between the CO_2 Dissociation Curves of Blood and of Sodium Bicarbonate Solution of a concentration of 0·0484 N. The amounts of CO_2 held in physical solution in water are also shown (lowest line). (Redrawn from data by PARSONS. *Journ. Physiol.*, 1919, **53**, 42, 340.)

Carriage as Bicarbonate. Valuable information has been obtained by the study of the CO_2 dissociation curves of blood, and of somewhat similar chemical systems. These are made by saturating samples of the fluid with a series of gas mixtures of varying CO_2 pressure, and then determining the volume of CO_2 which can be expelled from the fluid by addition of a strong acid.

The CO_2 dissociation curve of blood when plotted on logarithmic paper gives a straight line, the slope of which depends on the oxygen capacity.* The slope between 60 mm. and 30 mm. CO_2 can be calculated from the equation :—

$$\Delta\,(CO_2)_{60-30} = 0{\cdot}334\,(O_2\ \text{Cap}) + 6{\cdot}3.$$

Using this, a curve can be constructed from one point.

If we compare the CO_2 dissociation curve of blood with that of a solution of sodium bicarbonate, containing the same amount of available base (0·0484 N.), it is evident, as is shown in Fig. 493, that there is a very great difference between them. For, whereas all the carbon dioxide is removed from the blood when the pressure of CO_2 is reduced to zero (*i.e.* in a vacuum), it is impossible, by lowering the pressure, to remove from the bicarbonate solution more carbon dioxide than corresponds to its conversion to carbonate, according to the equation—

$$2NaHCO_3 = Na_2CO_3 + CO_2 + H_2O\,;$$

i.e. from an aqueous bicarbonate solution only half as much carbon dioxide can be expelled by a vacuum as by addition of a strong acid :—

$$2NaHCO_3 + 2HCl = 2NaCl + 2CO_2 + 2H_2O.$$

The carbon dioxide in blood is chiefly bound in the plasma in the form of sodium bicarbonate. This is shown by the fact that the amount of carbon dioxide which can be expelled from the plasma by addition of a strong acid agrees with the amount of base found by titration, and further, all this bicarbonate can be removed as such by dialysis. If plasma is saturated with carbon dioxide at atmospheric pressure, practically all the available base of the plasma will be present in the form of sodium bicarbonate. The amount of bicarbonate present in the plasma under any circumstances can readily be determined, and is called the "*alkali reserve.*" *

---

* PETERS *et al.* *J. Biol. Chem.*, 1923, **56**, 745 ; **58**, 769.

If we examine the dissociation curve of blood plasma, we find that separated plasma behaves less like blood than like an aqueous bicarbonate solution (Fig. 494). This is confirmed by the well-known fact that, although all the CO_2 can be removed from blood by a vacuum, this cannot be done with blood plasma; after plasma has been thoroughly pumped out *in vacuo*, addition of acid can still set free carbon dioxide from it. It is clear then, that if the carbon dioxide *is* fixed in the form of bicarbonates in the blood, there must also be in the blood some substance which, while not interfering with the taking up of carbon dioxide by the base when the blood is exposed to increasing pressures of carbon dioxide, will yet act as an acid does, and drive out carbon dioxide, ultimately to completion, as the partial pressure of CO_2 falls. *This substance must be contained in the corpuscles.* It is the corpuscles which *in vacuo* act like an acid, expelling carbon dioxide. This can be proved by the simple experiment of mixing thoroughly well-evacuated plasma with corpuscles, when CO_2 is at once evolved on further evacuation.

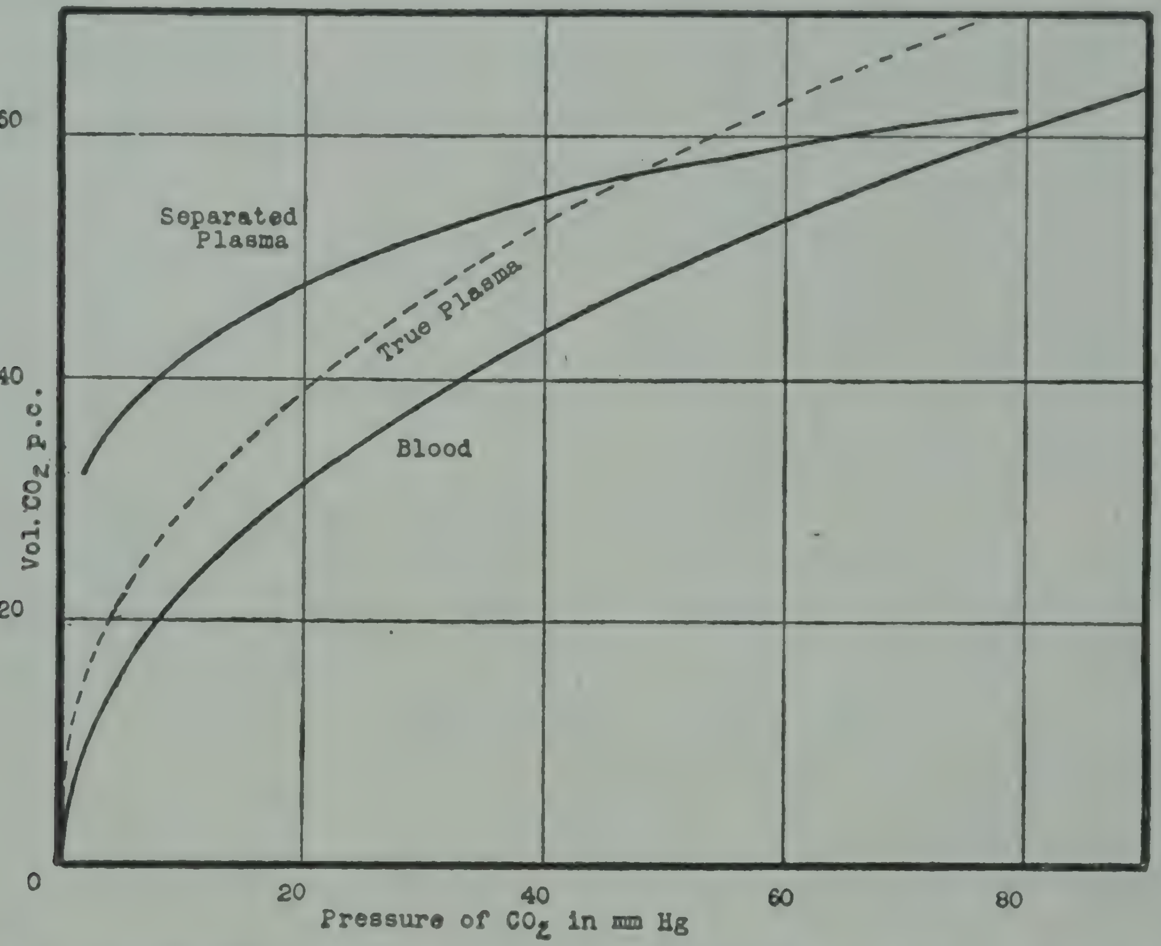

FIG. 494. Comparison between the CO_2 Dissociation Curves of Blood, and of Separated Plasma and true Plasma from the same Blood. (Redrawn from data by JOFFE and POULTON. *J. Physiol.*, 1920, **54,** 129.)

It is also shown by the comparison of true plasma with separated plasma. The name "*true plasma*" is given to plasma drawn direct from the blood, without any change in its gas content. Specimens of true plasma are obtained by centrifuging the blood under a layer of liquid paraffin, to hinder exchange of gases at the surface, and then pipetting off the plasma layer. This represents the plasma which was in a state of equilibrium with the corpuscles of the blood when this was centrifuged.

Now, if blood be exposed to gas mixtures containing different pressures of carbon dioxide, as in making a CO_2 dissociation curve, it is a simple matter to separate off samples of true plasma corresponding to each pressure of CO_2, to determine their bicarbonate content, and thus to obtain a curve which may be called the dissociation curve of true plasma. Such a curve represents the carbon dioxide content of plasma which at each point is in equilibrium with the corpuscles. When this is done, it at once becomes evident that the true plasma behaves in a way entirely different from the separated plasma discussed above. Fig. 494 illustrates this difference.

---

* Strictly speaking, the "alkali reserve" is defined as the volume per cent. of CO_2 yielded by the plasma on treatment with acid after the plasma has been previously brought into equilibrium with a gas mixture containing CO_2 at 40 mm. pressure (alveolar air).

The true plasma shows a curve which has much the same slope as that for blood, but at a higher level; the plasma of blood, when in equilibrium with its corpuscles, has sometimes a higher percentage bicarbonate content not only than separated plasma, but even than the whole blood. This is because the carbon dioxide-fixing power of corpuscles is less than that of plasma.

The explanation of the way in which the corpuscles confer upon the plasma the power of fixing CO_2 by the formation of bicarbonate was given by Hamburger,* who showed that when carbon dioxide is added to blood the following changes occur :—

(1) The bicarbonate content of the plasma is increased.
(2) The chloride content of the plasma is diminished.
(3) The chloride content of the corpuscles is increased.

The cations (base) of the plasma and corpuscles are unchanged.

The reason why blood can carry much more carbon dioxide than can water is that the H· ions formed in the reactions :

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^{\cdot} + HCO_3{}'$$

are all mopped up by buffers in the blood, so that the reaction is accelerated from left to right. In consequence of this the CO_2 carrying power of the blood runs parallel to its buffering power. Some of the buffers of the blood are present in the corpuscles and some in the plasma : in the corpuscles we have the non-diffusible anions of hæmoglobin, diphosphoglycerate and adenosine triphosphate, while in plasma we have small amounts of phosphate, and the plasma proteins.

Since the red cells are freely permeable to CO_2, and since hæmoglobin is quantitatively the most important blood buffer, it follows that when carbon dioxide enters the blood and reacts with potassium hæmoglobinate, far more $HCO_3{}'$ ions are formed in the corpuscles than in the plasma. The red cells are also easily permeable to $HCO_3{}'$ ions, and so, since there is a gradient of $HCO_3{}'$ from cells to plasma, this ion will tend to migrate out again into the plasma. But the envelope of the red cell is not permeable to cations, and so the $HCO_3{}'$ ions cannot be accompanied out by the positively charged ions, such as $K^{\cdot}$. Hence, owing to the tendency of the $HCO_3{}'$ to migrate, the cell becomes positively charged, and this, so to speak, sucks into it negatively charged ions, such as Cl′, which are abundant in plasma. This offers an explanation of the so-called Hamburger interchange, viz. that as CO_2 is added to blood the plasma bicarbonate increases and the plasma chloride diminishes. The advantage of this is that it enables the excellent buffering power of the corpuscles to be shared out with the poor buffering power of the plasma.

The buffering functions of the organic phosphates are of a different nature. Unlike hæmoglobin, their amounts in the corpuscle can change. When CO_2 or other acid is added, for instance, diphosphoglycerate is diminished, and so base is set free.

The Effect of Oxygenation on Carbon Dioxide Carriage. It was found by Christiansen, Douglas and Haldane † that reduced blood has a greater carbon dioxide capacity than oxygenated blood (Fig. 495).

In other words, oxygen tends to displace carbon dioxide from the blood, much as carbon dioxide is known to displace oxygen. They explained this phenomenon on the hypothesis that reduced hæmoglobin is a weaker acid than oxyhæmoglobin, *i.e.* its salts mop up $H^{\cdot}$ ions more easily.

The importance of this observation lies in the fact that during its passage along the systemic capillaries, not only is carbon dioxide added to the blood, but also oxygen is withdrawn from it, and so the buffering power of the blood is raised, thus enabling more CO_2 to be taken up and *vice versâ* in passing the lungs.

---

* HAMBURGER. *Arch. f. Phys.*, 1892, 513 ; 1893, Suppl. 153 ; *Bioch. Ztschr.*, 1918, **86,** 309.

† CHRISTIANSEN, DOUGLAS and HALDANE. *J. Physiol.*, 1914, **48,** 244.

It is of interest in this connection to attempt to form an opinion of the carbon dioxide absorption curve of blood under the conditions which prevail in the body. Such a curve (for an R.Q. of about 0·8) is shown in Fig. 495, in which portions of the carbon dioxide curves for fully reduced and fully oxygenated blood are shown on a large scale. The curve AVB represents the *physiological carbon dioxide absorption or dissociation curve.* At the point A, which may be called the "*arterial point,*" since it represents the condition in arterial blood, the fully oxygenated blood at 41 mm. CO_2 contains 52·5 volumes CO_2 per cent. The point B represents the condition if the blood were fully reduced; it would then contain, at the pressure of CO_2 of 64 mm., not 61 per cent. of CO_2 (as would be the case had there been no loss of oxygen), but 66·5 per cent. Usually the blood does not nearly reach the fully reduced state in passing through the capillaries, but would in most cases stop at a point about in the position indicated by V in the figure. This corresponds to a gain of 5 volumes of CO_2, and therefore a loss (since the R.Q. is assumed to be 0·8) of about 6·3 c.c. of oxygen. The point V is thus a typical "venous point." It will be seen that in this instance at least half the increase in CO_2 content of the blood is due to the simultaneous reduction of oxygen content.

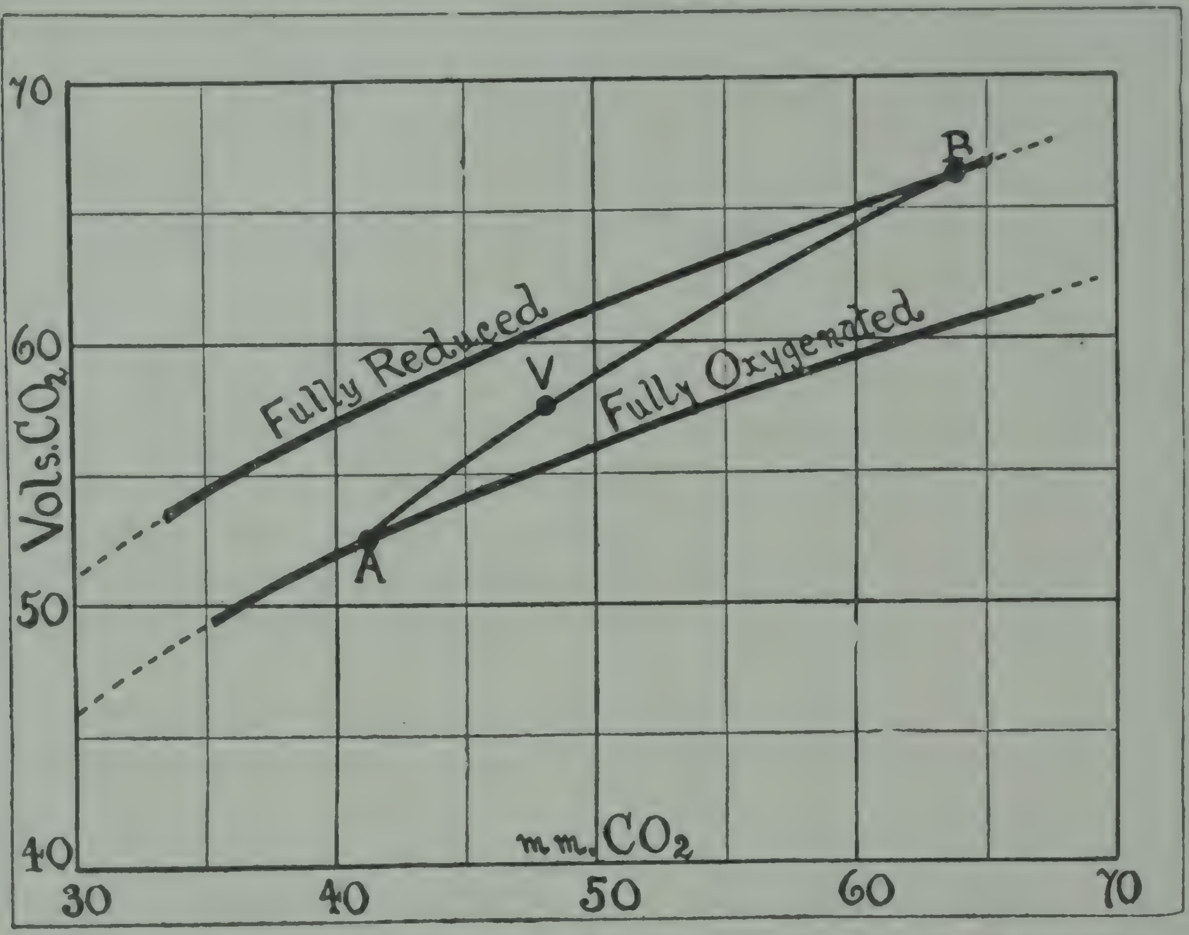

FIG. 495. CO_2 Dissociation Curves of Fully Reduced and Fully Oxygenated Human Blood (only part of the curve is shown). A V B is the physiological curve, along which the CO_2 dissociation operates in the body. (Redrawn from CHRISTIANSEN, DOUGLAS and HALDANE.)

The Blood Nomogram. We have seen that various quantities in the blood are related to more than one other quantity, *e.g.*—

(1) Oxygen saturation is related to oxygen partial pressure and to CO_2 partial pressure.
(2) CO_2 content is related to CO_2 partial pressure and to oxygen partial pressure.
(3) pH is related to (1) and (2).
(4) Plasma Cl is related to plasma CO_2, and so to (2) and (3),

and so on.

A little reflection makes it clear that all these properties of the blood are inter-related, and, in fact, L. J. Henderson showed that blood is a physico-chemical system in which many important variables are concerned. Some of these variables are :—

(1) Free oxygen (expressed by oxygen partial pressure).
(2) Combined oxygen (oxygen saturation of Hb).

(3) Free carbon dioxide (CO_2 partial pressure).
(4) Combined carbon dioxide (bicarbonate, etc.).
(5) *p*H of plasma.
(6) *p*H of corpuscles.
(7) Cl of plasma.
(8) Cl of corpuscles.
(9) Water distribution between plasma and corpuscles.

Now the relation between these and other variables for a given blood is such that, if *any two* of them are arbitrarily fixed at definite values, the remainder will thereby be fixed according to definite laws. For instance, if the p.p. of O_2 and of CO_2 are given particular values, then the *p*H of plasma and of corpuscles, the oxygen saturation, CO_2 content, Cl of plasma and of corpuscles must acquire certain values. Conversely, if we take that blood in a state of equilibrium, all the variables must have a certain value: if we alter any one of them, there will result compensatory changes in all the others when the new state of equilibrium has been reached. Henderson showed that the mutual relationships between these variables in a given blood can be expressed in the form of an alignment chart of the type shown in Fig. 496.

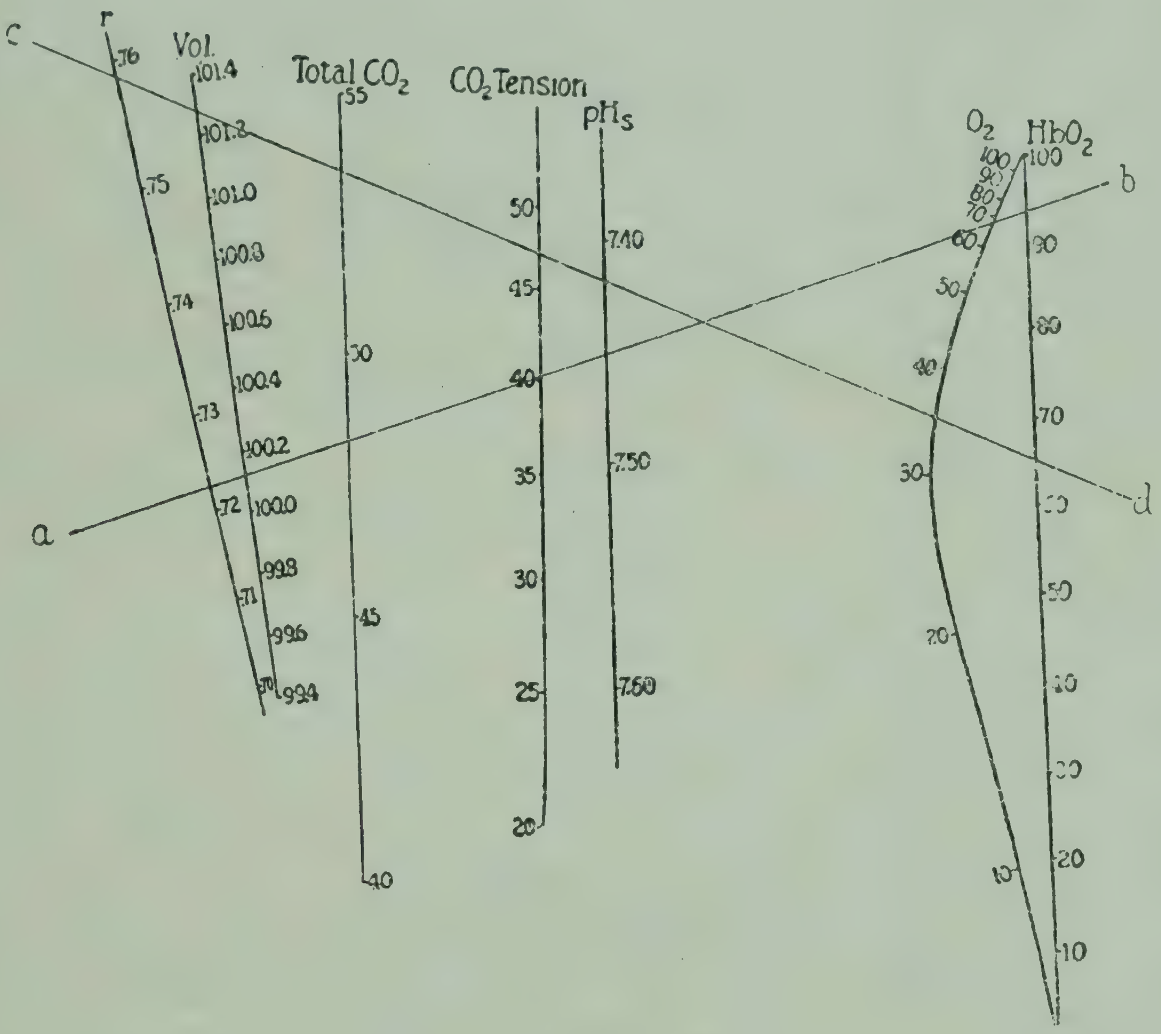

FIG. 496. Alignment Chart for a specimen of Human Blood. (From L. J. HENDERSON. *The Blood.*)

In using the nomogram of a particular individual's blood, any two determined points are joined by a straight line, which, if produced, will then cut the other points so as to give the remaining data for that blood. Thus the line *ab* might represent the conditions in arterial blood, and the line *cd* those in venous blood. Various other data are expressed in, or deducible from, this nomogram, which may be said to represent in graphic form the law of the blood. Thus, the line *r* represents the "Donnan ratio," and expresses the equilibrium between serum and corpuscles, *i.e.*,

$$r = \frac{[BHCO_3]_c}{[BHCO_3]_s} = \frac{[HCO_3]_c}{[HCO_3]_s} = \frac{[Cl']_c}{[Cl]_s} = \frac{[H]_s}{[H]_c}$$

while the line *Vol.* shows the volume of the corpuscles, as a p.c. of their volume at O_2 = 80 mm. and CO_2 = 39 mm. The line pH_s shows the *p*H of the serum (or plasma) from which, and from *r*, the *p*H of the corpuscles can be found too.

Carbonic Anhydrase. All the above facts have been found out by experiments with saturators in which blood is brought into final equilibrium with various gas mixtures—which may take from 15 to 30 minutes. The important question is, however, whether such equilibrium could occur in the short time of one or two seconds during which the blood is passing along the capillaries of lung or tissue. Most of the separate reactions are ionic ones, and therefore extremely rapid, but the reaction of formation of carbonic acid :

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

is easily shown to be quite slow, and if uncatalysed, would, in fact, limit the whole chain of reactions to about one hundredth of the speed of those that do occur in the blood. The catalyst concerned in speeding up this reaction is an enzyme to which Roughton,* its discoverer, gave the name of *carbonic anhydrase.* Carbonic anhydrase is a protein substance which contains zinc. It accelerates the reversible reaction by which CO_2 and H_2O combine to form carbonic acid, and *vice versâ.* Its action is inhibited by cyanide (and by sulphanilamide), so that after the blood has been poisoned by addition of a trace of cyanide the reactions take place much as they do in inorganic solution.

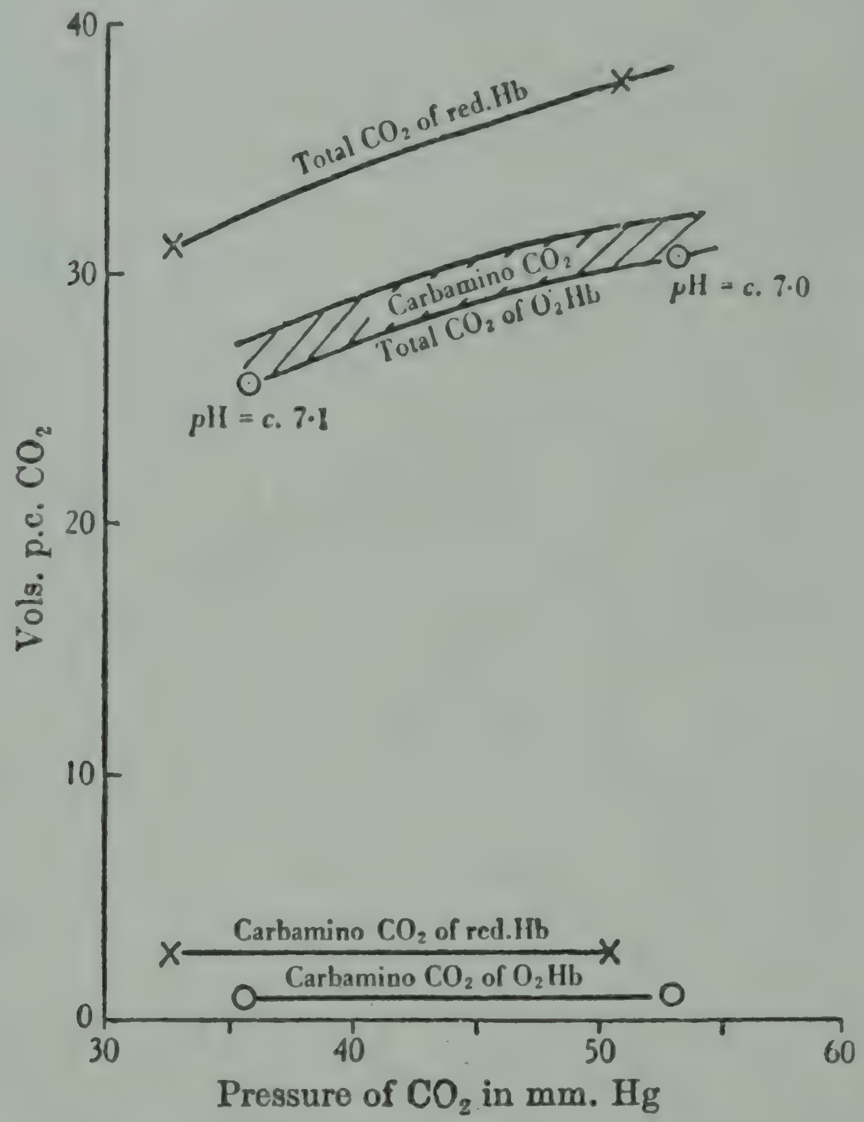

FIG. 497. Showing the CO_2 Dissociation Curves of Oxygenated and Reduced Hæmoglobin. The shaded area represents the CO_2 released from carbamino-compounds in the change from reduced to oxygenated hæmoglobin, and is seen to be a considerable fraction of the total change, although the total *amount* of carbamino-fixed CO_2, shown by the two lower lines, is never great when compared with total CO_2 content. (FERGUSON and ROUGHTON. *J. Physiol.*, 1934, **83,** 87.)

When a bicarbonate solution is acidified, we may regard its decomposition as occurring in two stages :—

$$(1)\ NaHCO_3 + HCl \rightleftharpoons H_2CO_3 + NaCl.$$
$$(2)\ H_2CO_3 \rightleftarrows CO_2 + H_2O.$$

Acceleration of reaction (2) must therefore accelerate the rate of evolution, or uptake, of CO_2. In presence of this enzyme, the rate of evolution of CO_2 from slightly acidified bicarbonate solutions is greatly accelerated. The enzyme can be precipitated by an alcohol-ether mixture, and 1 gram of the precipitate in 200 litres of solution can accelerate the evolution of CO_2 five-fold. The enzyme also accelerates the converse reaction when carbon dioxide is added to the blood. It is evident that the presence of this enzyme must considerably hasten the uptake of CO_2 in the blood in the tissues and its evolution in the lungs.

* BRINKMAN, MAGARIA, MELDRUM and ROUGHTON. *J. Physiol.*, 1932, **75,** Proc. 3
MELDRUM and ROUGHTON. *J. Physiol.*, 1932, **75,** Proc. 15.

Carbonic anhydrase in blood is present only in the red corpuscles. Many tissues contain traces of it, but the only other tissues which contain an appreciable amount of it are the pancreas and the stomach, in which it probably has a function connected with the secretion of bicarbonate and of HCl.

Carriage of Carbon Dioxide by Hæmoglobin. It has often been suspected that hæmoglobin may be capable of combining with CO_2, the suggestion being that the hæmatin part of the molecule combined with oxygen and the globin portion with CO_2. This anticipation has been confirmed by the work of Roughton and others.

When blood, poisoned with cyanide to eliminate the carbonic anhydrase, is exposed to CO_2 the gas is at first still taken up too quickly for the rate to be explicable on the ground that it was fixed in the form of bicarbonate, though the rate of uptake does ultimately slow down and accord with that supposition. This first quick absorption of carbon dioxide is due to the formation of *carbamino-compounds* by reaction with NH_2 groups in the protein molecule :—

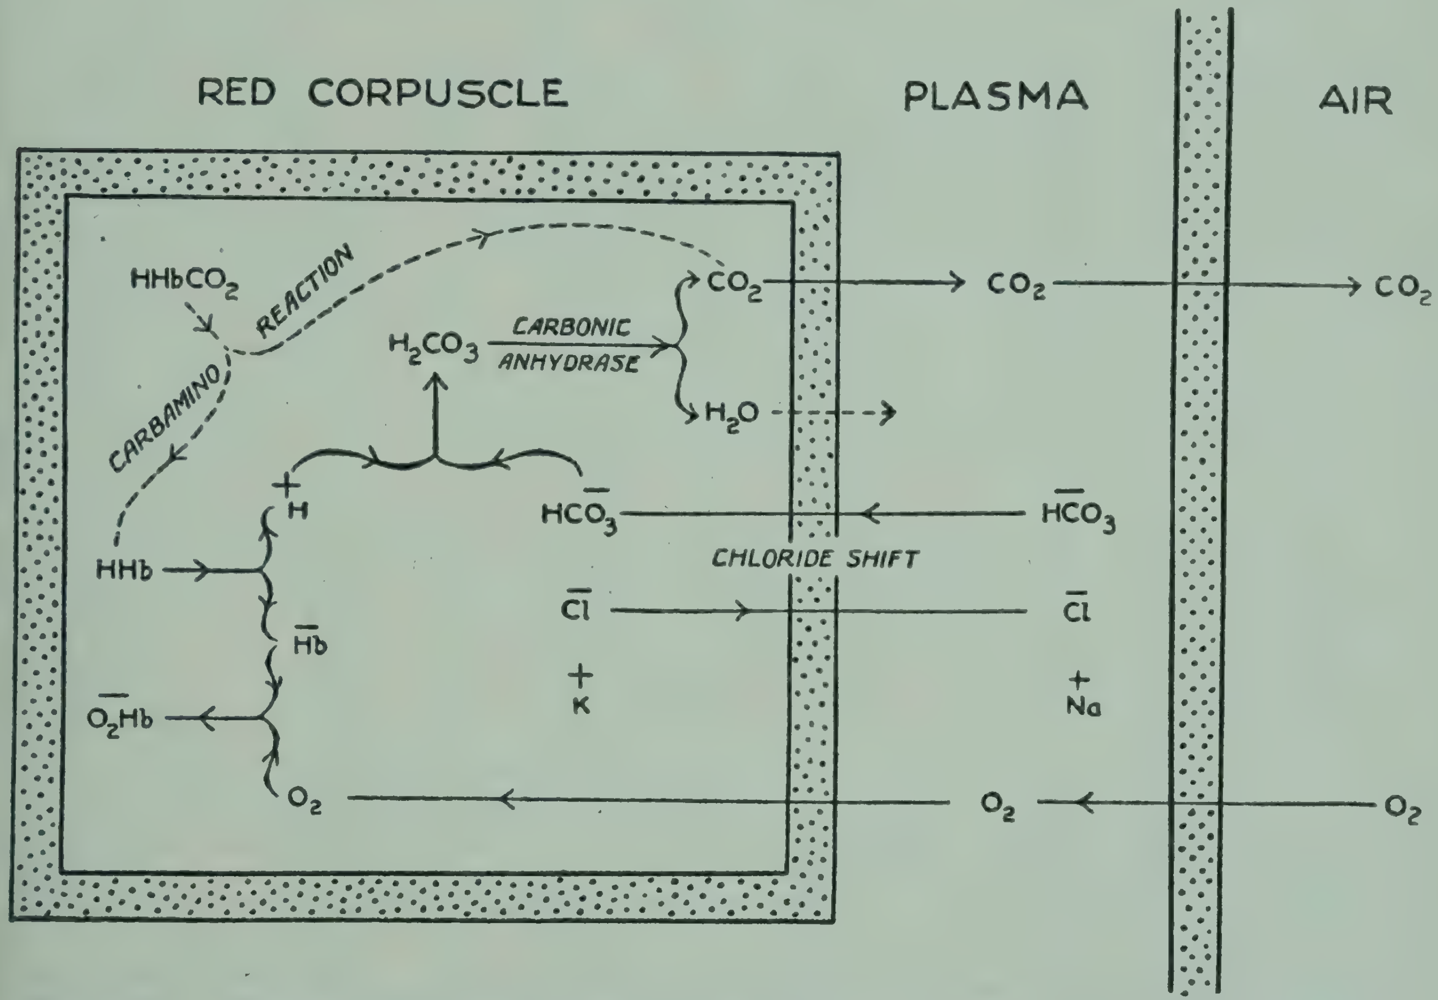

FIG. 498. Diagram of Interchanges in Corpuscle and Plasma consequent on taking up of Oxygen and expulsion of CO_2. (ROUGHTON.)

$$CO_2 + Pr.NH_2 \rightleftarrows Pr.NHCOOH.$$

The reaction is reversible, and is not interfered with by the presence of cyanides. The carbamino-compound, unlike bicarbonate or CO_2, is not precipitated by calcium or barium salts, and can actually be separated from blood in this way. In alkaline blood, and especially when the blood is deoxygenated, relatively more of the carbamino-compound is formed than when the blood is less alkaline and oxygenated. Therefore, just as with the bicarbonate CO_2, oxygenation of the blood tends to expel the carbamino-bound CO_2; although the latter may only represent 5 or 10 per cent. of the total CO_2 of the blood, it is the most mobile part, and hence is responsible for a relatively large *fraction* of the difference between the CO_2 content of oxygenated and reduced blood, as Fig. 497 shows.

The various reactions in plasma and corpuscles which take place in the lungs in connection with the uptake of oxygen by, and the expulsion of CO_2 from, the blood are shown diagrammatically in Fig. 498.

EXCHANGE OF GASES IN THE LUNGS

A liquid gives off gas to, or takes up gas from, any other medium with which it is in contact, according to the relative pressures of the gas. The question arises whether we can account by physical means for the interchange which occurs between the alveolar air and the blood in the pulmonary capillaries. In order to answer this question we must know the partial pressures or tensions of oxygen and of carbon dioxide in the alveolar air, in the venous blood coming to the lungs, and in the arterial blood leaving the lungs. If a physical explanation is to be accepted, the partial pressures and hence the flow of oxygen must be,

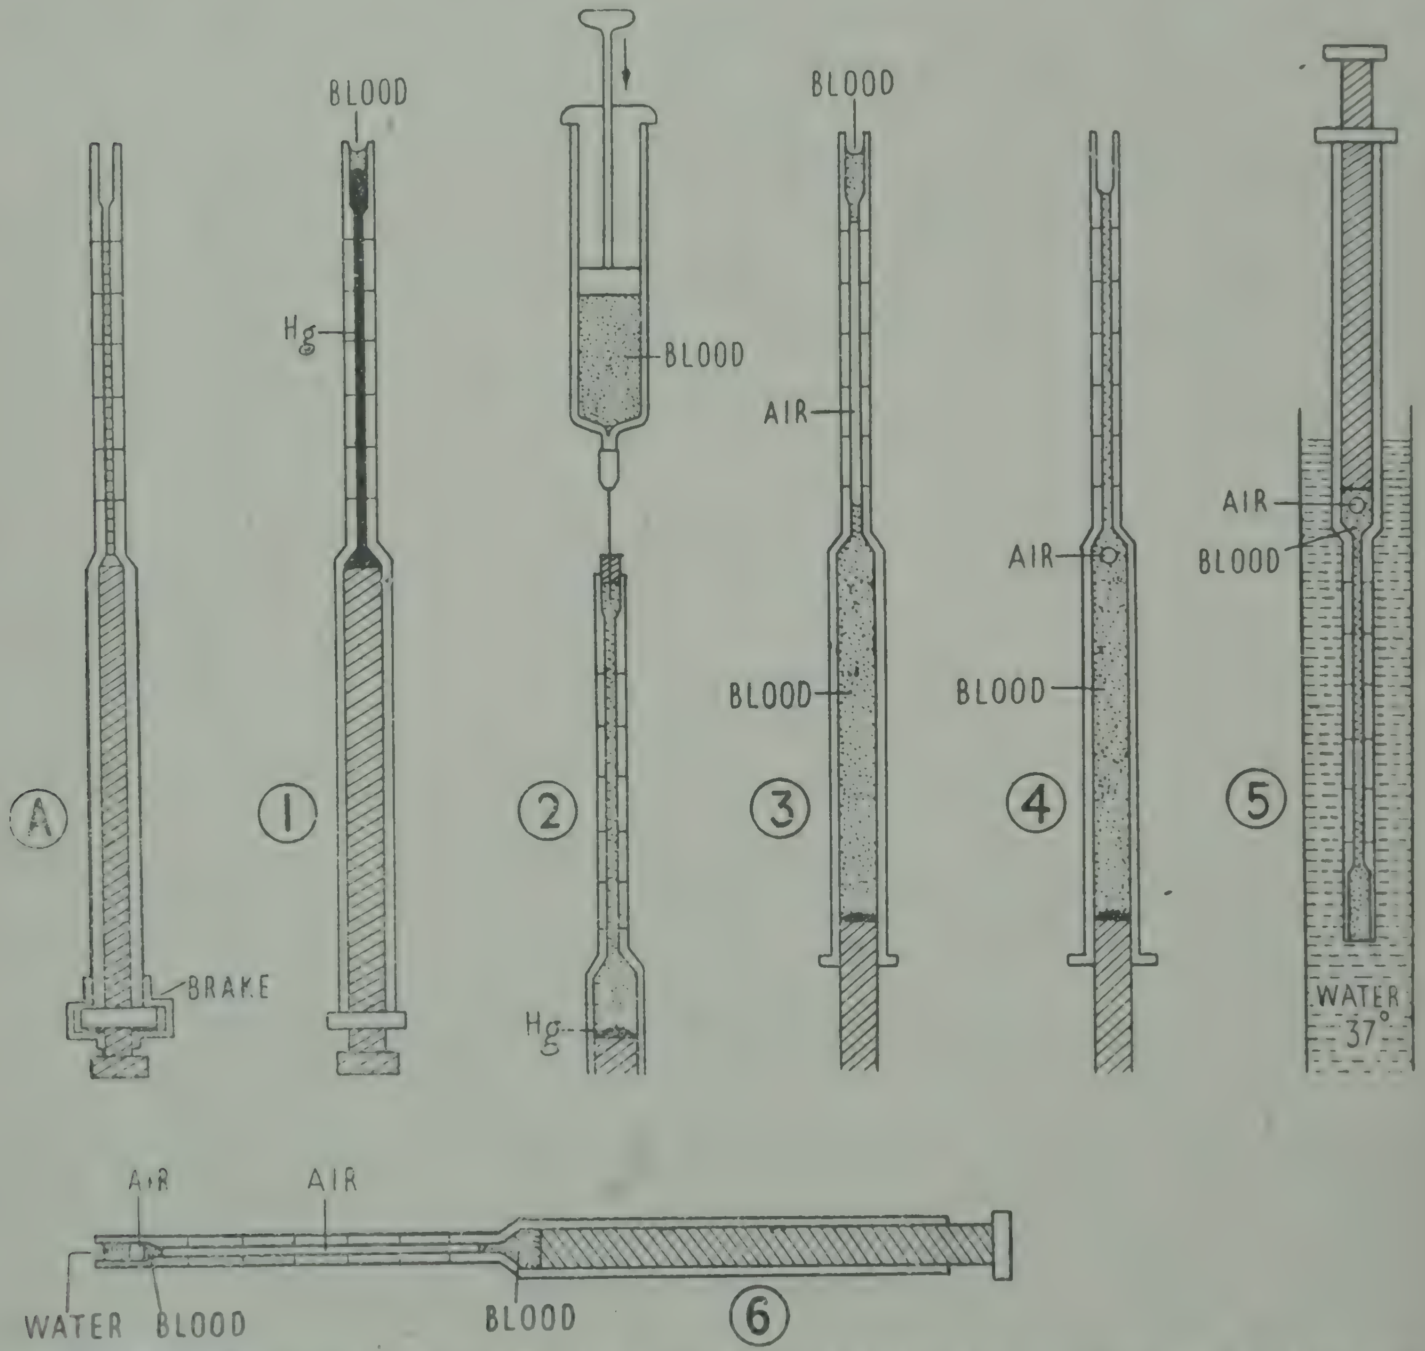

FIG. 499. Illustrating use of the Roughton-Scholander syringe for finding gas tensions in blood. A, the syringe : (1) Dead space filled with mercury : (2) Introducing the heparinised blood : (3) Bubble of alveolar air in capillary : (4) Bubble drawn into syringe : (5) After equilibration ; expelling the blood : (6) Bubble transferred to capillary for measurement and analysis. (After description by RILEY *et al.* *J. Biol. Chem.*, 1945, **161,** 621.)

in descending order: alveolar air, arterial blood, venous blood; and those of CO_2 in the reverse order.

The partial pressures of gases in the alveolar air are calculated from its analysis. The gaseous tensions in the blood, however, can only be got by finding the gaseous mixture with which the blood will be in equilibrium. If we know the percentage of any gas in this mixture, we know its partial pressure, and therefore the tension of that gas in the liquid. In all such experiments, the main difficulty is in ensuring that a sufficient volume of blood is equilibrated with a very small volume of the gas mixture. A relatively small volume of gas must be used in order not appreciably to alter the blood gas tensions. Krogh * therefore in his *microtonometer* adopted the ingenious device of limiting the volume of air to a small bubble, the superficial area of which is large in proportion to its bulk. This bubble, after equilibration in a stream of blood for some minutes, is transferred to a special capillary tube, in which its analysis can be carried out.

Modifications of this method enable the gas tensions in human arterial blood to be determined with reasonable accuracy.

The blood is drawn by arterial puncture and heparinised without air contact. One ml. of the blood is transferred to a specially modified syringe, bearing a graduated capillary having a terminal cup (Roughton-Scholander syringe)†,—again without air contact. A small bubble of alveolar air is drawn into the capillary and then into the syringe (Fig. 499). The syringe is then placed horizontally and rotated at 37° C. for five minutes to gain equilibrium: next the blood is nearly all expelled, the bubble driven into the capillary and measured. The bubble is then brought into contact with 4 per cent. NaOH, and again measured. Finally it is exposed to alkaline hydrosulphite to absorb oxygen and the residual nitrogen measured.

From this analysis of the gas bubble, its partial pressures, which are identical with the gas tensions in the blood, are calculated in the usual way.

The main aim in this method is to get the *oxygen* tension of the arterial blood. Carbon dioxide tensions are got indirectly, since it has been shown by simultaneous samplings of arterial blood and alveolar air (by Haldane and Priestley's method), that samples of alveolar air collected at the end of a normal *expiration* have approximately the same carbon dioxide pressure as that of the arterial blood, both during rest ‡ and during exercise.§

Rather varying figures have been given for the oxygen tension of arterial blood, but the more recent determinations tend to show that it is either equal to the partial pressure in the alveolar air,‖ or within a few mm. of it.¶ We may take 95 mm. as a probable figure at rest: this would correspond to about 98 per cent. saturation at 40 mm. CO_2, on the dissociation curve (Fig. 491). In exercise the O_2 tension in arterial blood may be as much as 16 mm. below that of alveolar air.‖ The value for CO_2 tension is generally agreed to be about 40 mm. at rest, or nearly the same as alveolar air.

There is also some doubt about the exact values of the pressures of both gases in the venous blood going to the lungs. An indirect method of finding them is by employing the lung itself as an aerotonometer. By a method already described (p. 569) a suitable gas mixture is held for about fifteen seconds in the lungs, and the alveolar air has then the gas tensions of pulmonary venous blood. By this means the tension of the oxygen in the venous blood was found to be about 40 mm. Hg, and that of the carbon dioxide 46 mm. Hg.

Another indirect method of finding the gas tensions in man is by reference to the oxygen or carbon dioxide dissociation curves. If we can find the oxygen and carbon dioxide contents of the bloods in question, reference to the dissociation curves will give their partial pressure.

The probable partial pressures and tensions concerned in respiratory interchange at rest are summarised in the following table :—

Approximate Partial Pressures in Inspired, Expired and Alveolar Air, and Tensions in Arterial and Venous Blood, at Barometric Pressures of 760 mm. Hg.

Gas	Pressure or Tension, mm. Hg.				
	Inspired Air	Expired Air (35·5° C.)	Alveolar Air (37° C.)	Arterial Blood	Venous Blood (Rest)
Oxygen	158·3	116	99	95	40
Carbon dioxide	0·3	30	39	40	46
Nitrogen	596·4	575	577	548	570
Water vapour	[*]5·0	39	45	47	47
Total pressure	760·0	760	760	730	703

It should be noted that the total pressure in blood is lower than that of the air.

As the venous blood enters the lungs, there is thus a difference of oxygen pressure of about 60 mm. Hg, which will tend to cause a flow of oxygen from alveolar air to blood, and a difference of 6 mm. Hg, tending to cause a flow of carbon dioxide from blood to alveolar air. Are these differences sufficient to account for the amounts of gases given off or taken up by the blood in its passage through the lungs ? The lungs have been estimated to contain 700×10^6. alveoli, each of a diameter of 0·2 mm., so that at medium distension the total surface amounts to at least 90 square metres (about 1,000 square feet). The lung capillaries have a total length of about 1,000 miles and an area of about 40 sq. m. when at rest.[†] Here some 60–95 c.c. of blood suddenly spreads out into a layer the thickness of which is not much more than that of one blood corpuscle, and is exposed to the air over this huge area, whence it is collected again into the pulmonary veins. The thickness of the tissue separating this layer of blood from the alveolar air is on the average 1·4 μ. If the "alveolar membrane" is reasonably permeable the chances for diffusion should be good, despite the fact that the blood only takes about a second to pass a lung capillary in resting states, and about one-third sec. in hard work.[†]

The diffusion constant (= c.c. O_2 passing from alveolar air to blood per mm. Hg tension difference of O_2, per min.) has been measured in man and found to vary from 21 at rest, to 62 in exercise.[‡] Let us call it 30 c.c./mm./min. Then it would be physically possible for $30 \times 60 = 1{,}800$ c.c. of oxygen to pass through into the blood per minute. The oxygen actually absorbed by a man at rest amounts to about 250 c.c. per minute, so that the physical conditions allow an ample margin for increase in the consumption of oxygen ; in fact, a difference of pressure of only 9 mm. would suffice to cause a passage of the 250 c.c. per minute which is required by the resting man. It is still easier to account for the passage of carbon dioxide in the reverse direction, although the pressure difference is only 6 mm. This gas diffuses through a wet membrane about twenty-five times as rapidly as oxygen, so that a difference of pressure between the venous blood and the alveolar air amounting to only 0·03 mm. Hg would suffice to cause a passage outwards of the 215 c.c. of CO_2 normally expired per minute.

It is evident that the limitation to the absorption of oxygen is really set by the capacity of the hæmoglobin to combine with it. From the oxygen dissociation curve of blood we see that the amount of oxygen which can be taken up by blood in the presence of the normal tension of carbon dioxide, *i.e.* 40 mm.

---

Hg, begins to diminish very rapidly when the pressure of the oxygen falls below 50 mm. Hg. Thus, at 40 mm. oxygen pressure, and a carbon dioxide tension of 40 mm., blood is about 75 per cent. saturated, and at 30 mm. it is only 60 per cent. saturated. Under normal circumstances, the blood leaves the lungs about 98 per cent. saturated with oxygen. If the saturation fell to 60 per cent. we should expect to obtain evidence of failure of oxygen supply to the tissues. Probably the oxygen tension in the alveoli can sink to between 30 and 35 mm. Hg before any signs of oxygen lack make their appearance. These results were obtained by exposing a man, in a state of complete rest, to reduced pressure in an air-chamber. Under these conditions, the slightest muscular exertion would cause distress from deficient oxygen supply. The exact percentage of oxygen in the inspired air, which would give an alveolar oxygen tension of 30 to 35 mm., varies with the depth of respiration. Thus, with shallow respiratory movements the pressure may sink to 35 mm. Hg when the inspired air contains as much as 12 per cent. oxygen. If the movements be deeper, the oxygen content of inspired air may be reduced to 9 or 10 per cent. before respiratory distress is observed.

The view that, in the interchange of gases in the lungs, the membrane between the blood and the alveolar air plays simply a passive part is now almost universally accepted since experiments show conclusively that the difference between the tensions in the alveoli, and in the blood, respectively, is always such as to allow of the passage by diffusion of oxygen inwards and carbon dioxide outwards from the blood. Moreover, the structure of the pulmonary epithelium lends no support to the view that it acts as a secreting membrane. In mammals the cells are of two kinds, viz. small granular nucleated cells lying in the interstices of the capillaries, and larger, extremely thin, structureless plates, *without nuclei*, covering the capillaries.

The view that the pulmonary epithelium actively secretes oxygen was held by Bohr,* and Haldane † held that, at all events under circumstances when the oxygen pressure is low in the alveoli, oxygen may be secreted, so as to attain a *higher* tension in the arterial blood than in the alveolar air. Thus, at high altitudes, Haldane claimed that such a secretion could be demonstrated if the subject is given air containing a low percentage of carbon monoxide to breathe. Under these circumstances the blood is found to contain less CO than when shaken with the same alveolar air (containing CO) *in vitro* ; *i.e.* the uptake of oxygen had been favoured, and the uptake of CO therefore impeded, in the lungs.

A reinvestigation by Barcroft,‡ of the tensions of oxygen in the blood under such conditions, and using direct methods, failed to confirm Haldane's conclusions.

ABSORPTION OF GAS FROM THE PLEURAL CAVITY. If air is introduced into the pleural space in sufficient amount to cause an artificial pneumothorax (*e.g.* in treatment of pulmonary tuberculosis) the lung on that side collapses. The air so introduced is soon altered in composition and comes into approximate equilibrium with the blood in the lung capillaries by diffusion through the visceral pleura. This result having been achieved, it might be expected that the gas would stay there indefinitely, but actually it disappears by absorption into the venous blood entering the lung capillaries. The reason for this is that, whereas the total pressure of the air in the pleural space is practically atmospheric, that in the venous blood (*v.* table, p. 740) is some 57 mm. Hg below atmospheric. Hence all the gases finally diffuse into the blood.

EXCHANGE OF GASES IN THE TISSUES

The considerations which determine the exchange of gases between air and blood in the lungs are also operative in determining the gaseous exchanges which take place during the circulation of the blood through the capillaries of the tissues. Blood enters the capillary network as arterial blood, and having, therefore, an oxygen pressure of the order of 95 mm. Hg and a carbon dioxide pressure of the order of 40 mm. Hg. In the tissues the oxygen pressure is lower and the CO_2 pressure higher than in the arterial blood.

The rate of passage of oxygen out of the capillaries into the tissues must be proportional to the difference of oxygen tension between the capillary blood and the tissue cells. If Pb is the oxygen pressure in the capillary blood and Pt that in the tissues, the rate of flow of oxygen from capillaries to tissues must be proportional to Pb—Pt. If the blood is to lose oxygen during the whole of this passage through a tissue, we may take for Pb the tension of the oxygen in the venous blood as it leaves the tissue. This is, say, 30 mm. Hg. Pt, the tension of oxygen in the tissues, may be determined in various ways,* but is usually considerably lower than Pb.

* BOHR. *Skand. Arch. f. Physiol.*, 1890, **2**, 236.

† DOUGLAS and HALDANE. *J. Physiol.*, 1912, **44**, 305.

‡ BARCROFT *et al.* *J. Physiol.*, 1920, **53**, 450.

Krogh † determined the rate of diffusion of oxygen through different thicknesses of various tissues (connective tissue, muscle, etc.) under varying pressures. Then, partly on the living muscle, partly on injected specimens, he estimated the relation of the number and size of the capillaries to the intercapillary muscular tissues. He found that extremely small pressure differences were necessary to supply the muscle fibres with oxygen. Some of his results on the guinea-pig are shown in the accompanying Table.

Guinea-pig muscle	c.c.O_2 per minute per 100 c.c. tissue	Capillaries per mm.^{2}	Pb − Pt mm. Hg.	Total surface capillary in 1 c.c. muscle	Capacity of capillaries in 100 c.c. muscle
Rest	0·5	31	45	3 cm.^{2}	0·02 c.c.
	0·5	95	12	8 ,,	0·06 ,,
	0·5	270	3	32 ,,	0·3 ,,
Massage	0·5	1,400	0·04	200 ,,	2·8 ,,
Work	5	2,500	1·4	390 ,,	5·5 ,,
Maximum circulation	10	3,000	1·2	750 ,,	15 ,,

The first thing that strikes us in this Table is the enormous difference between the capillary circulation of resting and that of active muscle. In the resting muscle the majority of the capillaries are empty and collapsed, so that relatively large volumes of muscle intervene between the few capillaries in which the circulation of blood is proceeding. Under these conditions, the oxygen pressure head necessary to supply the total oxygen needed by the whole of the muscle, *e.g.* 45 mm. Hg, may be greater than the venous oxygen tension, so that in parts of the muscle the oxygen tension may be zero: capillaries in these anoxic parts then open up, and others close. After massage, a number of new capillaries open; the number is still further increased by work, so that there may be a hundredfold increase in the number of capillaries in every square millimetre of a cross-section of the muscle. Under these conditions, the passage of oxygen from the capillaries is so facilitated that the oxygen pressure in the muscle tissues becomes practically equal to that of the blood. It would appear that, so far as the supply of oxygen to the muscle is concerned, the increase in the capillary area during muscular exercise is far ahead of the actual needs of the muscle.

Under normal circumstances the blood never stays in the capillaries long enough to lose the whole of its oxygen. The fraction of the arterial oxygen abstracted, which is called the *coefficient of oxygen utilisation*, varies from tissue to tissue, and from time to time. In states of activity, the venous blood may be more than usually deoxygenated, but generally not more than 0·4 of the arterial oxygen is utilised. If, however, the further supply of oxygen to the blood be prevented, as in asphyxia, the last traces of oxygen may disappear from the blood.

As a result of the oxidative changes in the tissues, carbon dioxide is produced, and the tension of this gas in the tissues therefore rises.

The alteration in reaction of the blood, caused by a rise in CO_2 tension or by the presence of small amounts of lactic acid, markedly quickens the rate at which oxyhæmoglobin gives up its oxygen, as is shown in Fig. 500.

As Barcroft has pointed out,‡ in cold-blooded animals the hæmoglobin is different in its properties from that of warm-blooded animals, being less affected by temperature changes. In them, too, the dissociation of oxyhæmoglobin must be largely conditioned by the rise of carbon dioxide tension in the tissues, since at the normal temperature of these animals the evolution of oxygen from hæmoglobin would be slow.

* VERZÁR. *J. Physiol.*, 1912, **45**, 39.

† KROGH. "The Anatomy and Physiology of the Capillaries." (Yale Press, 1929.)

‡ BARCROFT. *Physiol. Rev.*, 1925, **5**, 596.

The determination of the pressures of oxygen and carbon dioxide in the tissues is a matter of some difficulty. They may be approximately determined by taking the tensions of the gases in secretions, such as the urine or bile or, more generally, by injecting air beneath the skin, or into body cavities, etc., and analysing it after the lapse of a suitable interval to allow of equilibration.* It is found to be from 45 to 55 mm. Hg for CO_2 (14 to 23 mm. for cold-blooded animals),† and since in venous blood it is rarely above 50 mm. Hg, there is a gradient of partial pressure of CO_2 from tissues to blood, *viâ* the tissue fluid. The gas therefore passes in that direction by simple diffusion, and the oxygen in like manner passes in the opposite direction, also by diffusion. We have already seen that the oxygen pressure may vary from one tissue to another, or in the same tissue, from time to time. It is certain, however, that the oxygen pressure in the tissues is always lower than that in the arterial blood and tends to vary inversely as the activity of the tissue. By the method mentioned above the oxygen pressure of the body cavities and of subcutaneous tissue appears to range from 20 to 45 mm. Hg. In muscle it may be lower than this, especially during activity. Under the skin, on the contrary, O_2-tension is raised during exercise, because the cutaneous vessels are dilated.

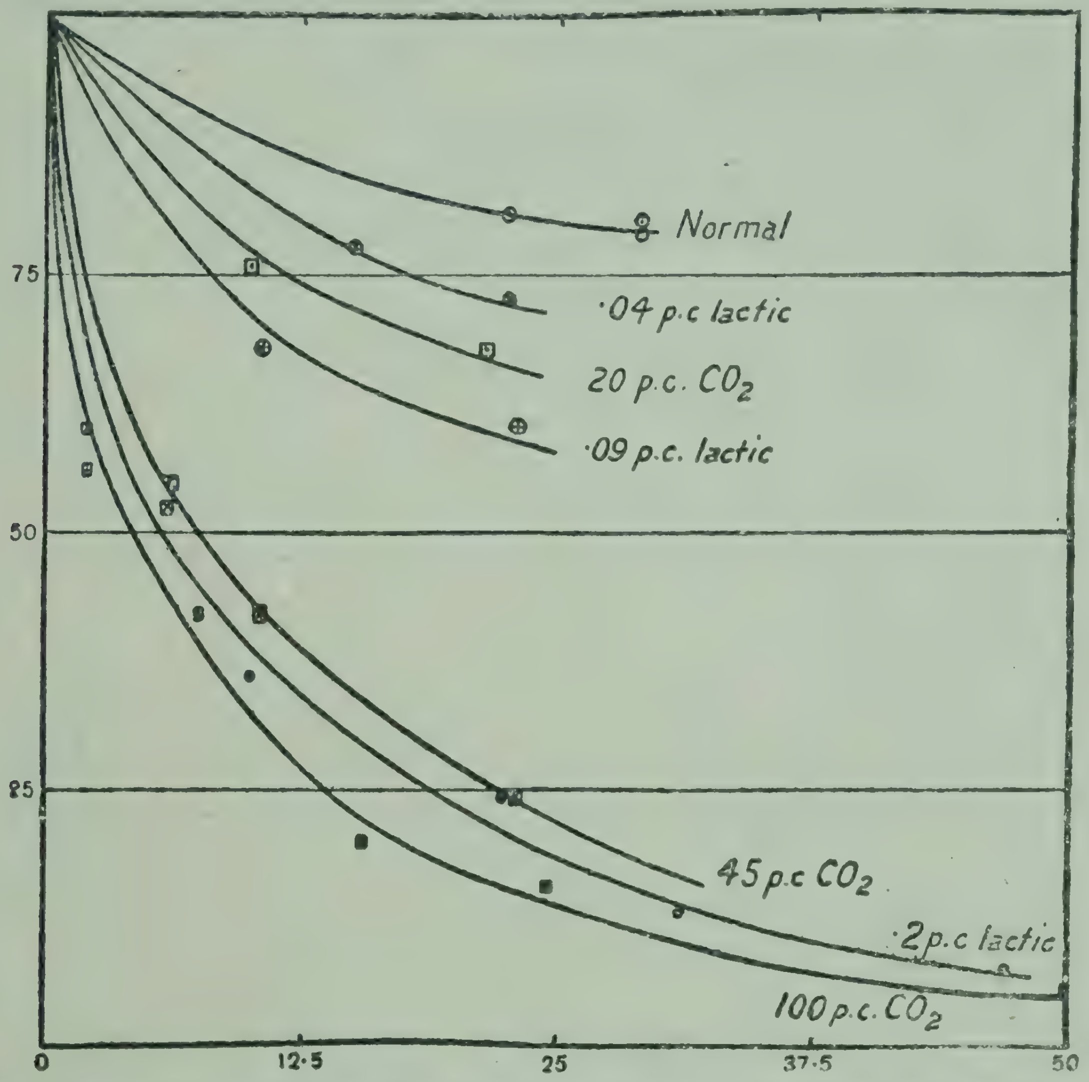

FIG. 500. Curves showing the Rate at which Arterial Blood is Reduced on Bubbling through it a gas free from Oxygen, and the effect on the rate of the presence of CO_2 and of Lactic Acid.

Ordinates = percentage saturation of oxyhæmoglobin. Abscissæ = time in minutes. (MATHISON. *J. Physiol.*, 1911, **43**, 347.)

Increasing or reducing the oxygen tension in the air breathed causes a change in the same direction in both the oxygen and the CO_2-tensions in the tissues. The CO_2-pressure is increased when the oxygen-pressure is increased because CO_2 is then less readily taken up by blood and so accumulates in the tissues.‡

* CAMPBELL. *J. Physiol.*, 1924, **59**, 1.
† CAMPBELL. *J. Physiol.*, 1926, **61**, 248.
‡ CAMPBELL. *J. Physiol.*, 1925, **60**, 20.

In muscles that exhibit strong and repeated contractions there is a modified form of hæmoglobin present in the cytoplasm of the fibres. It is called *myohæmoglobin*, or *myoglobin*, and serves a useful purpose in facilitating the transport and storage of oxygen. It differs from blood hæmoglobin in its absorption spectrum, in having only one atom of iron per molecule, in having a relatively small affinity for CO, but especially in showing a very small Bohr effect (p. 729), and in having an oxygen dissociation curve that is a rectangular hyperbola. Consequently, it will take up oxygen much more readily at low pressures than will blood hæmoglobin, so that it will easily deprive the latter of oxygen, particularly if CO_2 is also present. It also has a higher velocity of combination with oxygen than has blood hæmoglobin, so that it can act as a quickly filled store of oxygen for the muscle fibres. It has been calculated that the myoglobin of heart muscle can hold enough oxygen for about 7 secs. of moderate activity, or about half a second of maximal activity of the heart muscle, and so should be able, with its quick rate of oxygen uptake, to keep the tissue always supplied with oxygen. It will be seen from the dissociation curves of Fig. 501 that even at the venous oxygen tension of 40 mm. the myoglobin is still 94 per cent. saturated, whereas the blood Hb is only 66 per cent. saturated. Hence the tissue could suck oxygen out even from the venous blood.

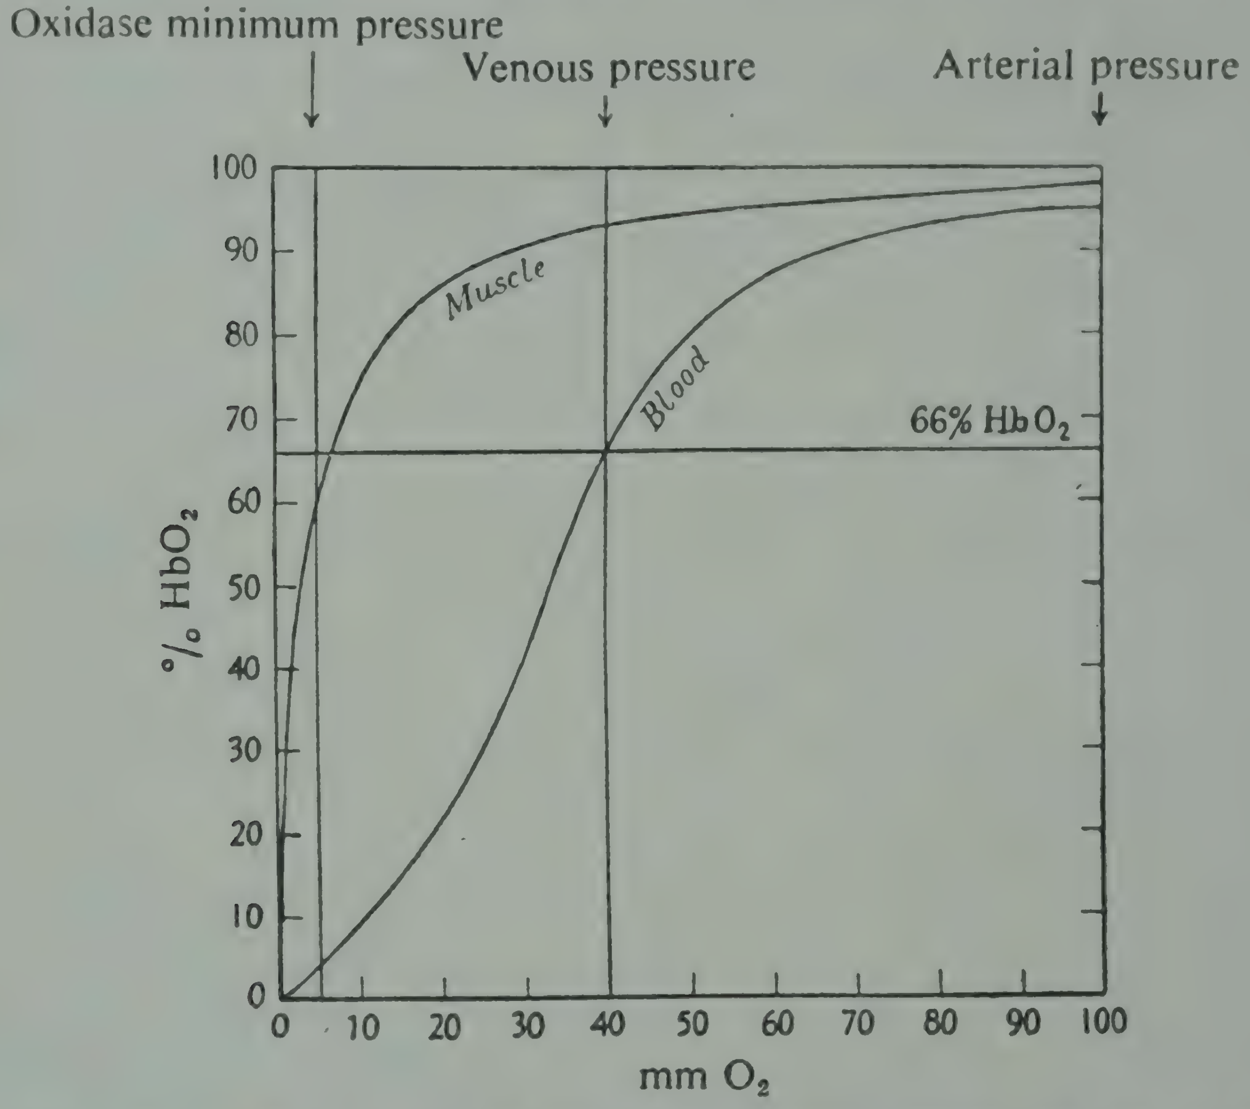

FIG. 501. Dissociation curves of muscle hæmoglobin (myoglobin) and of blood, showing relation to minimum oxygen pressure required by the tissue oxidases. (After R. HILL. *Proc. R. S.*, 1936, **120B**, 472.)

As a store of oxygen, however, the myoglobin would be of no use if it held its oxygen so firmly that the active systems of the tissue cells were unable to withdraw it. It will be seen from Fig. 501 that this is not the case, for the tissue oxidases can function at oxygen pressures of 5 mm. or less, so that much of the myoglobin can be readily reduced.

Use has been made by Millikan * of the presence of myoglobin in the muscle fibres for studying the utilisation of oxygen by living muscles. Light is passed through the living soleus muscle of the cat, and falls on to a differential photocell colorimeter, by means of which a continuous record of the degree of oxygenation of the myoglobin is made on photographic paper. When the muscle was tetanised the myoglobin showed reduction in 0·2 sec., and had lost up to 40 per cent. of its oxygen in the first second, even when the blood supply was intact. On relaxation the oxygen was restored. These facts are of importance in emphasising the speed with which reactions occur in the mammalian tissues with intact circulation.

---

* MILLIKAN. *Proc. R. S.*, 1937, **123B**, 218.

Tissue Respiration. The enormous avidity of the tissues for oxygen is shown by the following experiment (Ehrlich).[*] If a saturated solution of methylene blue be injected into the circulation of a living animal and the animal be killed ten minutes later, it is found, on first opening the body, that most of the organs present their natural colour, although the blood is of a dark blue colour. On exposure to the atmosphere, all the organs acquire a vivid blue colour. This phenomenon is due to an intense reducing activity of the tissues, whereby hydrogen is added to the methylene blue with the production of a colourless reduction product, which on re-exposure to oxygen is oxidised, by loss of hydrogen, into the blue compound. It is shown by surviving minced tissues as well as *in vivo*. In this reaction the tissue obtains oxygen, for carrying out its oxidative processes, by the decomposition of water, the oxygen from the water being transferred to an oxidisable substance (oxygen acceptor), provided there be present a substance, such as the methylene blue (hydrogen acceptor), which can take up the active hydrogen (*v.* p. 98).

All tissues use oxygen and form CO_2, in amounts varying with their state of activity, since their energy is derived from combustion processes. The heart, brain and liver are among the most actively respiring organs, but during muscular work the contracting muscles also consume large amounts of oxygen. The intake of oxygen and output of CO_2 by the lungs represents the sum total of the gaseous exchanges of all the individual tissues of the body. The lungs themselves have a small oxygen usage and CO_2 production, but, apart from this, all the oxygen taken in from the air is carried away in the arterial blood, and all the CO_2 expired is carried to the lungs by the venous blood. In other words, the lungs do not effect, or finish off, combustions on behalf of the other tissues.[†]

The respiratory exchanges can be studied (i) in the whole body, by measuring the exchanges effected in the air in the lungs. This aspect of the subject will be dealt with in Chapter XLI, and need not be further discussed here.

(ii) in a whole organ or mass of tissue. This can be done by determining the rate of blood flow through it, and by measuring the arterio-venous oxygen and/or CO_2 differences.

(iii) in thin slices of tissue, or membranes, such as the diaphragm, retina, etc. Since a circulation of blood is not indispensable for carrying out of tissue respiration, provided that oxygen and CO_2 exchanges are provided for in some other way, advantage is taken of the fact that thin slices of fresh surviving tissue still respire when placed in oxygen-rich atmospheres. The study of the respiration of such tissue slices by means of the various types of microrespirometer (*e.g.*, that mentioned on p. 146) is now much in vogue. The slices must be thin enough to ensure an adequate oxygen supply, and must be suspended in a suitable isotonic fluid, to which various substances of metabolic importance can be added, and the oxygen uptake and CO_2 production followed. To offset uptake of water by the slices, it is common to express the results as so-called Q_{O_2} values, *i.e.* μl (= c.mm.) O_2 consumed per mg. dry weight of tissue per hour. To facilitate comparison of results it is also a practice in microrespirometry to express all quantities of substances, solids, liquids or gases, as though they were in gaseous form, and so to express 1 millimol. as = 22,400 μl.

(iv) in finely ground tissue pastes, in which most of the cells are destroyed. As a rule it is found that the greater the cell destruction the smaller is the survival respiration : one explanation of this is that cellular structure implies the existence of intracellular apparatus in which the chemical changes are brought about. If we minced up an automobile, we should hardly expect it to display any trace of its normal functions, particularly if all the gasoline and oil had run away. Another explanation of the reduced respiration of ground-up tissue is that substances essential for the combustion process, either as fuel or as catalysts, have diffused away from the cells. In support of this, it has been shown that when certain substances, believed to be metabolites, are added to the paste, a normal rate of respiration is resumed. Does this, in fact, mean that the normal function and normal respiratory process is reinstated, or is it more comparable with pouring gasoline or oil over the red-hot debris of our automobile ? Perhaps a little of both !

(v) in isolated enzyme systems extracted from the tissue, and acting on appropriate substrates, as already explained on pp. 98 and 99).

It will be evident that these various methods of approach give us, in the order named, an increasing power of analysis of the biochemical processes concerned in tissue respiration, but at the same time conditions which depart more and more from those of the normally functioning cells of the tissue in question. All available methods must, therefore, be employed, and the evidence which they provide carefully sifted.

As an example of the application of the various methods we may take first the gaseous metabolism of the heart. We can determine this in the actively working organ by the use of the heart-lung preparation. First, we can determine the oxygen uptake and CO_2 output of the HLP by way of the lungs, and then subtract the quantities due to the metabolism of the lungs themselves. In this way we find that the heart of the dog, while doing moderate amounts of work, uses about 350 c.c. O_2/100 g./hr. Next, we can collect and measure the blood flowing through the coronary circulation during a given time, find the oxygen content of it, and of the arterial blood, and so calculate how much oxygen the heart used. For instance, if the heart weighed 67 g., the total venous blood flow from the heart was 42·5 c.c./min., and the arterio-venous oxygen difference 0·061 c.c. O_2/c.c. blood, then the oxygen usage of the heart would be :

$$\frac{42{\cdot}5 \times 0{\cdot}061 \times 60 \times 100}{67} = 232 \text{ cc./100 g./hr.}$$

By the study of a tissue pulp in oxygen in a microrespirometer, heart tissue weighing 375 mg. in one hour consumed 711 μl. O_2, which = 189 c.c./100 g./hr. On adding to the pulp a 0·02 M. solution of pyruvate, the consumption rose to 1134 μl./hr., *i.e.* to 302 c.c./100 g./hr.* This observation confirmed an earlier one, made with the heart-lung preparation, in which the heart was doing a steady rate of work. The heart was at first using oxygen at the rate of 360 c.c./100 g./hr. : addition to the circulating blood of 0·8 g. of sodium pyruvate raised the oxygen usage to 435 c.c./100 g./hr.† In both experiments disappearance of pyruvate was proved by analysis. We may infer that, especially in the case of the tissue pulp, the pyruvate provided combustible material which was lacking, and so brought up the oxygen usage of the pulp to much the same figure as that shown by the intact heart tissue doing mechanical work.

As another instance of the use of the microrespirometer in pointing to possible combustible substrates, we may take the following figures, which show the combustion of glucose and of pyruvic acid by rat brain cortex in a phosphate buffer solution ‡ :—

Addition to medium	Q_{O_2}
None.	2.98 ± 0.18
Glucose, 0.01 M.	12.20 ± 0.33
Pyruvate, 0.02 M.	11.10 ± 0.65

* Smyth. *Bioch. J.*, 1940, **34**, 1046.

† Braun-Medendez *et al.* *Q. J. Exp. Physiol.*, 1939, **29**, 91.

‡ Jowett and Quastel. *Bioch. J.*, 1937, **31**, 565.

It is becoming increasingly clear that the biochemical processes involved in tissue respiration are inseparably connected with those of metabolism in general, and that, between the entry of oxygen into a living cell and the final output of CO_2 from it there lie concealed many happenings which appear to us, in our limited way of thinking, to be inordinately complex and mysterious.

We have already seen in Chapters IX and X something of the biochemical mechanisms of tissue oxidations, and learned that this is a result of a complicated chain of reactions, which probably differ in detail from tissue to tissue, though on the whole conforming to a common plan. There are also in all probability, alternative paths by which oxidation may take place, in a given tissue, according to the conditions.

By way of further illustration and recapitulation of data given in Chapters IX and X, we may take the following examples of experiments illustrating processes that occur in heart muscle.

(i) By the use of the microrespirometer, thin slices of heart suspended in a buffer solution at *p*H 7·3 and 37° C. are found to use oxygen at a regular rate. If a trace of HCN is added to the solution, the oxygen uptake ceases.

(ii) Fresh heart tissue is minced, washed with water, ground thoroughly with M/25 phosphate buffer, *p*H 7, and centrifuged. The cloudy fluid is treated with M/5 acetate buffer, *p*H 4·5, centrifuged again, and the solid suspended in M/10 phosphate buffer, *p*H 7·3. This suspension contains powerful oxidases. If we place, say, 0·5 c.c. of this in a microrespirometer, with 2·3 c.c. of M/10 phosphate buffer, *p*H 7·3, and 0·3 c.c. of 6 per cent. *p*-phenylene diamine, and shake, a steady oxygen usage is seen, say, 50 μl. in ten minutes. The *p*-phenylene diamine is being oxidised, and oxygen is absorbed.

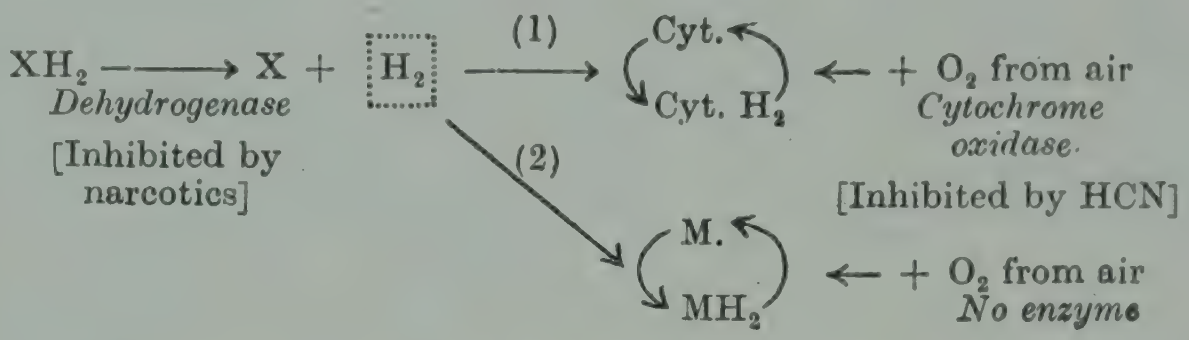
Now let us repeat the above experiment, but with the addition to the contents of the microrespirometer of a few mg. of cytochrome (prepared from heart muscle): it is now seen that the oxidation of the *p*-phenylene diamine proceeds much more rapidly than before, say about 120 μl. in ten minutes. If a trace of cyanide be now added the oxygen usage stops altogether. The addition of cytochrome was effective because in the preparation of the oxidase much of the original cytochrome of the tissue was lost.

What happens to the substrate (in this case the *p*-phenylene diamine, but in the living tissue some other substance, which is to be oxidised) is that it hands hydrogen to cytochrome under the action of a dehydrogenase, and so is oxidised, while the cytochrome is reduced. The reduced cytochrome is then re-oxidised, with absorption of oxygen, by another enzyme, cytochrome oxidase. This oxidase is inhibited by cyanide, so that the oxygen usage ceases. Presumably a similar thing happens in the tissue slice when cyanide is added.

(iii) If we mix in an evacuated tube 0·3 c.c. of M/2 sodium succinate, 1 c.c. of a washed heart suspension, 0·5 c.c. of M/1,000 methylene blue, and 1·5 c.c. of M/10 buffer, *p*H 7·3, and keep at 37° C., the blue colour will be discharged in a few minutes, but returns at once if air is admitted. If the succinate is omitted, the methylene blue is not reduced by the washed heart tissue *in vacuo*. Here the substrate is succinic acid, the enzyme a dehydrogenase which oxidises the succinate to fumarate by removal of hydrogen: the hydrogen is taken up by the methylene blue, which is decolorised, but on admitting air is reoxidised by the free oxygen. If we perform the experiment in a microrespirometer, we find that succinate plus heart tissue uses oxygen, and that the addition of cyanide stops this usage, but if methylene blue is also added, the oxygen usage goes on in spite of the presence of the cyanide. The hydrogen acceptor now is not cytochrome, but methylene blue (and in the body might well be some cell constituent): cyanide does not inhibit either the action of the dehydrogenase, nor the autoxidation of the methylene blue, and so, if methylene blue is present, the oxygen usage can continue in spite of the presence of the cyanide.

(iv) Although in the above example the cytochrome oxidase plays no part in the oxidation of succinate, it can do so under the proper conditions. If a mixture of oxidase and cytochrome is examined spectroscopically, the indefinite absorption of oxidised cytochrome is all that is seen. If now a few drops of succinate solution are added, the distinct absorption bands of reduced cytochrome immediately appear (Fig. 332, p. 514) : on shaking with air, they vanish again, to reappear after a few seconds further standing. If, before the succinate, a few drops of a solution of urethane be added, no reduction is produced by succinate : if, on the other hand, succinate and oxidase-cytochrome mixture be made, and cyanide added, the reduced cytochrome remains unchanged when the solution is shaken with air.

These various facts can be brought together in the following scheme, in which XH_2 is the substrate to be oxidised (*e.g.*, succinate), X is the oxidised substrate, M is methylene blue, MH_2 the reduced "methylene white," and Cyt. is oxidised cytochrome.



We have already seen (pp. 98–99) that the dehydrogenases may be quite complicated systems, consisting of an enzymic protein part, and one or more co-enzymes, which may themselves at certain stages act as substrates for the enzyme. For example, in the reversible oxidation of lactic to pyruvic acid, we may have a complex system consisting of a dehydrogenase enzyme, DPN, (*v.* p. 93), flavo-protein (p. 94), and a carrier, such as methylene blue. First, the lactate is oxidised and the DPN reduced : then the reduced $DPNH_2$ is reoxidised to DPN, and the leucoflavin is reduced to the leuco form : then the leuco flavoprotein is oxidised again, and the methylene blue reduced to its leuco form : finally this takes up oxygen and is converted into the blue again (*v.* p. 99). Here it is not easy to draw the line between substrate and catalyst, and the same is true of many types of biochemical change, when we go into detail.

So far, we have spoken mainly of the uptake of oxygen, and have had little to say about the processes by which carbon dioxide is produced. Some hint of the sort of chemical change which may be responsible for this is given on p. 142, but there are other possibilities which are too complex to be considered here.

CHAPTER XL

THE REGULATION OF THE RESPIRATORY MOVEMENTS

Each movement of inspiration involves the co-ordinated activity of a number of muscles, and the extent to which they contract will determine the depth of the inspiration. Similarly, if expiration is to take place, they must simultaneously cease to act. The rhythm and extent of the alternate contractions and relaxations of the respiratory muscles are so regulated that the total ventilation is sufficient to keep the composition of the gas in the alveoli at a practically constant level.

Each act of inspiration involves a discharge along a number of nerves, *e.g.* the facial to the muscles moving the alæ nasi, the vagus to the muscles of the larynx, the branches of the cervical and brachial nerves to the muscles of the neck, the phrenic nerves to the diaphragm, and the thoracic nerves to the intercostal muscles. These nerves are derived from motor nerve cells, situated at various levels in the medulla and spinal cord. In each act of inspiration or expiration the activities of all these groups of cells must be correlated.

RESPIRATORY CENTRES

The co-ordination is effected by the subjection of these motor nuclei to the control of specialised neurone pools in the central nervous system, which act as receiving centres for afferent impressions from the lungs and various other parts of the body, and which are also sensitive to changes in the composition of the blood circulating through their vessels. These dominant parts are called *respiratory centres.* If the spinal cord be cut across at the seventh cervical nerve roots, the respiratory action of the intercostal and abdominal muscles ceases permanently, although respiration is still continued by the diaphragm and the other muscles supplied by nerves leaving the central nervous system above the point of section. It has been known since Galen that division of the cord at the first or second cervical nerves abolishes the action of the diaphragm as well, though ineffectual movements of the muscles supplied by the facial, vagus, and spinal accessory nerves continue. A section of the brain stem through the mid-brain leaves the respiratory movements unaltered. We must conclude from these experiments that the respiratory motor neurones of the cord are subject to control by impulses originating in the hind brain, and transmitted therefrom down the spinal cord.

Many experiments have been made with the idea of locating the position of the medullary respiratory centre more accurately. Legallois and Flourens * described it as near the apex of the *calamus scriptorius.* The centre is bilateral, each centre presiding more especially over the muscles of the same side of the body, so that longitudinal section at the middle line does not destroy the respiratory movements † ; it lies in the reticular formation, in close connection with the central terminations of the vagus nerves.

Accurate delimitation of the respiratory centre has been made in the cat.‡ It is probably similar in position in man. By electrical stimulation of known regions of the brain stem, respiratory responses were obtained from two neighbouring neurone pools, one giving inspiration and one expiration, so showing clearly for the first time that there is both an *inspiratory and an expiratory centre.*

† Porter. *J. Physiol.,* 1895, **17**, 455.

‡ Pitts, Magoun and Ranson. *Amer. J. Physiol.,* 1939, **126**, 673.

The *inspiratory centre* is in the ventral reticular formation immediately over the cephalic four-fifths of the inferior olive (Fig. 502). When this region is stimulated by rapid faradic shocks, regular breathing is suspended and a deep inspiration, involving both thorax and diaphragm, occurs, and the breath is held in that position as long as the stimulus is kept up (Fig. 503, A).

The *expiratory centre* lies slightly cephalic and dorsal to the inspiratory centre. When it is stimulated a full expiratory standstill occurs (relaxation of diaphragm and other inspiratory muscles, and often also a contraction of expiratory muscles) and this expiratory position is kept up (within limits) for as long as the stimulation is maintained (Fig. 503, B). On prolonged stimulation (over about 3 mins.), however, inspiration breaks through.

(Modified from PITTS, MAGOUN and RANSON. *Amer. J. Physiol.*, 1939, **126**, 673.)

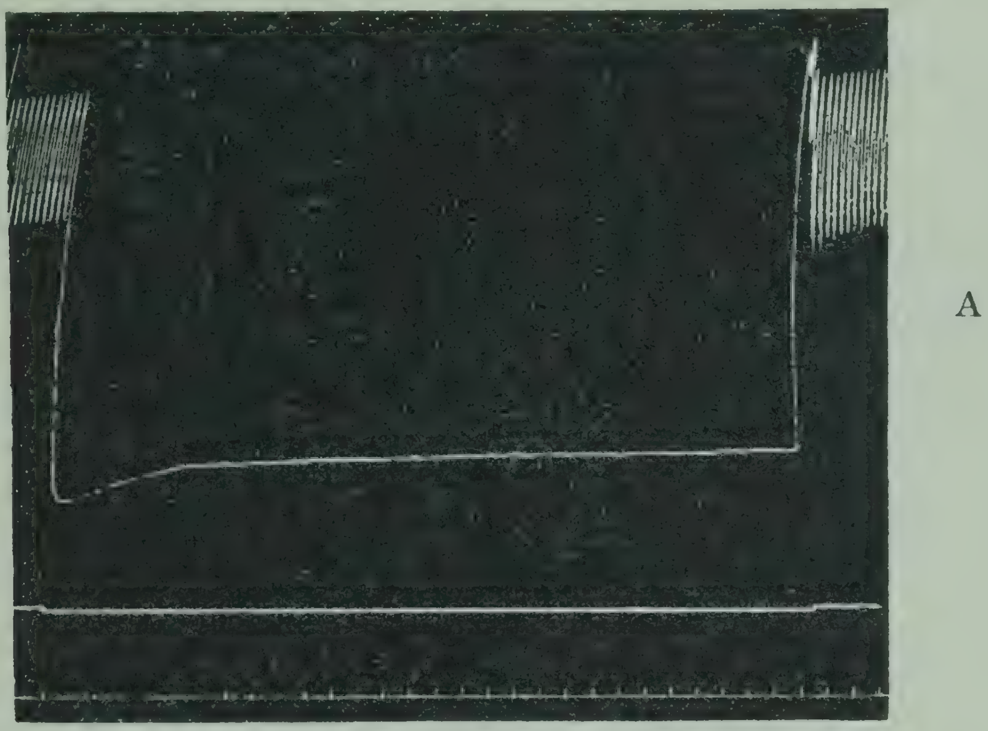
The inspiratory centre is the dominant one if both are equally stimulated together: by alternate stimulation of the two centres regular respirations of any desired depth or frequency can be obtained.

The neurones of the two centres are freely connected (Fig. 506), so that irradiation over the whole of a centre follows if only a small part of it is excited;

moreover, the other centre of opposite function is also affected, but in the opposite direction. Thus a stimulus applied to the inspiratory centre spreads over the whole of that centre, causing excitation, and also spreads to the expiratory centre, causing it to be inhibited. This reciprocal action between centres recalls the "half-centre" functions of limb locomotor centres advanced by Graham Brown (p. 266).

It is claimed by some physiologists that the primary neurones that are concerned with inspiration and expiration are not segregated, but are intermixed within a common centre, and that, owing to the reciprocal action mentioned above and to sundry incidental factors, the clear-cut results of inspiration or expiration on excitation necessarily follow. They claim that the electrical stimulus may be affecting afferent or efferent connections, rather than the neurocytons of the respiratory centre.*

Like all complex co-ordinated movements, the act of respiration, though perhaps capable of being carried out under the control of neurone pools, such as the medullary centres in question, is subject to various refinements of adjustment which can be brought into play through the intervention of superior centres.† These centres have often been grouped with the medullary centre as representing specialised departments of a central respiratory control mechanism, as by Lumsden, for example.‡



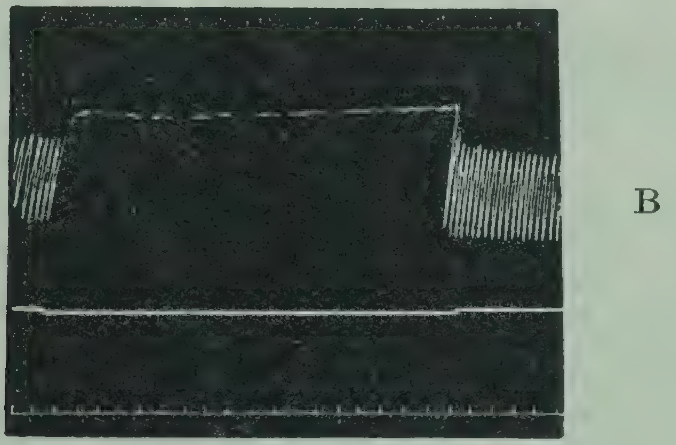


FIG. 503. Spirometer tracings of respiratory reactions to stimulation of respiratory centres in the medulla of the cat. Same strength of stimulation used in both records, viz. 8 volts at 240 stimuli per second. Duration of stimulation shown by signal line. Time, 6 second intervals. Inspiration down, expiration up. A. Maximal inspiratory standstill on stimulation of inspiratory centre. B. Maximal expiratory standstill on stimulation of expiratory centre. (PITTS, MAGOUN and RANSON. *Amer. J. Physiol.*, 1939, **126**, 673.)

The relative positions of these centres are shown in Fig. 504, and their effects on respiration in Fig. 505. Pitts § regards the central mechanism as four-fold, viz. (1) The motoneurone pool in the reticular formation of the medulla; (2) the vagal inhibitory system; (3) the brain-stem inhibitory system; and (4) other inhibitory and excitatory systems: the second and third are essential for normal functioning of the first: the third has been called by Lumsden the "pneumotaxic centre."

---

* *v.* BERNTHAL. *Ann. Rev. Physiol.*, 1944, **6**, 155.

† V. E. HENDERSON and SWEET. *Amer. J. Physiol.*, 1929, **91**, 94.

§ PITTS. *J. Neurophysiol.*, 1942, **5**, 403.

From the medullary centres on each side, the efferent impulses to the motor nuclei of the respiratory muscles pass down in the ventral and ventro-lateral columns of the cord. Hemisection of the upper cervical cord, *e.g.* on the right side, causes cessation of the contractions of the diaphragm on the same side. There must, however, be commissural fibres joining the motor nuclei on the two sides. If the right phrenic nerve be divided, after hemisection on the left side, the left half of the diaphragm at once commences to contract rhythmically with each respiration.* It is evident that the cessation of respiration after section of the cord is due to the fact that the spinal motor centres cannot act without higher control, and is not due to a condition of shock of the lower spinal centres, since it is possible for impulses to pass down the cord and to cross over to the contra-lateral diaphragm nucleus *immediately* after hemisection of the cord on the side of the nucleus.

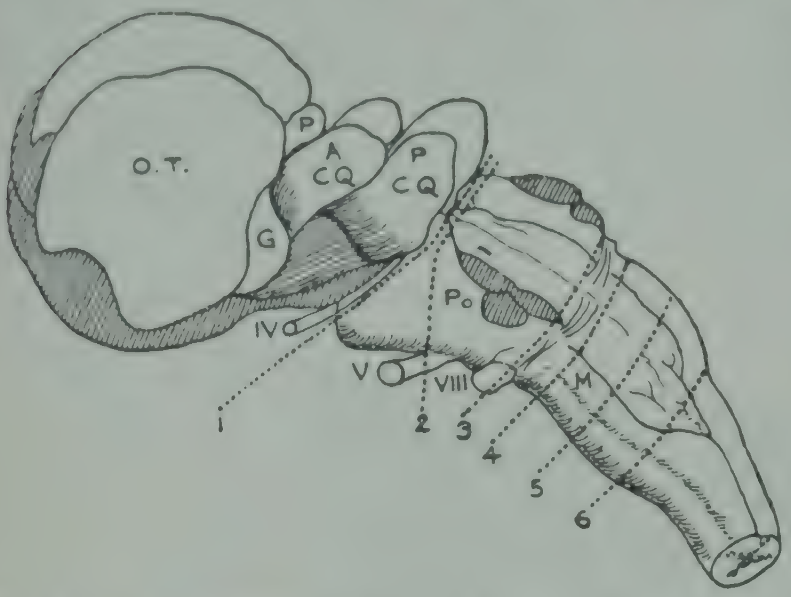

Fig. 504. Diagram of Brain Stem of Cat, showing Levels at which cross section alters the Type of Respiratory Movement. (Lumsden.)

Section 1 leaves respiration unaltered.

Section between 2 and 3, causes development of inspiratory type of respiration (apneusis), if vagi are also cut.

Section 4 causes gasping respiration.

Section 6 abolishes respiratory movements.

Cortical Control. It is common knowledge that respiratory movements can voluntarily be controlled in any direction for a time, and in accordance with

(*a*) Normal. (*b*) After vagotomy. (*c*) Prolonged inspiratory tonus (*apneusis*) after section 2, Fig. 504, and vagotomy. (*d*) Gasping respiration after section 4. Time tracing = 5 secs. Inspiration upwards.

---

* Porter. *J. Physiol.*, 1895, **17**, 455.

this, certain parts of the cerebral cortex can be shown to affect the breathing when stimulated. Certain parts of area 6 of the cortex in cats, dogs and monkeys when stimulated cause acceleration, while the excitation of other areas gives inhibition of breathing. These areas have corresponding cytoarchitecture in all these species.*

The Automaticity of the Respiratory Centres. The respiratory centres are often described as automatic. By this we mean that, although they can be affected reflexly, or by chemical changes in the blood, their rhythmic activity is primarily dependent on the metabolism of their own cells.† It is true that the centres continue to function rhythmically after almost complete isolation, *e.g.* after afferent impulses have been cut off from them by section of the brain stem at the corpora quadrigemina, of the cord at the eleventh thoracic segment,

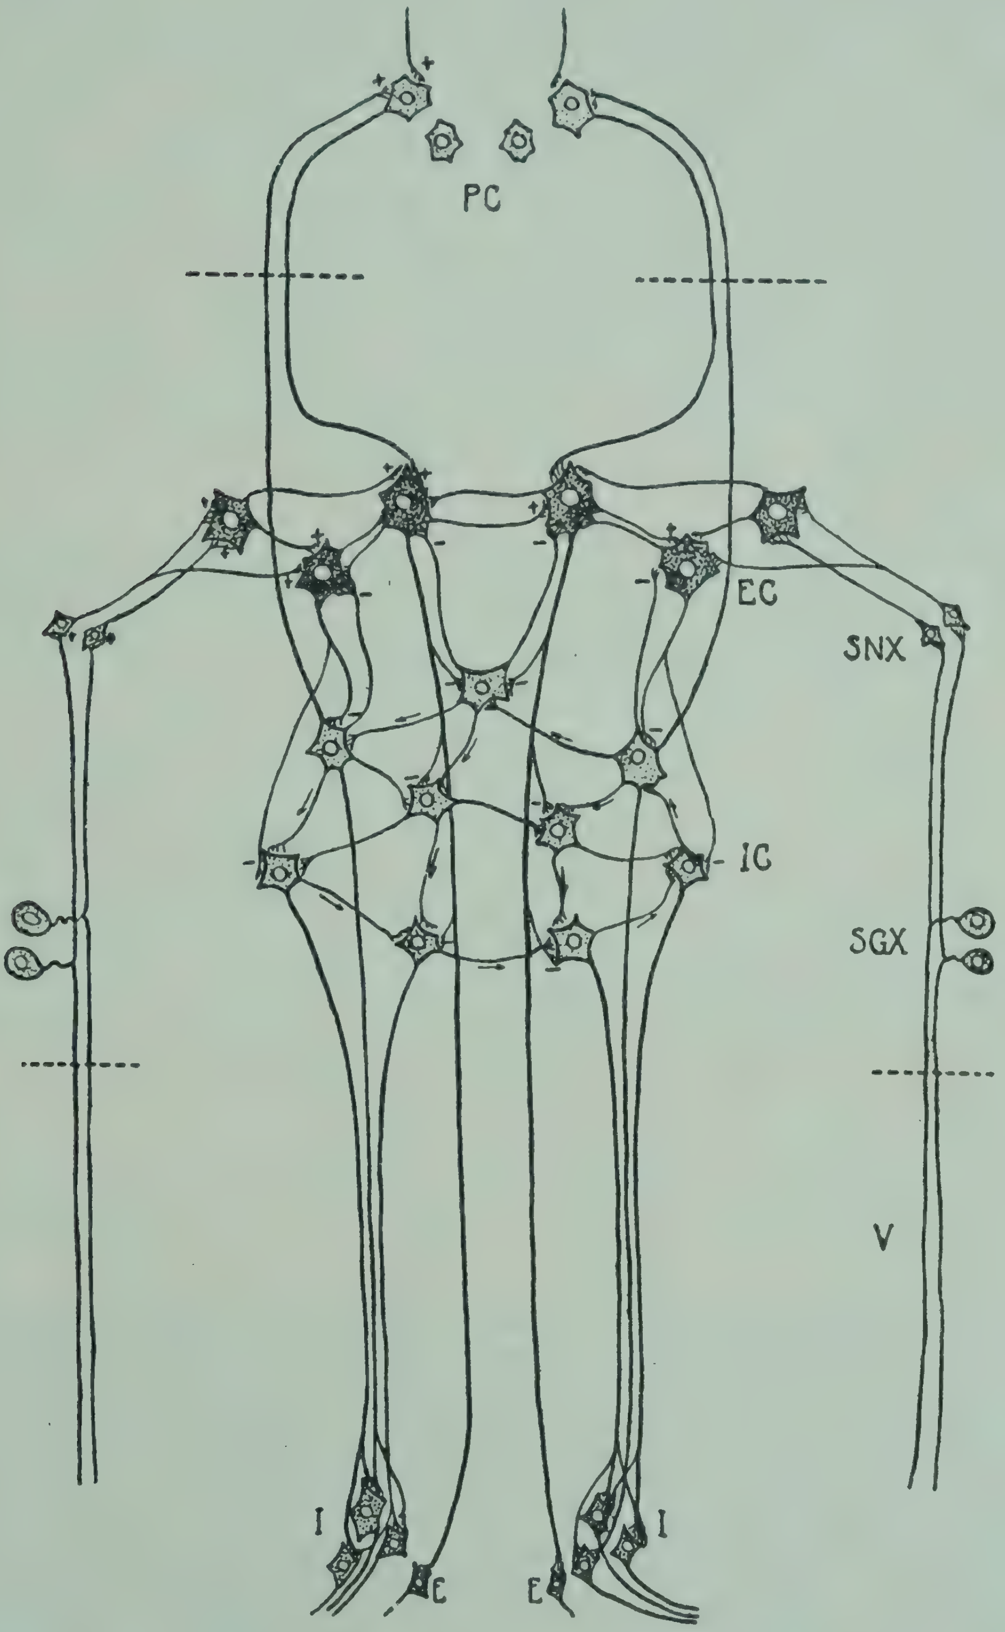

Fig. 506. Diagrammatic representation of possible linkages which would account for rhythmic respiration and apneusis. of the dorsal roots of all the spinal nerves above that, and of both phrenics, th vagi, fifth, seventh and eighth cranial nerves.* Taking the brain stem centre as a whole, therefore, it does seem that they can act independently of th receipt of afferent impulses. But if we separate off the pontine pneumotaxi centre from the medullary centres by a section across the lower pons, afte section of the vagi, rhythmic respiration is at once replaced by apneusis. Eithe the vagus, or the pneumotaxic centre, must therefore be left in connection wit the medullary centres if these are to continue to function rhythmically. Otherwise the inspiratory centre enters into sustained activity, causing apneusis.

The vagus is connected chiefly with the expiratory centre, and Fig. 50 suggests the kind of linkages in the central nervous system which would accoun for the phenomena of rhythmic breathing and apneusis. The pneumotaxi centre is in the tegmentum of the extreme upper part of the pons, and is connected with the medullary centres by a pathway ventral and slightly medial t the descending root of the fifth cranial nerve.†

The respiratory centres as a whole tend to respond to all stimuli, continuous or rhythmic, by means of rhythmic discharges. This means that the inspiratory and expiratory centres tend to function alternately, as also do many other opposed motor centres, such as those concerned with flexion and extension movements of the limbs.

If the impulses passing down phrenic nerve fibres are recorded, it is seen that at each inspiration a rapid shower of impulses is propagated. This probably means that the inspiratory neurones have reached such a level of depolarisation (p. 247) that repetitive firing ensues, after which the depolarisation subsides. In states of apneusis the discharge is continuous ; both cease on afferent vagal stimulation.‡ As each inspiration proceeds it gathers strength in two ways, viz. by the recruitment of new motor units and by an increasing frequency of nerve impulses in the active units.

By warming the blood in the carotid arteries, there may be a considerable quickening of respiration unaccompanied by any deepening, a condition which is spoken of as *tachypnœa*. On the other hand, we may slow the respiratory movements by cooling the floor of the fourth ventricle.

THE CHEMICAL REGULATION OF THE RESPIRATORY MOVEMENTS

Asphyxia. If the proper aeration of the blood be interfered with in any way, the respiratory movements increase in depth and frequency, and if the disturbing factor be not removed, the animal dies of "asphyxia." The asphyxia may be caused by occlusion of the trachea, paralysis of respiratory muscles, by pneumothorax, etc.

The phenomena of asphyxia may be divided into three stages :

(1) In the first stage, that of *hyperpnœa*, the respiratory movements are increased in amplitude and in rhythm. This increase at first affects both inspiratory and expiratory muscles. Then the breathing becomes *dyspnœic.* Gradually, the force of the expiratory movements becomes increased out of all proportion to the inspiratory, and the first stage merges into :

(2) the second, which consists of *expiratory convulsions*, in which almost every muscle of the body may be involved. Just at the end of the first stage

---

* Stella. *J. Physiol.*, 1938, **93**, 10.

‡ Pitts. *J. Neurophysiol.*, 1942, **5**, 403.

consciousness is lost, and almost immediately afterwards there appear a number of phenomena of central excitation extending to almost all the functions of the body. Thus the vasomotor centre is excited, causing widespread vascular constriction. There is often also secretion of saliva, inhibition or increase of intestinal movements, constriction of the pupil, and so on.

(3) At the end of the second minute the expiratory convulsions cease almost suddenly, and give way to *slow deep inspirations.* With each inspiratory spasm, the animal stretches itself out and opens its mouth widely, as if gasping for breath. The whole stage is one of exhaustion : the pupils dilate widely, and all reflexes are abolished. The pauses between the gasps become longer and longer, until, at the end of four or five minutes, the animal takes its last breath.

In asphyxia, two factors are present, namely, an increase of carbon dioxide and a diminution of oxygen in the blood. Each factor is responsible for certain effects, and it is important to distinguish between the separable states of *oxygen deficiency* (local or general), *hypercapnia* (or hypercarbia, *i.e.* CO_2 excess), and *asphyxia*, in which last the two preceding are combined, and to which both factors contribute, though in different ways (*v.* p. 769), just as we saw that both factors are involved in causing the changes in the circulation in asphyxia (p. 651).

The Normal Chemical Stimulus. At various times the stimulus for respiration has been ascribed, either to the increased tension of carbon dioxide, or to the diminished tension of oxygen, in the arterial blood. Increase of this stimulus, it was believed, augmented the activity of the centre and caused hyperpnœa, reduction lowered its activity, so that breathing was suspended—a condition called *apnœa.* Haldane and his pupils believed that the respiratory centre could itself be excited either by excess of carbon dioxide or by lack of oxygen, but that its sensitivity to carbon dioxide was by far the more important factor in the determination of the increased respiratory movements in asphyxia, and was the only chemical variable in the blood which could be regarded as playing a large part in the regulation of the respiratory movements under normal conditions. This factor is well brought out if we investigate in man the effect on the respiratory movements of altering the tensions of the two gases in the air breathed.* If, by this means, we alter the tension of the two gases in the alveolar air, we may assume that the tensions of the gases in the arterial blood are similarly changed.

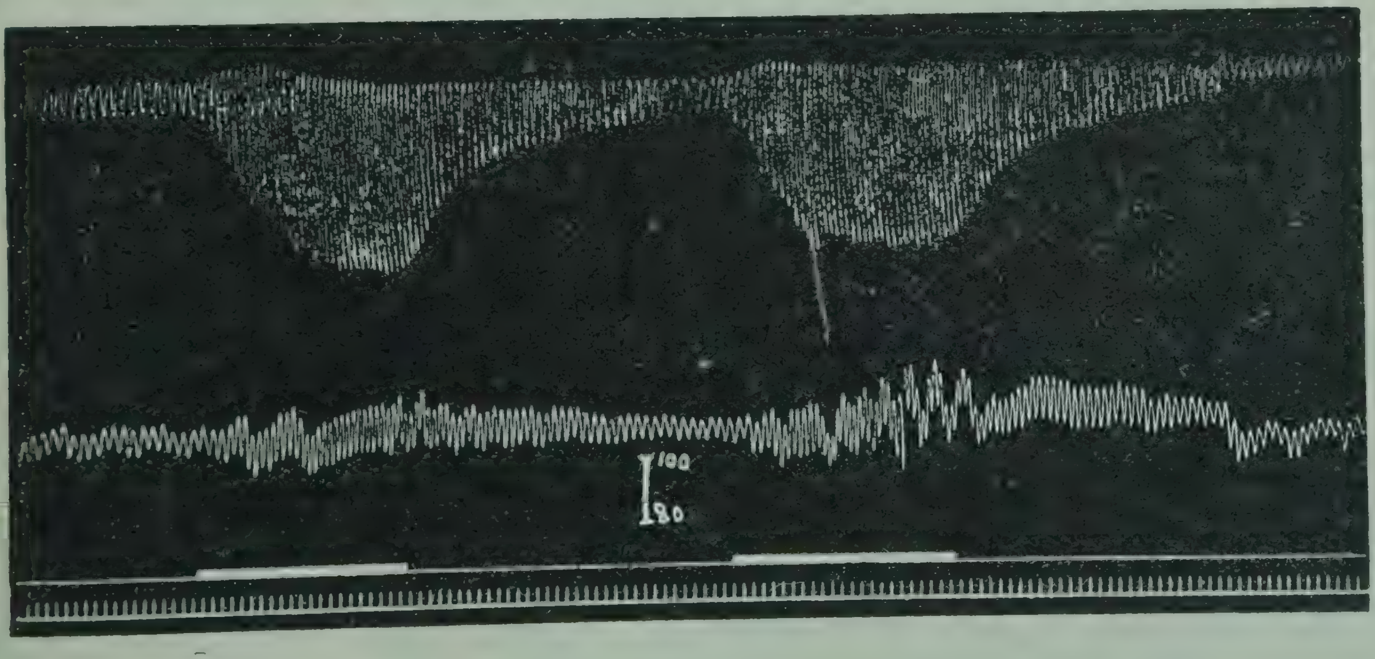

FIG. 507. Effect of CO_2 on Respiratory Movements of Rabbit. (SCOTT. *J. Physiol.*, 1908, **37**, 301.)

Upper line, tracing of diaphragm slip (Head's method). Lower tracing, carotid pressure. During the first period indicated on the signal line the animal breathed 9·6 per cent. CO_2 in air and during the second period 10 per cent. CO_2 with 33 per cent. oxygen. Time tracing = 2 secs. Scale = mm. Hg blood pressure.

---

* HALDANE and PRIESTLEY. *J. Physiol.*, 1905, **32**, 225.

Carbon Dioxide. Even a slight increase in the percentage of carbon dioxide in the air causes an increase, first in the depth and later on in the rhythm, of respiration (Fig. 507). This is shown in the following Table (Haldane and Priestley), which represents the average ventilation effected by the respirations when the subject was breathing either normal air or air containing varying percentages of carbon dioxide. For instance, a rise of carbon dioxide *in the atmosphere* to 1·74 per cent. increases the total alveolar ventilation by 43 per cent.

CO_2 p.c. in inspired air	Mean CO_2 p.c. in alveolar air	Relative rates of alveolar ventilation
0·03	5·71	100
1·74	5·65	143
3.98	6·03	277
5·28	6·55	447

The second column of figures in this Table shows that, in spite of the very large variations in the air breathed, the alveolar content of CO_2 remained practically constant until the CO_2 in the atmosphere was increased to such an extent that the processes of compensation were no longer feasible. We must conclude, therefore, that the pulmonary ventilation is so arranged as to react to the slightest increase of CO_2 tension in the blood, any increase in this giving at once a compensatory increase in ventilation, so that the alveolar CO_2 pressure may be maintained almost constant.

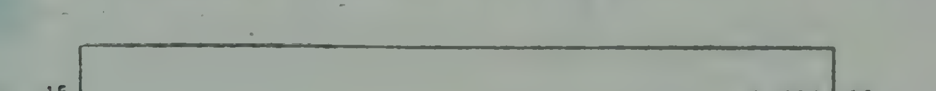

Fig. 508. Effects of Alterations in the Barometric Pressure on the Alveolar CO_2 Tension, the Alveolar CO_2 Percentage and on the Alveolar O_2 Tension. Note that the excitant effects of O_2 lack are not seen until the atmospheric pressure falls below 500 mm. Hg. (Boycott and Haldane. *J. Physiol.*, 1908, **37**, 355.)

That it is the *partial pressure*, and not the percentage amount of CO_2 in the alveolar air, and therefore in the blood, which is really the determining factor, is shown by a comparison of the composition of the alveolar airs of subjects under different atmospheric pressures. Thus at sea level (barometer = 760 mm.) the alveolar CO_2 content of a subject was 5·3 per cent., which represented an alveolar CO_2 pressure of 37·8 mm. Hg. When the subject was placed in an air-chamber compressed to a pressure of 4,640 mm., the mean percentage of CO_2 in the alveolar air was 0·9, corresponding, however, to a *tension* of 41·3 mm. Hg. Thus, the pressure of CO_2 in alveolar air remains practically constant with widely varying limits of atmospheric pressure as well as with very different percentages of CO_2 in the inspired air, showing that the reactions of the organism are directed so as to maintain, by alterations in the ventilation, a constant *tension* of this gas in the alveoli, and therefore in the arterial blood (Fig. 508).

Actually it is the ratio of CO_2 to $NaHCO_3$ in the blood (*i.e.* the pH of the blood) which is kept constant. Hence if the bicarbonate of the blood is altered, the CO_2 of the blood is adjusted by an alteration of the breathing. Just after a meal, for instance, when the HCl of the gastric juice is being separated off from the blood, there remains an excess of base, in the form of bicarbonate in the blood. This leads to a reduction of the breathing so that the alveolar CO_2 shows a slight rise.* A similar result follows if bicarbonate is taken by the mouth † and the converse result if acid or ammonium chloride is taken.‡ In the latter case the ammonia is converted into urea leaving the HCl behind in the blood. The alveolar CO_2 shows a definite fall; it does this under any circumstances, *e.g.* in diabetes, where there is an excess of acid in the blood. In all cases the effect of the response is to regulate the output of CO_2 so that the ratio of $\frac{CO_2}{NaHCO_3}$ remains constant.

While these facts and deductions are incontrovertible, they do not justify the conclusion that the effects of altered CO_2 content of the blood are exerted directly upon the respiratory centres. The effect might be upon some peripheral structure from which the respiratory centre is affected secondarily by reflex action. Experiments on man do not permit of an answer to this objection, which, as will be shown later, is in part justified. We may state here, however, that even when, in animals, all likely afferent nerves are severed, respiration is still augmented by a rise in the CO_2 content of the blood supplied to the centre, so we may conclude that the centre itself does respond directly to that chemical change in the blood; it responds less than in the intact animal, however, as the effect is partly reflex.

STIMULATION BY OXYGEN LACK. Very different are the phenomena observed on sudden alteration of the partial pressure of oxygen (Figs. 508 and 509). Here, within wide limits, the partial pressure of oxygen in the alveolar air is determined by its pressure in the inspired air. Thus, if we take the above series of observations, with a pressure of 646 mm., the *percentage* of oxygen in the alveolar air was 13·19, corresponding to a *tension* of 78·6 mm. Hg. At an atmospheric pressure of 755 mm. the percentage of oxygen in the alveolar air was 13·97, corresponding to a tension of 98·5 mm., which we may take as the

normal figure at the sea-level. In air compressed to a pressure of 1,261 mm. the percentage of oxygen was 16·79, corresponding to an alveolar oxygen tension of 203 mm. Hg.

Similar results are obtained by altering the percentage of oxygen in the air breathed at constant pressure. The oxygen tension or percentage in the inspired air can be lowered from its normal of 20·95 to 13 per cent., at which the alveolar oxygen is about 8 per cent. (= 57 mm. Hg), without altering the depth or rhythm of respiration, and, in fact, without any change being noticed by the subject of the experiment. With a further reduction of the oxygen content, however, there is increased pulmonary ventilation (Fig. 509), but the diminution in oxygen may be pushed to such an extent that the patient becomes blue, without any considerable distress being caused. In fact, the subject may suddenly lose consciousness before he has felt serious discomfort. In all probability such effect as lack of oxygen has upon respiration is not exerted directly upon the respiratory centre, as will be shown later.

The difference in the sensitiveness of the response to increase of carbon dioxide and lack of oxygen respectively, is well shown by an experiment of Haldane's, in which the same person breathed in and out of a bag, in the first place allowing the carbon dioxide produced in respiration to accumulate, and in the second, removing the carbon dioxide by means of soda lime, so that the sole effect of respiration was to produce a continual diminution in the percentage of oxygen. In the first case, when the carbon dioxide was allowed to accumulate, it was found that intolerable hyperpnœa was produced when the content of the bag had reached 5·6 per cent. carbon dioxide and 14·8 per cent. oxygen. When the carbon dioxide was absorbed, no hyperpnœa was produced, and the experiment was stopped as soon as the subject was becoming blue in the face and experienced slight throbbing in the head. The pulse frequency had gone up from 80 to 108. The bag contained no carbon dioxide and only 8·7 per cent. oxygen.

We must conclude that the respiratory apparatus is peculiarly sensitive to variations in the pressure of carbon dioxide. Since the animal has developed a mechanism by which the reaction of the blood can be rapidly adjusted by varying the excretion of carbon dioxide, whilst the excretion of other acids is relatively slow, carbon dioxide may be regarded as, in effect, the normal respiratory stimulant. Although the breathing can be excited by lack of oxygen, this effect is rarely brought into play. Under all ordinary circumstances, an increased need for oxygen is associated with an increased accumulation of carbon dioxide in the body, and the augmentation of respiration, produced by the excitatory effect of a small excess of carbon dioxide tension in the blood, suffices also to provide fully for the increased needs for oxygen.

THE REFLEX REGULATION OF RESPIRATION

Afferent Nerves. Although the sensibility of the respiratory centre to CO_2 is the most important factor in determining the respiratory ventilation, the respiratory centre is modified in a large degree by impulses arriving at the centre along the vagi and the carotid sinus nerves. Through other sensory nerves the respiratory movements can at times be altered reflexly, but under normal circumstances it is only through these nerves that a continuous stream of impulses passes to the centre, so that every respiratory movement is modified by these impulses.

If both vagi be divided, a change in the respiratory rhythm is at once seen. The movements become less frequent, but are increased in amplitude. If, now, the central end of one of the vagi be stimulated with weak stimuli at a low frequency, *e.g.* 30 per sec., an inspiratory increase of the movements of respiration results. With more rapid stimuli, *e.g.* 250 per sec., an expiratory hypertonus results, or a definite expiration. The vagus is connected mainly with the expiratory centre, excitation of which inhibits inspiration and provokes expiration.

Expiration may be strikingly brought about by stimulation of the central end of the superior laryngeal nerve, which produces first an inhibition of inspiration and then a forcible expiration. The superior laryngeal nerve supplies sensory fibres to the mucous membrane of the glottis, and we know that the slightest irritation of these fibres—the presence of a crumb or a particle of mucus—causes forcible expiratory spasms, with spasmodic closure, of the glottis, which we term a cough. It must not be imagined that the fibres of the superior laryngeal nerves are concerned in the reflex maintenance of the normal respiratory rhythm. They are cited here merely because the result of their stimulation somewhat resembles that which would be caused by stimulation of the analogous expiratory fibres which run in the trunk of the vagus from the *lungs* to the respiratory centre.

Since section of both vagi causes slowing of respiration, impulses which exert some influence to quicken respiration must travel up the vagi from the lungs. The respiratory movements cause an alternate inflation and deflation of the lungs, and it appears that these changes in the volume of the lungs start or stop the accelerating impulses that travel up the vagus nerves. To test the truth of this hypothesis, it is necessary to see the result, on the respiratory movements, first of distension, and secondly of collapse, of the lungs.

When it is wished to study the effects of artificial distension or collapse of the lungs we may use the method described by Head.* In the rabbit, a slip of the diaphragm serves as a sample of the diaphragm, the contractions of which may be recorded, uninfluenced by passive movements. Alternatively, in the dog, the movements of the larynx up and down with each respiratory movement can be recorded.

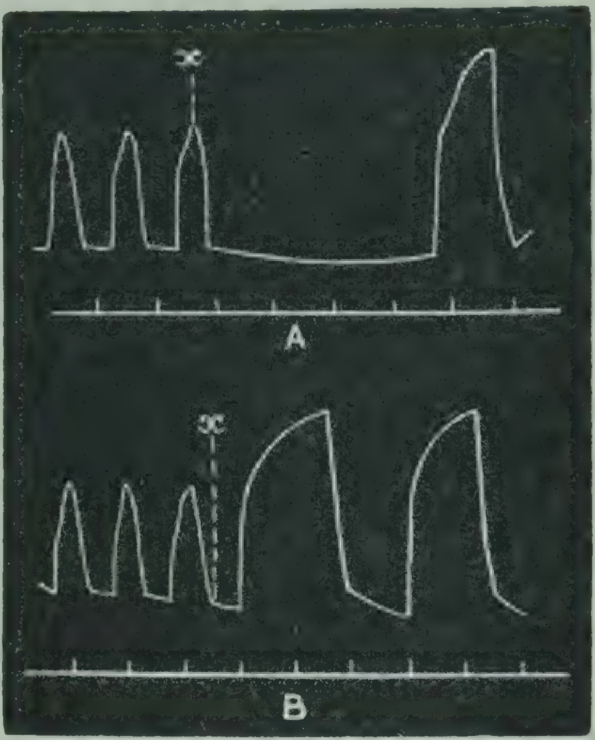

FIG. 510. Effects of Distension and Collapse of Lung. Contraction of diaphragm slip of rabbit. Upward movement = inspiration (contraction). (FOSTER.)

In A, the trachea is closed at x, the height of inspiration; a long pause follows, and finally an inspiration (a very powerful one) sets in.

In B, the trachea is closed at the end of expiration, x; powerful inspirations follow at once.

The effects of simply closing the trachea at the end of inspiration or of expiration are shown in Fig. 510, and similar results are obtained by experiments on man.† A still more marked effect is produced if the lungs be artificially inflated. The inflation produces an instantaneous and complete relaxation of the diaphragm (Fig. 511), which by clamping the tracheal tube may be prolonged for several seconds. Forcible deflation of the lungs produces the opposite effect, viz. contraction of the inspiratory muscles.‡

When the action potentials in a single vagus fibre from the lungs are recorded, it is found that it conveys impulses in rapid succession each time the lungs are

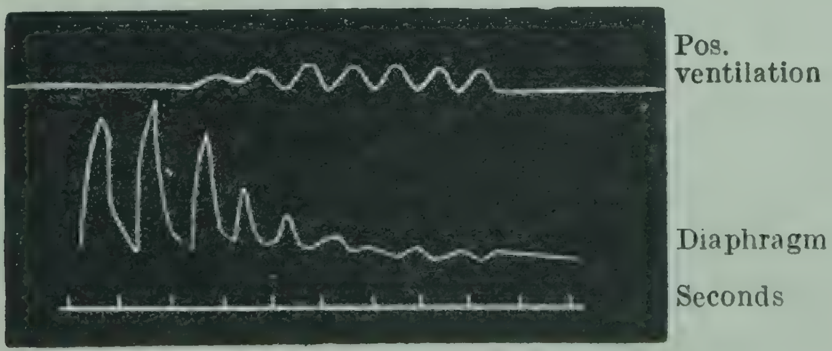

FIG. 511. Positive Ventilation. (HEAD.)

Under the influence of positive ventilation, the inspiratory contractions of the diaphragm become less and less till they disappear completely.

distended, the impulses being more numerous and in more rapid sequence the more powerful the distension.* The lung evidently possesses stretch-receptors similar to those of muscle, and like them causing reflexly an inhibition or moderation of the movement that produced the stretch—in this case the act of inspiration (Fig. 512). In deflation of the lung these impulses cease; but on forcible suction fresh impulses ascend the vagus. These are probably not present in normal breathing movements.

It is not known where the receptors which respond to inflation of the lungs are situated, though it seems probable that they are in the walls of the bronchi and bronchial tubes. Fibres of the vagus have been traced to the bronchialis muscle, where they terminate in sensory endings resembling those of the carotid sinus, and presumably, like these, acting as stretch receptors.†

The Hering-Breuer Reflex. These inhibitory and augmentor effects of changes in the volume of the lung must also result from the normal movements of respiration. Let us consider, for instance, what will happen if the influence of the two vagi could be suddenly restored after these nerves have been divided. (This experiment can in fact be realised if the functional division of the vagi be effected by cooling.) The animal would be breathing slowly and deeply. If, at the beginning of an inspiration, the vagi became functional, the expansion of the lungs caused by the inspiratory movement would send impulses up the vagus to the expiratory centre, which would arrest the movement of inspiration. The movement of expiration would then begin, but the collapse of the lungs thereby produced would stop the impulses up the vagi, and so allow the inspiratory centre to cause an inspiratory movement. Both inspiration and expiration would therefore be shortened, and the successive movements would follow one another at a shorter interval than if the vagi were not functional. This reflex is called the Hering-Breuer reflex.‡ It is abolished when both vagi are divided (Fig. 513). By its operation the *rhythm* of the respiratory centre must be determined reflexly through the agency of the vagi, while the chief factor in determining the total pulmonary *ventilation* is, as we have seen, the carbon dioxide tension of the blood.

C. Decerebrate Cat. Natural breathing (one breath).

The light line shows degree of inflation of lung. (ADRIAN. *J. Physiol.*, 1933, **79**, 332.)

Though the effect of double vagotomy is to produce slowing of the respiration, it is necessary to answer the objection that this may not be due to the section of the pulmonary fibres in the vagus, but to the division of fibres running in the trunk of the vagus from some other source. We know that other afferent fibres which would also be divided can influence respiration, *e.g.* the fibres of the "aortic" nerve, from the cardio-aortic area, and perhaps the fibres of the recurrent laryngeal nerve.* These objections have been answered by the experiment of dividing these nerves, while leaving the pulmonary branches of the vagus intact, a procedure which leaves the respiratory rate unchanged, and then by the converse experiment of sectioning only the pulmonary branches of the vagus, which produces the same slowing as division of the entire cervical vagus,† and, like it, abolishes the Hering-Breuer reflex (Fig. 513).

Although extreme collapse of the lung may also cause afferent impulses to pass up the vagi, it seems certain that these are not engendered by the moderate degree of collapse accompanying normal expiration. When such impulses are produced by the unusual stimulus of strong suction, they seem able to excite the opposite reflex to that produced by inflation, viz. an inspiratory movement. The production of inspiration by weak slow stimulation of the central end of the vagus is further evidence that such a reflex is feasible though it does not justify the assumption that it is involved in the production of normal inspiratory movements.

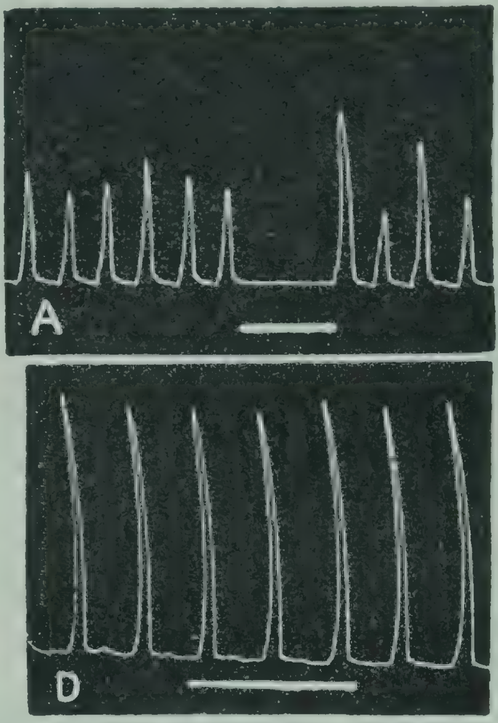

FIG. 513. Respiratory movements of larynx of chloralosed dog. A. The left vagus has been divided in the neck. Inflation of lungs during white line arrests respiration. D. The pulmonary branches of the right vagus have now been divided. The Hering-Breuer reflex is abolished. (ANREP and SAMAAN. *J. Physiol.*, 1932, **77**, 1.)

Collaboration of Nervous and Chemical Control. After division of both vagi, the total pulmonary ventilation does not, as a rule, undergo any marked change, and the aeration of the blood is carried out as well as in the intact animal. The effect of the impulses travelling up the vagi, by reining in the activity of the centre, is to economise its energy and the energy of the respiratory muscles. The result of the vagal impulses will therefore be to increase the delicacy of the respiratory centre and make it more susceptible to slight changes in the carbon dioxide tension of the blood, while maintaining a sufficient margin of energy to meet the increased needs thrown on the respiratory mechanism by augmented metabolism, such as occurs in violent muscular exercise. The importance of the vagus action for the organism is shown if we put an increased strain on the respiratory mechanism, as, for instance, by increasing the carbon dioxide in the air breathed.‡ In the intact animal, this

procedure leads first to increased depth, and later to increased frequency of respiration, the total ventilation being thereby augmented to such an extent as to keep the alveolar tension of carbon dioxide almost constant. If the same percentage of carbon dioxide be administered to a chloralosed rabbit after section of both vagi, the effect is deepening of respiration, but not quickening (Fig. 514). Each inspiratory movement, however, was already large, so that the margin by which increase of pulmonary ventilation is possible, by increase of depth of respiration alone, is not so great as in a normal animal. Therefore, since no quickening of respiration takes place, the increased ventilation rapidly becomes inadequate for the maintenance of the normal alveolar carbon dioxide tension. In the following Table the total amounts of pulmonary ventilation, obtained on administration of mixtures containing carbon dioxide to a rabbit before and after section of the vagi, are compared.

	Respirations per minute	Vol. of each respiration	Total ventilation per minute

The Vagus and Apneusis. We have seen that the respiratory centre (*i.e.* the inspiratory and expiratory centres) cannot function rhythmically when isolated from both the pneumotaxic centre and the vagus. Hence, if the influence of the pneumotaxic centre is removed by section across the upper pons, suspension of the action of the vagi, as by local cooling, produces a prolonged holding of the breath in the position of inspiration, a state called apneusis. This is due to a condition of *tonic* activity of the inspiratory centre and is caused by the presence of carbon dioxide in the blood reaching the centre. If the carbon dioxide tension in the blood is raised, as by breathing air containing CO_2, the apneustic contraction of the inspiratory muscles is increased, while if the

FIG. 515. Illustrating the effect of CO_2 content of the blood on apneusis. Cat decerebrated by section through the upper pons. Between c and *w*, vagi were blocked by local cooling. Between arrows in A, inhalation of air containing 8 per cent. CO_2. At V, in B, excessive artificial ventilation of the lungs with air. Time, 4 secs. (STELLA. *Journ. Physiol.*, 1938, **93**, 263.)

CO_2 in the blood is lowered by excessive artificial respiration, the apneusis remains in abeyance until such time as the CO_2 of the blood has mounted up to a level adequate to excite the centre (Fig. 515). When the action of the vagi is restored again by re-warming the vagi, apneusis ceases because the expiratory centre is now stimulated by the afferent impulses along the vagi from the stretched lung, and so rhythmic breathing is restored.

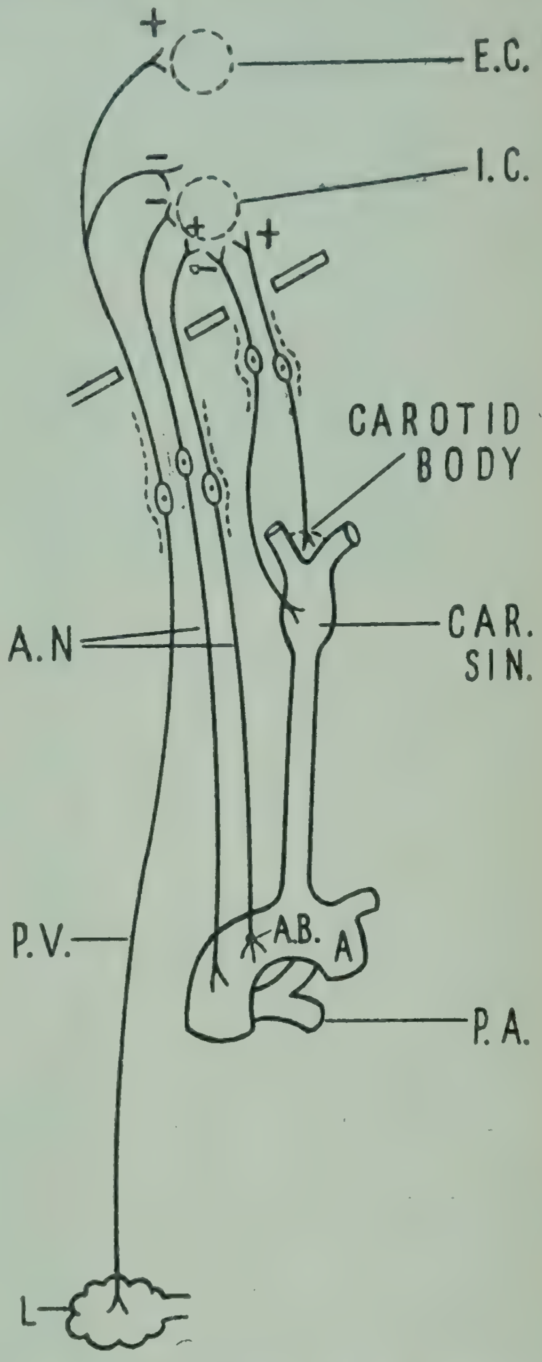

Fig. 516. Relations of vagus, aortic nerve, and nerves of the carotid region to control of respiration. E.C., Expiratory centre; I.C., Inspiratory centre; A.N., Aortic nerve; A.B., Aortic body; A., Aorta; P.V., Pulmonary vagal afferent; L., Lung alveolus.

Chemical Respiratory Effects on the Carotid Body. An important means by which the activity of the respiratory centre may be affected is the influence of the chemical composition of the blood upon nerve endings ("chemoreceptors") in the carotid body and aorta. These we have seen to be important regions in connection with the regulation of arterial blood pressure and heart rate; they, and especially the carotid body, or glomus, must now be regarded as also of importance in the regulation of the respiratory movements.

It has been shown by Heymans and his collaborators,* that when the carotid sinus region (including the glomus), with its nerve supply intact, is isolated from the circulation by appropriate ligatures, and perfused with blood which never enters the general circulation, and so never reaches the respiratory centre at all, definite respiratory reflexes are produced when the composition of that blood is changed; these are of the same nature as would have resulted had the blood perfused through the carotid region been circulating through the entire animal (Fig. 517).

Thus, perfusion of the sinus region with blood containing a deficit of oxygen, or an excess of CO_2, or with asphyxial blood, causes hyperpnœa, while perfusion with oxygenated blood deficient in CO_2 reduces the breathing. Similarly, if the carotid sinus of a dog A is perfused with blood from the carotid artery of a dog B, this blood being returned to B and not allowed to enter the general circulation of A, then asphyxia of B leads to hyperpnœa of A. The carotid body is especially sensitive to oxygen lack and less so to carbon dioxide excess. When the carotid bodies are denervated (and even if the sinus innervation is preserved), these chemical effects produced by alteration of the blood perfusing it are no longer seen. Moreover, the usual effects of oxygen lack or of HCN (which abolishes oxygen usage of tissues) on respiration in the whole animal are not seen if the carotid bodies and aorta are denervated. Under these circumstances oxygen lack rather depresses than excites the respiratory centres.† (Fig. 518).

That the chemical effects arise from the carotid body and not from the stretch-receptors of the carotid sinus has been shown by denervating the latter while leaving the innervation of the former intact.‡ Under these conditions a regular succession of impulses was shown to pass along the carotid body nerve normally, *i.e.* provided the O_2 tension in the arterial blood was below 100 mm. Hg. and the CO_2 pressure over 35 mm. If and when the O_2 tension fell, or CO_2 pressure rose, the frequency of the impulses was augmented. It seems reasonable to suppose, then, that impulses from these chemo-receptors represent one of the normal driving forces that keep the respiratory centre working. In proof of this are the facts that denervation of the carotid *body*, or inhalation of pure oxygen, lead to a small reduction of breathing in animals.

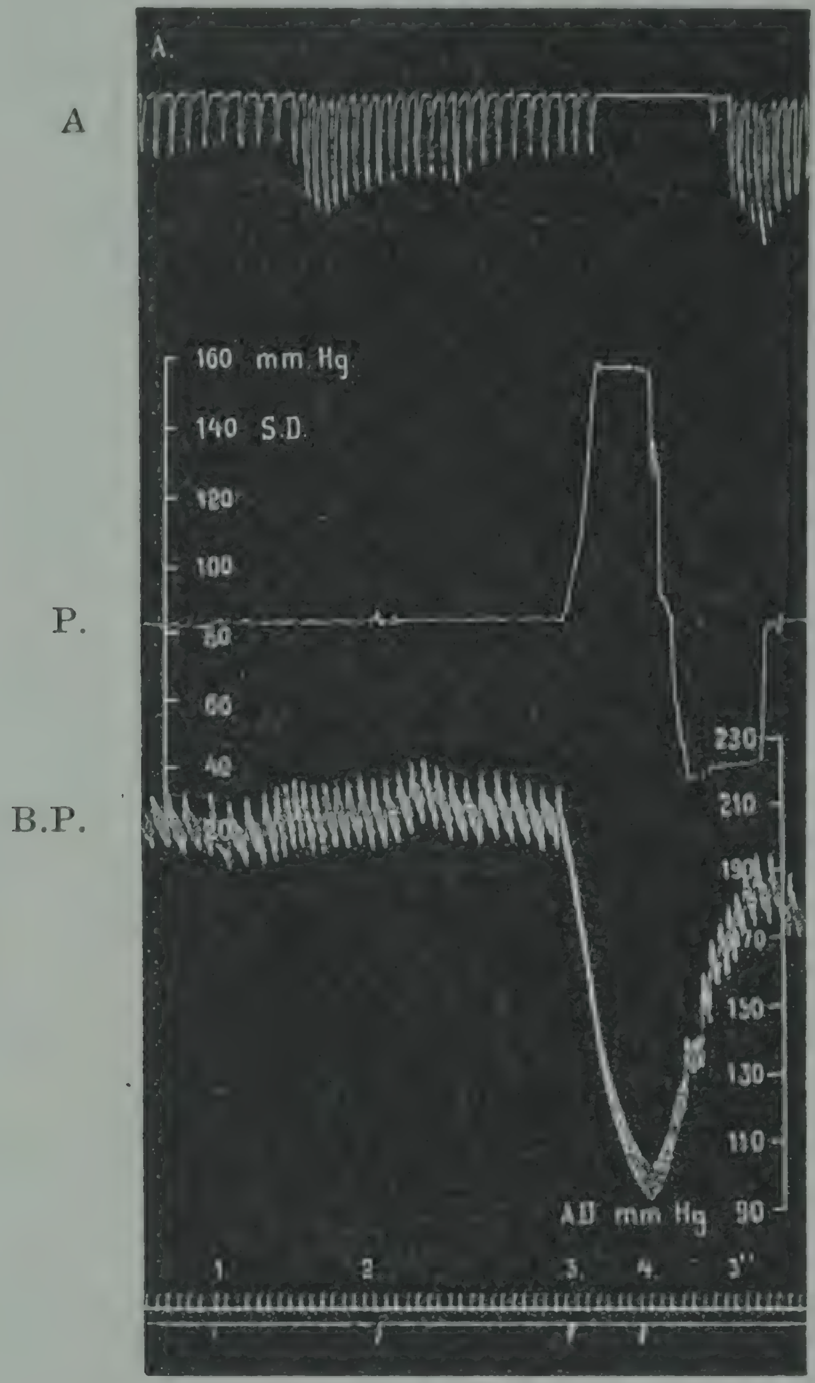

FIG. 517. Effect on respiration of dog of alteration of CO_2 content, and of pressure of fluid in the carotid sinuses. The isolated carotid sinus was perfused with a CO_2-Ringer solution from a pump. At the start the fluid contained 11 vols. CO_2 per cent. and had a pH of 7·25 ; at 1 changed to fluid containing 79 vols. p.c. CO_2 and pH also 7·25 (by increasing the $NaHCO_3$) ; at 2 returned to original fluid ; at 3–4 the perfusion pressure was raised ; at 4 pressure lowered to 40 mm. Hg. A = respiration. P = perfusion pressure. B.P. = arterial pressure. Time = 3 seconds. (HEYMANS, BOUCKAERT and DAUTREBANDE. *Pflüger's Arch.*, 1932, **230,** 283.)

The response to oxygen lack is thus mainly due to a reflex from the carotid and aortic bodies ; to raised CO_2 tensions, the respiratory centre is probably more sensitive than are the chemo-receptors.

That alteration in the composition of the blood in the aorta caused respiratory reflexes was shown by the fact that if the head of a dog was separately perfused, changes of blood composition in the trunk still caused respiratory changes in the larynx movements, provided the vagi were intact.* These reflexes arise from the aortic body, which resembles the carotid body in structure and function.

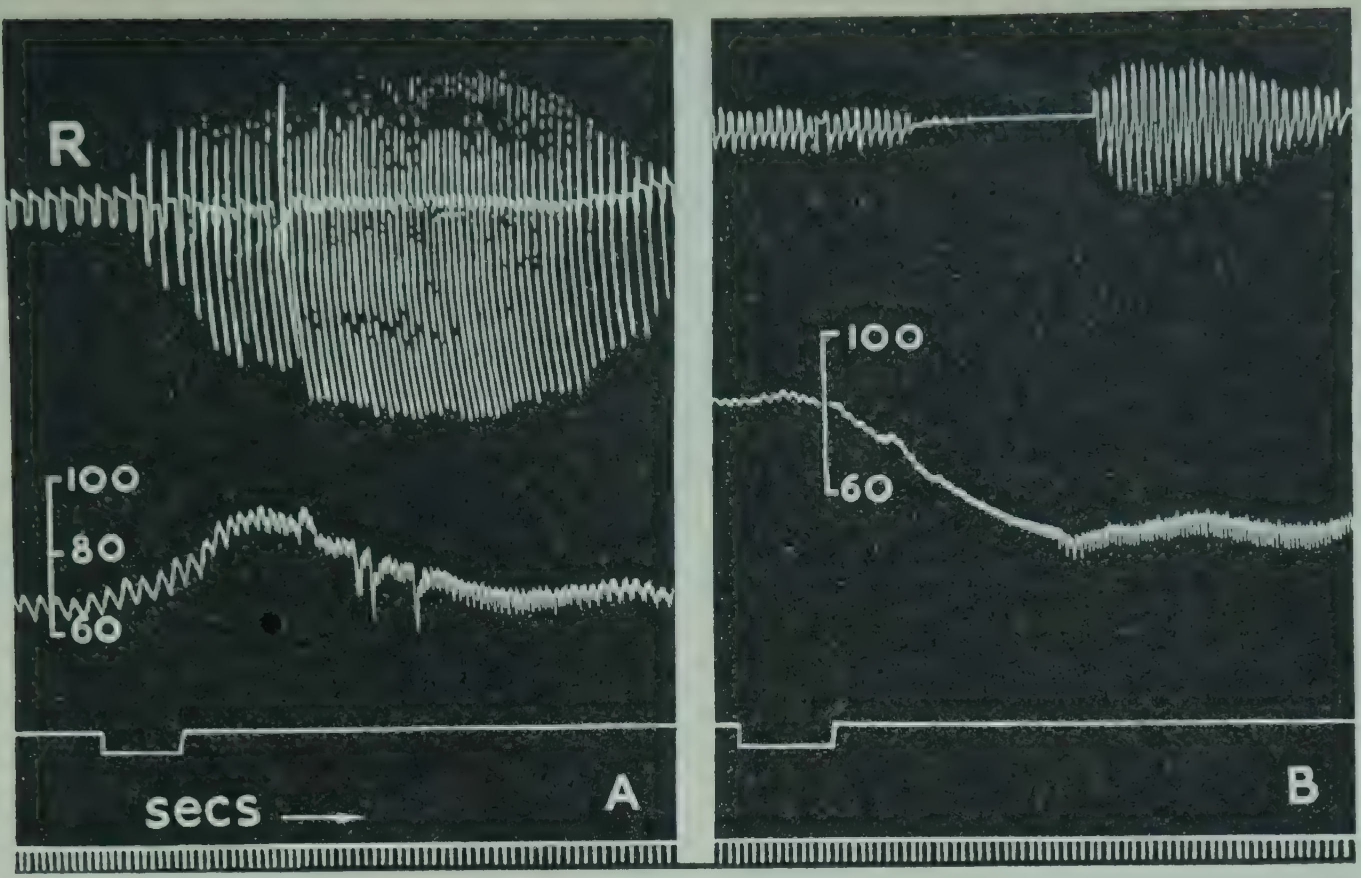

FIG. 518. Rabbit, Nembutal. A. Intravenous injection of 0·35 mg. HCN, vagi and carotid body innervation intact. B. The same dose after section of vagi and denervation of carotid bodies. R. Respirations; below, arterial pressure. Note the short time to produce effect in A (*i.e.* to reach carotid body) as compared with B (to reach medulla). The late augmentation of breathing in B is probably due to CO_2, acting on the centres.

Question of a Single Chemical Influence. Considerable discussion has taken place as to the exact nature of the stimulus to the respiratory system, when the chemical composition of the arterial blood is altered. The breathing is particularly sensitive to changes in blood CO_2. For instance, when the CO_2 pressure of the alveolar air is raised by only 2 mm., the breathing is increased about threefold.* Yet there would be a decrease of pH of the blood of only 0·012. Can we, then, regard the respiratory apparatus (*i.e.* the centre *plus* the peripheral structures such as carotid body, etc.) as exquisitely sensitive to the H-ion concentration of the blood, and consider this as the real stimulus ? The answer is that we cannot, because, under some conditions, the centre behaves as though it were indifferent to the blood reaction, though sensitive to CO_2 or, sometimes, to the HCO_3' ion.

Thus, after administration of ammonium chloride, an acidæmia results, because the NH_4 is converted to urea, leaving HCl behind in the body. Hence there is a rise of H-ion concentration of the blood (*e.g.* a *fall* of pH of, say, 0·07) yet only a small increase of breathing (say 0·5 l./min.). But the same subject when breathing air plus CO_2 to get a smaller fall of pH (*e.g.* 0·04) showed a larger increase of breathing (*e.g.* 10 l./min.).† Again, intravenous injection of $NaHCO_3$ solution raises the pH of the blood, but does not notably depress the breathing. It is admittedly a complex problem, because we cannot easily alter the pH of the blood without also altering the CO_2 pressure in the opposite direction. Hence, as a rule, a fall of pH is accompanied by increased pulmonary ventilation.

The real reason for the excitation produced in the respiratory centre by lack of oxygen, which, as we have seen, is a reflex from the carotid body, is even more obscure. Lack of oxygen might reasonably be expected to act, not as a stimulating, but as a paralysing agent, both on the cells of the respiratory centre and on any peripheral structures. Can we find any common ground on which to explain the action of both oxygen lack and CO_2 excess ?

Freely interpreting the views of Gesell, we might regard the excitation of the cells of the respiratory centre and reflex zones as dependent upon a complex heterogeneous equilibrium between these cells and the blood. According to this view, the cells of the respiratory centre and of the chemo-receptor zones are excited when their cytoplasm becomes more acid. These cells are believed to be continually producing lactic acid, which is normally being removed, chiefly by oxidative processes, but partly by passing into the blood. There would thus be a state of balance between the rate of production and the rate of removal of the acids (lactic and CO_2), and on this balance would depend the reaction, and through that, the excitability, of the nervous structures. Oxygen lack also has a paralytic effect, however, and this is its main action on the cells of the respiratory centre. A lowered oxygen tension in the carotid body would lead to a diminished rate of oxidative removal of lactic acid (as in any other cells), and consequently to its accumulation in the cells, which would cause their H-ion concentration to rise. If the oxygen utilisation of the structures is abruptly checked, as by the injection of a trace of cyanide into the blood, the same thing would happen at once, and there would be an instant hyperpnœa. Addition of lactic acid or carbon dioxide to the blood, with increase of its hydrogen-ion concentration, would also indirectly affect the reaction of the cells of the centre and of the carotid body. In the long run the addition of any strong acid to the blood is equivalent to addition of carbon dioxide, since it displaces that gas from the bicarbonate of the plasma; carbon dioxide diffuses so readily through the walls of all animal cells that it very speedily affects the hydrogen-ion concentration of the cell interior, and it is probably this high penetrating power which explains the dominant *rôle* played by carbon dioxide in regulating the respiration.

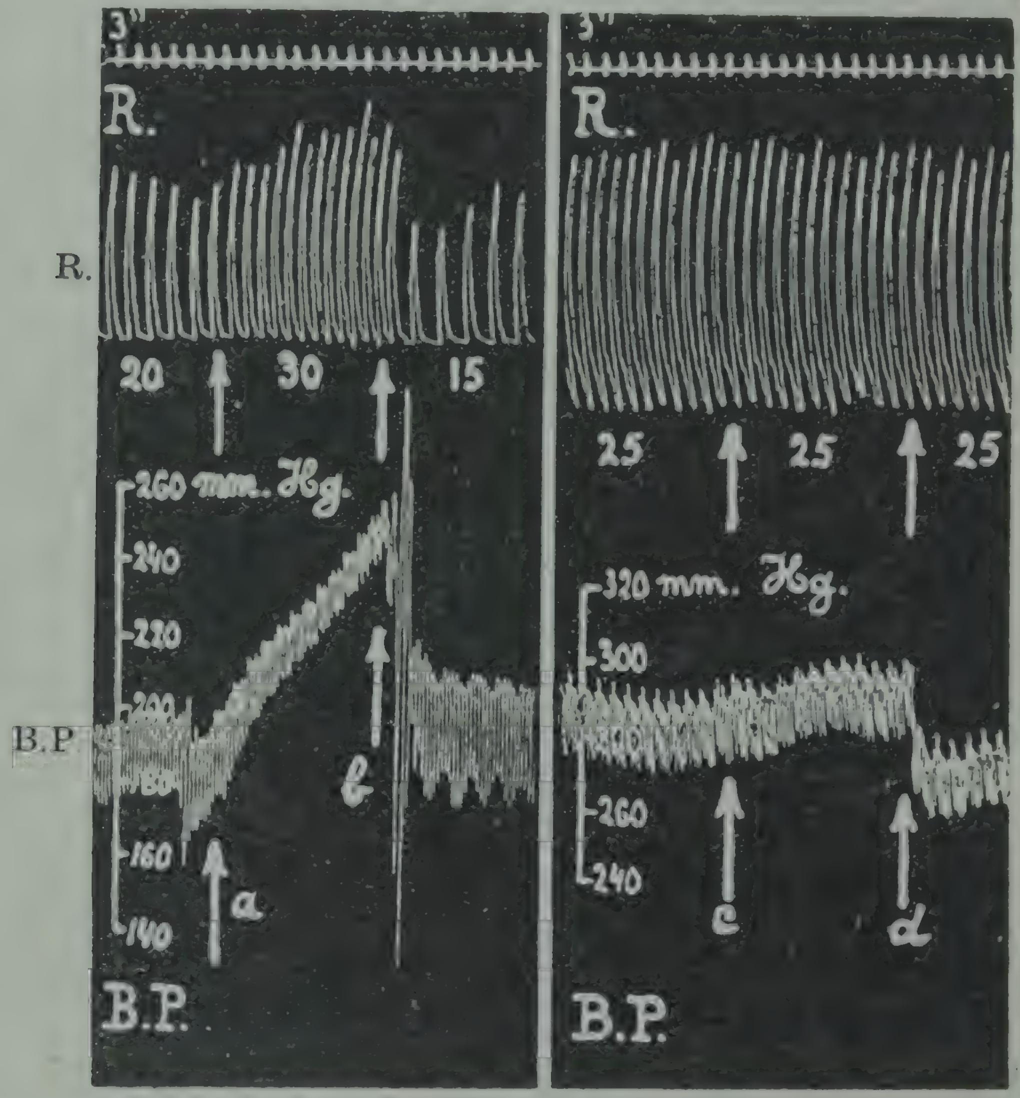
---

* CAMPBELL, DOUGLAS and HOBSON. *J. Physiol.*, 1914, **48**, 303.

† NIELSEN. *Skand. Arch. Physiol.*, 1936, **74**, *Suppl.* 10, 83.

This view would bring under one head all the chemical factors which we know to act upon respiration, namely, tension of carbon dioxide, presence of acids in the blood and considerable diminution of oxygen supply. In a more recent attempt, Gesell * has incorporated the hypotheses of humoral transmission of excitation. According to this view a rise of intracellular *c*H not only excites the cells of the respiratory centre, but also delays the destruction of acetyl choline by which synaptic transmission is effected. Acetyl choline injected intra-arterially causes a normal hyperpnœa, potentiated by eserine, and opposed by atropine, in dogs deprived of chemo-receptors; it also augments the effects of various respiratory reflexes.

Influence of Blood Pressure Changes. Carotid Sinus. It has long been known that the activity of the respiratory centre is modified by alterations in the general arterial pressure. Thus, the occlusion of both carotid arteries leads to a rise of arterial pressure, and to stimulation of respiration. It has been shown by Heymans and Bouckaert † that this effect is due to the reduction of pressure in the carotid sinus, since it disappears if the sinuses are denervated (Fig. 519). They also find that alterations of pressure in the carotid sinuses, when these are isolated from the general circulation and separately perfused, lead to important changes in the respiratory rate (*v.* Fig. 517). A rise of the



A B

FIG. 519. Effect on respiration (R) of alterations of blood pressure of dog produced by occluding both carotid arteries at *a*, in Fig. A, and at *c* in Fig. B. The arteries were released again at *b* and *d*. In Fig. B the carotid sinuses have been denervated, which has caused a rise of respiratory rate by removal of tonic impulses from the sinuses, but change of pressure in the sinuses now produces no further effect. sinus pressure leads to inhibition of respiration, and a fall to acceleration. The afferent nerve for this reflex is the branch of the glossopharyngeal which supplies the sinuses, but the aortic nerves also collaborate with it, as in the regulation of the blood pressure and heart rate, and produce similar effects.

The nerves of the carotid sinuses, and the aortic nerves, must therefore be included with the vagi as exerting a constant effect on the respiratory rhythm *; the effect produced is, however, in the opposite direction. Yet after section of the carotid sinus nerves the respiration is usually depressed. This is because the tonic accelerating impulses arising from stimulation of chemical receptors in the carotid bodies are also cut off.† If, as in Fig. 519, these are not in action, then section of the carotid sinus nerve, by removing inhibitory impulses due to pressure receptors, causes acceleration. We cannot suppose that these reflexes from the carotid sinuses are the only means by which changes in general arterial pressure may affect the respiratory centre, for unquestionably any change which leads to an alteration in the blood supply to the brain will also affect it.‡

Reflex effects on respiration may also originate from the pulmonary vascular bed. Fibres analogous to those of the aortic nerve arise in the pulmonary arteries and veins, and their stimulus by stretching may cause either depression or increase of respiration. The hyperpnœa due to pulmonary embolism is probably an instance of the latter effect.

Apnœa. If artificial respiration be maintained in an animal, or if, in man, the respiratory movements be forced, so as to produce a greater ventilation than is effected by the normal respiratory movements, a standstill of respiration is ultimately brought about. This condition is called apnœa. The standstill cannot be due to over-oxygenation of the blood, because this is normally practically saturated with oxygen, and further, because a short apnœa can even be produced by excessive artificial ventilation with nitrogen.§ It is due to the fact that forced ventilation of the lungs, with any gas mixture free from CO_2, will reduce the carbon dioxide tension in the blood circulating round the respiratory centre.‖ A respiratory pause will thus ensue, and will last until the increasing accumulation of carbon dioxide in the blood raises its tension to the normal height at which the respiratory centre is "set," so to speak, to respond. If the carbon dioxide content of inspired air be increased to about 4·5 per cent., it is impossible to produce an apnœic pause, however rapidly the respiratory movements be carried out. It would seem, therefore, that ordinary apnœa is entirely due to deficiency of carbon dioxide tension in the blood ("hypocarbia" or "acapnia").

It should be noted that over-ventilation and apnœa cannot be caused by artificial respiration by Schäfer's method in the conscious human subject. Indeed, if the subject be brought into an apnœic state by voluntary over-breathing just before applying artificial respiration, it can easily be shown that the same procedure as will ordinarily produce a normal amount of ventilation now induces but little until the state of apnœa has passed off.¶ The reason for this is that the Hering-Breuer reflex is now abnormally sensitive, so that the smallest collapse of the lungs is sufficient to check any further expiratory movement and *vice versâ*, so that the movements of artificial respiration are reflexly resisted.

Stoppage of respiration is sometimes caused reflexly. A familiar example of this is the "*deglutition apnœa*" seen in man during swallowing. It lasts for about 1·5 seconds as a rule, but shows individual variations, and is shorter for swallowing of liquids than of solids. Deglutition generally occurs during the phase of expiration, which is afterwards resumed at the point at which it was arrested.* Similarly, when a duck plunges, there is immediate stoppage of respiration, which may last four or five minutes if the animal remains so long under water. The same stoppage may be produced by pouring water on the beak.

Breath-holding and Other Tests. After a deep expiration, followed by the deepest inspiration, the breath can be held for an average time of about 68 seconds in fit men,† though the actual times range from 30 to 120 seconds. When the " breaking-point " is reached, it is chiefly because of the accumulation of carbon dioxide in the blood rather than because of lack of oxygen, but the differences are partly due to psychological causes. The alveolar air at the breaking-point contains about 7 per cent. CO_2 and 10 per cent. O_2. Previous forced breathing will enable the breath to be held longer, as also will swallowing, or the filling of the lungs with pure oxygen. In the latter case the alveolar CO_2 may be 8 per cent. or more.‡ Conversely, the period is much shortened if the lungs be previously over-ventilated with nitrogen or with oxygen containing 5 per cent. CO_2.

The " endurance " test or " 40 mm. test " is carried out as follows : the subject's nose is clipped, he takes the deepest possible expiration, followed by the deepest possible inspiration ; the mouth is then applied to a tube connected with a mercury manometer, and he raises the mercury to a height of 40 mm. which is maintained as long as possible, the cheeks and lips being supported by the hand so that they take no part in the process. The pulse rate is counted meanwhile. A fit subject should maintain for 52 seconds, and show no great increase in pulse rate (or arterial pressure) until the point of discomfort is reached. Unfit persons maintain for a shorter time, and show a rise of arterial pressure and pulse rate, at an early stage of the test. Another test is the maximum force of expiration following a deep inspiration, as tested with a mercury manometer ; it should be 110 mm. Hg. These tests, with the requirement of a vital capacity of 3,800 c.c. or over, are employed for the selection of recruits for the Royal Air Force.

The value of the " 40 mm." test is that it tests the extent of abdominal pooling ; when this is large, the intra-abdominal pressure forces out blood from the abdominal area, and increases the return to the heart, so that the arterial pressure and pulse rate rise ; later pulse rate may drop reflexly.§

Adaptation of Breathing in Exercise

As an example of a normal adaptation, we may take the changes in respiration which occur as the result of muscular exercise. The cause of these changes is not entirely explained. During mild activity, the blood will reach the carotid region and respiratory centre with a slightly increased CO_2 tension. The carbon dioxide content of the alveolar air will be raised, but the respiratory centre is stimulated both directly and reflexly, and the increased pulmonary ventilation thereby produced prevents further rise in the alveolar carbon dioxide pressure, until a point is reached at which an equilibrium is maintained between the effect of the increased production of carbon dioxide in raising the arterial carbon dioxide tension and that of the increased respiratory activity in lowering it. Under these circumstances it is found that the increased consumption of oxygen in the contracting muscles is compensated ; in fact, there is a linear relationship between oxygen consumption and the volume of air breathed, when the exercise is moderate in amount.

When the exercise is more severe, however, the respiratory movements are usually increased to such an extent that the tension of carbon dioxide in the

blood falls *below* normal. Again, the hydrogen-ion concentration of the arterial blood has been claimed as the decisive factor. If enough lactic acid were produced, the respiratory movements might be augmented to such an extent that the CO_2 tension in the blood and alveolar air falls below normal and yet the hydrogen-ion concentration may be raised. Lastly, there may be deoxygenation of the arterial blood, which would cause further respiratory increase by action on the carotid body.

The fact remains, however, that hyperpnœa often occurs without demonstrable alteration of blood *p*H., O_2 or CO_2 tension. Even *passive* movements of the limbs can cause it, and when this is so, the effect, which can be abolished by section of the spinal cord, appears to be a reflex originating mainly in the joints concerned,* and perhaps in part in the lungs, great veins, and auricles, in consequence of circulatory changes there. In active movements of the limbs, pressor reflexes from chemo-receptors in the limbs may be set up,† and no doubt irradiation of excitation from cortico-spinal paths into the reticular formation of the medulla is a contributory factor. Rise of blood temperature, acting on carotid bodies and on nerve centres may also play a part.

Liberation of adrenaline is another factor that may augment ventilation. In all probability the hyperventilation of exercise cannot be explained as due to any single factor.

Asphyxia (*v.* p. 754). The first phase in the phenomena of *asphyxia* is conditioned simply by the changes in the carbon dioxide tension. A little later, the gradual exhaustion of oxygen in the blood begins to make itself felt, and the reflexes from the aorta and carotid body, due to this cause, further augment the breathing. During the second stage there is a discharge of energy throughout the whole nervous system, beginning in the bulbar centres and causing a great rise of blood pressure, with slowing of the heart, and extending thence to all the spinal centres with the production of muscular spasms. At this stage, too, there is a discharge of impulses causing contraction of the pupil. The phenomena of the third stage are due to the influence of oxygen lack upon the nerve centres, accompanied or preceded by exhaustion and dilatation of the heart, the circulation failing before the excitation of the lower centres has entirely come to an end. In this third stage it is impossible, even by the strongest stimuli, to evoke any reflex.

Dyspnœa. We are not generally aware of an increase in the volume of the pulmonary ventilation until this has been about doubled. With further increase the consciousness of respiration steadily obtrudes itself, until by the time the ventilation has been increased to about four or five times the normal resting value, there is real distress, and we say that dyspnœa has set in. Dyspnœa is seen during strenuous exertion, in conditions of oxygen lack, and in certain diseased states.

The dyspnœa of exercise is associated with deficient oxygenation and increased carbon dioxide content of the blood, and these in turn may be said to be due to an improper adjustment between circulation and respiration. Usually it is the heart which is at fault, and which is the limiting factor in athletic performances of endurance ; the heart is unable to pump the blood through the lungs quickly enough, so that it becomes increasingly venous and thus excites the respiration more and more.

If vigorous exercise is continued, there comes a time when the discomfort disappears, and the subject gets what is called "second wind." It is found that at this point there is a sudden fall in the carbon dioxide content of the alveolar air ; during the dyspnœic period this may have been as high as 7·5 per cent., which often falls after second wind to 6·0 per cent. At the same time there is a fall in the volume of air breathed, a rise of temperature, and onset of sweating.‡

‡ Cook and Pembrey. *J. Physiol.*, 1913, **45**, 429.

The phenomenon has not received a full explanation; it is probable that it represents the attainment of a steady state, in which the circulation rate, the chemical composition of the blood, the psychical condition of the individual, the state of the respiratory centre, of heat regulation, etc., reach new equilibria.

The dyspnœa in normal subjects associated with oxygen lack will be specially considered later.

Pathological causes of dyspnœa can only briefly be mentioned. Apart from those, such as pneumothorax, obstruction to the air-passages, etc., which are due to purely mechanical causes opposing the entry of air, the chief types are those seen in renal disease, cardiac disorders, diabetes and anæmia. In renal disease* and in diabetes, there is an excess of fixed acids in the blood, raising its hydrogen-ion concentration. In cardiac cases there is not only a reduced circulation rate, but usually some secondary alterations in the lungs themselves, for both of which reasons there is difficulty in keeping the blood properly arterialised. In anæmia, the number of red corpuscles in the blood is insufficient to carry the proper amount of oxygen to the tissues, so that the condition is virtually the same as in other states of oxygen lack. All these conditions, however, are actually more complicated than would appear from what has been said above, and often the cause of the dyspnœa remains obscure.†

Over-ventilation. (Forced Breathing.) There is a large amount of carbon dioxide, free or fixed, stored in the blood and tissues, and we may compute the whole body of an adult man to contain some 15 or 20 litres of carbon dioxide. The oxygen store of the body is held almost entirely by the hæmoglobin, and does not exceed 1 litre. Now, forced (*i.e.* voluntarily quick and deep) breathing moves large amounts of air; in fact the maximal ventilation so obtained can exceed that of exercise. This hyperventilation very rapidly washes out carbon dioxide from the large store, but does not at all increase the oxygen store. By continuing forced respiratory movements for a minute or two, the carbon dioxide tension, both in the alveoli and in the blood, may be brought down very considerably.

In consequence of the lowering of carbon dioxide pressure in the blood, this becomes more alkaline, and various secondary phenomena ensue. Thus, alkaline urine is excreted, and this always contains bicarbonate; it also contains less ammonia than previously and may contain aceto-acetic acid.‡ The bicarbonate of the blood plasma is lowered,§ partly by reason of the ionic interchange with the corpuscles, partly by excretion of base. The blood lactate is increased, because glycolysis in the blood is accelerated. The calcium ion concentration of the blood is lowered, and in consequence symptoms of tetany may appear. The rise in pH of the blood, together with the fall of CO_2 pressure, affects the vasomotor centre, causing a fall of arterial pressure,‖ and also depresses the respiratory centre. As a result, there is a prolonged period of

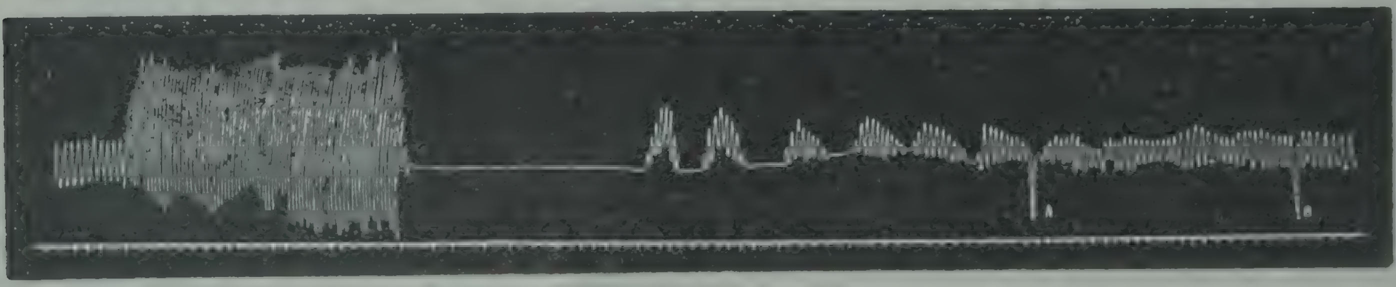

Fig. 520. Forced Breathing of Air for two minutes, followed by Apnœa for two minutes, and Periodic (" Cheyne-Stokes ") Breathing for about five minutes. (Douglas and Haldane.)

At A, sample of alveolar air contained O_2, 11·44 per cent.; CO_2 5·58 per cent. Second sample at B, O_2, 13·55 per cent.; CO_2 5·57 per cent.

apnœa. During this period of cessation of respirations, however, the oxygen is being used up, and the tension of this gas in the blood may fall to such an extent that the respiratory centre is reflexly excited by lack of oxygen before the carbon dioxide tension in the alveoli has risen to its normal value. As a result of the excitation by oxygen lack, a few breaths are taken, the carbon dioxide tension is further lowered, and the stimulation due to the oxygen lack disappears. There is thus again a cessation of respiration (Fig. 520).

"Cheyne-Stokes" Breathing. These periods of cessation alternate with periods of respiration, so that we get a condition of periodic breathing, which is spoken of as Cheyne-Stokes respiration.* During the period of apnœa resulting from forced breathing, the great diminution of oxygen tension in the alveoli is shown by the fact that the subject of the experiment becomes blue, and may indeed lose consciousness. There are, at the same time, rhythmic changes in the blood pressure, which rises towards the ends of the periods of apnœa, falling during the periods of respiration. The first respiration after excessive forced breathing is due to oxygen lack. The period of apnœa may therefore be considerably prolonged, if the onset of oxygen lack be postponed by increasing the tension of this gas in the alveoli at the commencement of the apnœic period. By forcibly breathing for a period of two minutes in an atmosphere of oxygen, men have succeeded in holding their breath for as long a period as eight minutes.†

"Cheyne-Stokes" breathing is almost invariably observed as one of the effects of exposure to high altitudes, and is then especially marked during sleep. It is often present when the activity of the respiratory centre is depressed, as in cases of uræmia or pernicious anæmia. Under these circumstances, it may be temporarily removed by administering either oxygen or carbon dioxide (in small percentage) to the patient. The oxygen removes the anoxic stimulus to the carotid body; the carbon dioxide prevents the hypocarbic apnœa.

ANOXIA

The name anoxia is given to the condition of oxygen lack of the tissues. Lack of oxygen in the blood is also called *anoxæmia*. Four types of anoxia are recognised, viz. *anoxic, anæmic, stagnant* and *histotoxic*.

Anoxic Anoxia is anoxæmia, *i.e.* a lowered partial pressure of oxygen in the blood, with consequent diminution in the degree of oxygen saturation of the arterial blood. It is produced by any condition which prevents the proper oxygenation of the blood in the lungs, *e.g.* by reduced oxygen pressure in the air breathed, by diseases in which the gaseous interchange in the lungs is impaired, and in congenital heart disease due to a patent foramen ovale.

Anæmic Anoxia. In this form the oxygen tension of the blood is unchanged, but the quantity of oxygen which can be made available from the blood is diminished. It is seen in hæmorrhage, in anæmia, and in states in which the hæmoglobin is converted into some form which will not carry oxygen, *e.g.* into nitric oxide hæmoglobin, as in poisoning by nitrous fumes, or into methæmoglobin, as in poisoning by aniline or chlorates, or into carboxyhæmoglobin in carbon monoxide poisoning.

Stagnant Anoxia is seen in conditions in which the circulation through a part or over the whole body is slowed. Thus it is seen in surgical shock, circulatory failure, and venous obstruction.

Histotoxic Anoxia results when, the oxygen pressure and content of the blood being unaltered, or even raised, the tissues, though in full receipt of blood, fail to utilise the oxygen from it. In this category may be placed the poisoning by cyanides, which paralyse the respiratory enzymes of the tissues, and probably also the toxic effects of very high oxygen pressures.

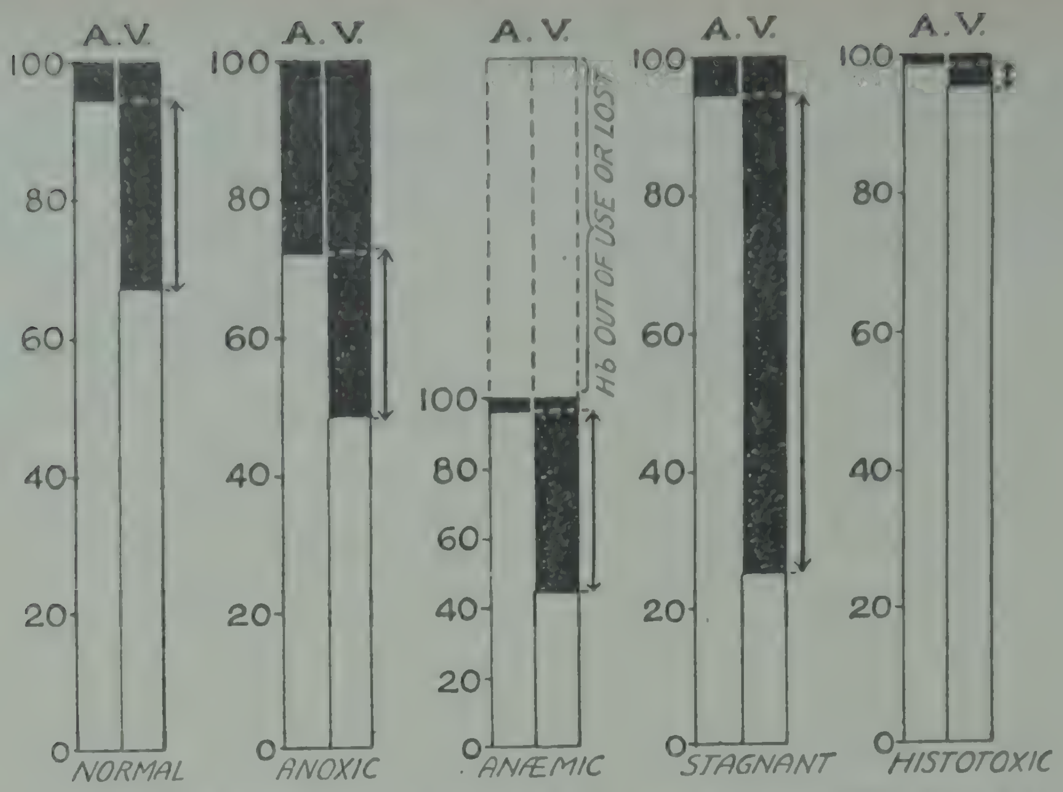

Fig. 521. Oxygen saturations of arterial (A) and venous (V) blood in the four types of anoxia. The black portion of each column represents the percentage of reduced hæmoglobin and the white portions the percentage of oxyhæmoglobin in the blood. All the bloods had the same initial oxygen capacity when the subject was normal. In anæmic anoxia some of this, shown by dotted lines, has been lost, *e.g.* by hæmorrhage or by conversion to carboxyhæmoglobin. The arrows show the coefficient of oxygen utilisation, *i.e.* the volume of oxygen removed from one unit of blood by the tissues.

The oxygen saturations of the arterial and venous bloods in the four types of anoxia are illustrated in Fig. 521.

CYANOSIS

Cyanosis is the name given to a bluish colour of the skin, especially of the lips, ears, hands and feet, and of the nails. It is due to the presence of reduced hæmoglobin in the blood, and so is met with in conditions in which this occurs, whether from inadequate oxygenation of the arterial blood, or from the utilisation of an undue proportion of the oxygen of the blood during its transit through the capillary circulation, as in sluggish local or general circulation.

The degree of cyanosis depends, not on the relative amount of reduced hæmoglobin in the capillary blood, but on its *absolute amount.* To cause cyanosis there must be at least 5 g. of reduced hæmoglobin per 100 c.c. of capillary blood. Since blood normally contains about 15 g. Hb per 100 c.c., this means that less than 66 per cent. oxygen saturation of the blood in the capillaries will cause cyanosis. But an anæmic person with half the normal Hb content would have to be only 33 per cent. saturated with oxygen before cyanosis was evident.

It is convenient in this connection to consider the *degree of unsaturation* of the blood. Normal arterial blood is about 5 per cent. unsaturated, which for an oxygen capacity of 20 vols. per cent. is 1 c.c. oxygen deficit or unsaturation per 100 c.c. blood. The mixed venous blood is about 6 c.c. per 100 c.c. unsaturated, *i.e.* the tissues have taken out 5 c.c. oxygen per 100 c.c. blood. The mean capillary unsaturation may be taken as midway between the arterial and venous levels, *i.e.* as 3·5 c.c. per 100 c.c. Since 1 c.c. oxygen will fully saturate 0·75 g. Hb, the capillary blood will therefore contain $3 \cdot 5 \times 0 \cdot 75 = 2 \cdot 5$ g. Hb in reduced form, *i.e.* there will normally be no cyanosis.

Suppose now that we consider the blood in a subject in a state of anoxic anoxia, due, suppose, to breathing an atmosphere in which the oxygen had been reduced. The blood leaving the lungs contains, say, only 15 vols. oxygen per 100 c.c.; the tissues abstract the usual quota of 5 vols. per cent., so that the venous blood contains 10 vols. per 100 c.c. The arterial and venous unsaturations are respectively 5 and 10 c.c. and the capillary unsaturation again the mean of these, viz. 7·5 vols. per cent., = 7·5 × 0·75 = 5·6 g. Hb. There would be cyanosis.

Again, suppose the arterial blood to be normal, *i.e.* 1 vol. per cent. unsaturated, but owing to slow circulation the venous blood was 15 vols. per cent. unsaturated. The capillary unsaturation would be 8 vols. per cent. = 8 × 0·75 = 6 g. Hb, and again there would be cyanosis.

An anæmic subject with an oxygen capacity of half the normal, viz. 10 vols. per cent., if exposed to the anoxic conditions would have 0·5 vol. per cent. unsaturation in his arterial blood, and 9·5 — 5·0 = 4·5 vols. O_2 or 10 — 4·5 = 5·5 vols. unsaturation per cent. in his venous blood. His capillary unsaturation would thus be the mean of 0·5 and 5·5, *i.e.* 3·0 c.c. = 3 × 0·75 = 2·25 g. Hb, so there would *not* be any cyanosis.

In the reverse condition of polycythæmia, or in states of "hæmoconcentration," in which the number of red cells is abnormally increased, the opposite would hold good, and cyanosis would ensue on relatively slight anoxæmia.

THE EFFECTS ON RESPIRATION OF CHANGES IN THE AIR BREATHED

We have already seen that a moderate increase in the carbon dioxide content in the air breathed (*e.g.* up to 4 per cent.) causes a proportional increase in the ventilation of the lungs and that this is due to the increase of CO_2 and not to the slight diminution in oxygen content. High percentages of CO_2 cause abnormal effects leading to narcosis and death.

Changes in Oxygen Tension. Oxygen usually exercises little, if any, effects on the respiratory ventilation. At the normal atmospheric pressure, the partial pressure of oxygen in the alveoli, when air is breathed, is amply sufficient to nearly saturate the hæmoglobin passing through the lungs. Hence little reduction in total ventilation will be produced by increasing the partial pressure of oxygen in the alveoli, even when pure oxygen is inhaled. But prolonged breathing of pure oxygen may cause lung damage.

This statement is true only for the healthy individual. If, from failure of the heart and circulation, from diminished oxygen partial pressure, or from severe loss of blood, the oxygenation of the blood is insufficient, amelioration of the symptoms may be produced by inhalation of pure oxygen. Especially is this noticeable where there is failure of the heart. In these cases, the heart, already affected, is unable to keep up an adequate circulation and to supply itself with sufficient oxygen. A vicious circle is thus established, in which the heart tends to get steadily worse. By administration of oxygen, an adequate supply of this gas to the heart muscle is assured; the heart beat therefore becomes more effective and the whole circulation is improved.

Breathing of oxygen at high pressures is an altogether different matter. If a warm-blooded animal be placed in a chamber containing pure oxygen at four atmospheres, or air at twenty atmospheres, it dies as rapidly as if it were placed in nitrogen.* If removed while living, recovery of the animal may be rapid, though after-effects on the nervous system may ensue. This fact assumed importance in naval diving practice † after the introduction of closed-circuit oxygen-breathing apparatus. The pressure rises, as the diver descends, at the rate of nearly 1/5 atm. per fathom, so that, *e.g.* at 90 ft. the pressure is raised by 2·73 atm. (= 3·73 atm. absolute). The time of onset, and the nature and severity of symptoms varies from subject to subject, and from time to time; but almost every subject will, at 90 ft. depth, be affected within the hour, and some in a few minutes. Some risk may be expected in sea-diving with oxygen at any depth below 25 ft. of sea water (= 1·75 atm. abs.). The symptoms include psychological changes, twitching of lip, facial and other muscles, and finally epileptiform convulsions and loss of consciousness.

* Paul Bert. *La Pression Barométrique.* 1878 (Paris); translation, 1943, *Barometric Pressure* (Columbus: College Book Co.); Lorrain Smith. *J. Physiol.*, 1899, **24**, 19.

† Donald. *B.M.J.*, 1947, *i*, 667, 712.

Two explanations of the phenomena are offered, and probably both are partly correct:[*] at the high pressure enough oxygen can be taken up by the animal's *plasma* to supply its wants, so that the oxyhæmoglobin does not become reduced. But then, the more acid oxyhæmoglobin retains the available base of the blood and so prevents this base from combining with CO_2 from the tissues. Hence there is a rise of CO_2 pressure within the tissues, which ultimately causes death. As pointed out by Campbell, it is the rise of CO_2 pressure in the tissues which causes the convulsions that precede death under high oxygen pressures. There is also some evidence that high oxygen pressures poison respiratory enzymes, *e.g.* dehydrogenase or, more particularly pyruvic oxidase, by attacking the —SH group of the enzyme.

We have seen that the oxygen pressure in the air may be lowered to about 13 per cent. without pronounced discomfort, though there may be blueness of the lips and nails, owing to deficient oxygenation of the blood. With further reduction, hyperpnœa occurs, owing to excitation of chemo-receptors in the carotid glomus, and, if the administration of low percentages of oxygen, *e.g.* about 10 to 12 per cent. of an atmosphere, be continued for some time, the subject of the experiment may suffer considerable discomfort. The symptoms of oxygen lack are severe headache, confusion of thought, vomiting or nausea and a feeling of discomfort in the precordial region.

Respiration at reduced Atmospheric Pressure. Many experiments have been made, on animals and on men, submitted to a lowered atmospheric pressure in chambers specially built for the purpose.[†] The limit to which the pressure may be reduced varies in different individuals, the variations being determined by the type of respiratory movement of the individual in question, since on the depth of respiration depends the relation between the tensions of oxygen in the alveoli and in the inspired air. The lowest limit at which human life is possible corresponds to an oxygen tension in the alveoli of about 25 mm. Hg. The physiology of respiration at reduced atmospheric pressures is particularly interesting in connection with exploits in mountaineering or aviation; the chief difference between the two being that in the former great physical exertion must be coupled with the drawbacks of reduced air pressure and adverse climate, while in the latter there is the drawback that the reduction of pressure is rapid and the onset of symptoms correspondingly sudden. A good deal of investigation has been carried out for the purpose of studying the phenomena involved in the response and acclimatisation to lowered air pressure, during both aircraft[‡] and mountain ascents.[§]

The phenomena of oxygen lack above described are similar to those which are regarded as characteristic of "mountain sickness." The Table on p. 775 shows the diminution in the atmospheric pressure at varying heights above the level of the sea.

At a height of 5,000 metres (16,400 feet) the pressure of the air is reduced to little over half an atmosphere, and the oxygen tension is therefore only about 11 per cent. of an atmosphere. Moreover a greater *volume* of the alveolar air

5,000	16,404	410	54
6,000	19,685	357	47
7,000	22,966	320	42
8,000	26,246	290	38
9,000	29,523	260	34

must consist of carbon dioxide since the *tension* of this gas tends to be kept nearly constant (cp. Fig. 508).

Because of this dilution with CO_2, and also with water vapour, at reduced atmospheric pressures, the effects of a lowering of oxygen content of air at normal pressure are not the same as those of a proportional lowering of air pressures, *e.g.* 10·5 per cent. oxygen at 760 mm. has not the same effect as 21 per cent. at 380 mm., because if p $CO_2 = 40$ mm., and p $H_2O = 47$ mm., then the oxygen pressures in the two cases are :—

$$(760 - 40 - 47) \times 0{\cdot}105 = 71{\cdot}7 \text{ mm. Hg.}$$
$$(380 - 40 - 47) \times 0{\cdot}21 = 61{\cdot}5 \text{ mm. Hg.}$$

This means to say that, in laboratory experiments, a reduction of O_2 content of the air to one-half of the normal corresponds to an altitude of only 17,000 ft. and not to 18,000 ft.*

The much greater diminution in the partial pressure of oxygen than in that of CO_2 in the alveolar air is shown by the following average results obtained during fourteen aeroplane flights, with five subjects :—

ALVEOLAR AIR DURING AEROPLANE FLIGHTS. (SCHNEIDER and CLARKE. *Amer. J. Physiol.*, 1926, **76**, 354.)

Altitude, feet	0	4,000	8,000	12,000	15,000
Alveolar oxygen pressure mm. Hg .	100·5	90·5	67·2	58·1	49·8
Alveolar CO_2 pressure mm. Hg . .	40·9	35·3	35·7	32·5	29·2

The carbon dioxide pressure, however, does fall somewhat, and this is due to the increased pulmonary ventilation, which shows a steady increase as the reduction of pressure progresses. If the low pressure is maintained, the breathing continues steadily to rise to a maximum ventilation some hours or days later. In the 1938 Mt. Everest expedition the alveolar partial pressure at 22,800 feet was 16·5 mm. CO_2 and 35·7 mm. O_2 after acclimatisation ; at 28,000 feet (reached) they would probably be 16 mm. and 25 mm. respectively. The increased breathing is a consequence of the reduced oxygen pressure and provides an increased lung surface, and also an increased excretion of carbon dioxide, and so leads at first to an increase in the blood alkalinity and to the excretion of an alkaline urine. If the volume of air breathed be reduced by calculation to normal pressures, it is found that less air is breathed than at sea level.

Deep breathing affords a means of immediate adaptation, and is also operative in the adaptation which comes on gradually during residence at a high altitude. Part of this acclimatisation appears to depend upon the excretion, by the kidneys, of bicarbonate from the blood, thus compensating for the low content of free CO_2. When this has been brought about, the pH of the blood returns practically to normal.

---

* HORVATH, DILL and CORWIN. *Amer. J. Physiol.*, 1943, **138**, 659.

Another important means of rapid adaptation is by means of the circulation. This is noticeable even in persons sitting quietly in a chamber in which they can be subjected to gradually lowered pressures, and no doubt holds good for aviators. It is evident that a deficient oxygenation of the blood may be compensated by increasing the rapidity of the circulation ; and this happens. Both the stroke volume of the heart and the pulse rate are increased in the early stages of oxygen deprivation. The following Table shows the changes in the pulse rate caused by exposure to varying pressures in a gas chamber :—

PULSE IN CHAMBER AT REDUCED PRESSURES

Pressure mm. Hg.	Pulse p. min.
720	64
650	72
424	84

This quickening of the pulse is to be observed also in the trained mountain soldier, and in individuals in whom there is no lowering of the alveolar carbon dioxide tension, so that apparently, in such cases, the whole adaptation to altered conditions is by means of the circulation. In cases where adaptation fails, it is in the circulation that the failure is most marked, so that the symptoms of severe mountain sickness closely resemble those produced by heart failure. But this mechanism, again, is only immediate and does not explain acclimatisation to life in mountain districts. Barcroft, in the Peruvian Andes (4,400 metres) found that at rest the pulse was normal and that there was no increase in the circulation rate.

As a result of extreme oxygen starvation, there may be an inadequate supply of this gas to the heart, which may tend to fail, especially on making muscular movements. But at a much earlier stage, the oxygen starvation of the brain produces failure of judgment, inability to carry out or to co-ordinate muscular movements properly, and then loss of consciousness. The disturbance of the central nervous system is shown by the almost invariable occurrence of Cheyne-Stokes breathing at great heights. The symptoms of oxygen lack, as a rule, do not become conspicuous until just before collapse, so that, although there is an oxygen starvation of the body, there must be some compensation to obtain a sufficiency of this gas for the lowered requirements of the body. As the subject of oxygen lack is unaware of these effects, one of which takes the form of extreme stubbornness, the insidious danger of the condition is of great importance in aviation. In rapid lowering of oxygen, or in rapid ascents consciousness is lost at 4·2—5·2 per cent. O_2, which corresponds to an altitude of 28,000 to 31,000 feet, but is soon regained on rise of pressure.* Breathing of oxygen-enriched air is essential for pilots at altitudes over 15,000 feet, if effects of oxygen lack are to be avoided. At over 43,000 feet even this does not suffice, as the barometer is too low to give the requisite oxygen pressure ; hence the pressure must be raised by the use of either a sealed flying suit filled with oxygen under slight pressure or a sealed cockpit filled with oxygen—also under slight pressure. With such arrangements, oxygen lack ceases to be a limiting factor in high flying, and heights of about 60,000 feet have been officially recorded.† In jet-propelled aircraft, thus equipped, it would seem that there would be no limit, mechanical or physiological, to the altitude attainable. An interesting point concerning this is the action to be taken by aircrews baling out at, say, 30,000 feet. Should a delayed drop be made, to try to clear the more rare levels before consciousness is lost, or should they open out as soon as free, and lose and regain consciousness during descent ? It seems to be a matter of taste, as well as of courage. Bale-out oxygen sets, with 10 minutes' supply provide the practical answer.

If a subject is able to withstand the immediate effects of exposure to a rarefied atmosphere, processes of adaptation come into play which finally

* HORVATH, DILL and CORWIN. 1943, *loc. cit.*

† Group-Capt. J. CUNNINGHAM, 59,492 feet (25 March, 1948).

fit him for discharging his functions normally, even at the high altitude. That the adaptation is effective, is shown by the fact that most individuals, if they remain at a height, gradually recover from the mountain sickness and may finally be able to carry out muscular movements with almost as great precision and force as they could previously on the plains. The main factor in rapid adaptation to lowered oxygen pressure is not an increase in the tissue O_2-tension, but an habituation of the heart and nervous tissues to the lowered O_2-tension.* As an immediate effect of change to a region of low atmospheric pressure, there is an apparent increase in the blood corpuscles, due to a concentration of the blood and a diminution of its plasma. Simultaneously, however, the blood-forming organs respond to the reduction in the oxygen saturation of the blood, so that, after a stay of four or five weeks' duration at a height, both corpuscles and hæmoglobin are considerably increased in total amount. The following Table shows the average number of red corpuscles contained in one cubic millimetre of blood from inhabitants of regions at varying altitudes :—

	Height above sea level, in metres	Red corpuscles
Christiania . .	0	4,970,000
Zurich . .	412	5,752,000
Davos . .	1,560	6,551,000
Arosa . .	1,800	7,000,000
Cordilleras .	4,392	8,000,000

As a result of the increase in the concentration of red cells, there would, in the later stages of acclimatisation, be an increase in the tissue O_2-tensions.†

At the same time, owing to a rise in the excitability of the respiratory centre, the total ventilation is increased, so that the alveolar oxygen tension is raised 10 or 12 per cent. above that which it would otherwise be.

There is, of course, a limit to the power of adaptation, a limit which varies in different individuals. Thus, for some men, it is impossible to stay any length of time in the high settlements in the Andes, while others, after two or three weeks' discomfort, become perfectly inured to their new conditions. It seems doubtful, however, whether any of the present race of men could become adapted to permanent residence at a height over 6,000 metres, though for a certain length of time, by bringing into play the reserve mechanisms already described, they may raise themselves to a height considerably above 7,000 metres. The highest summits in the Himalayas (*e.g.* Mount Everest, 8,865 metres), have a height approaching that attained in 1875 by Tissandier with two companions in his famous balloon ascent, namely, 8,600 metres. In this ascent, although oxygen inhalation was used (somewhat ineffectively), two of the party succumbed. The expeditions to Mount Everest showed, however, that when acclimatisation was gradual, men could live at about the same altitude, *e.g.* Mallory's party reached 8,200 metres (26,900 feet) without oxygen inhalation. But at such heights, the slightest exertion, *e.g.* changing from lying to sitting, caused extreme breathlessness. Oxygen often gives relief under these conditions, though its administration presents difficulties.‡

Respiration at High Pressures. New phenomena appear when the air pressure is greatly increased, as in deep diving, in caissons, or with those using submarine escape apparatus (*within* a submarine the pressure is normal). When the air pressure is raised to 8·6 atm. (= 250 ft. sea-water) or more, the *nitrogen exerts an intoxicating effect* within a few minutes; added to this is an enhanced effect of CO_2.[*] At normal pressures, 0·8 per cent. CO_2 causes no detectable mental impairment; if, however, the air containing it is compressed to 10 atm. (= 300 ft. sea-water), the partial pressure of CO_2 will be = 8 per cent. at sea-level, and for some reason this is more effective still at high pressure, since men become confused and clumsy, and mostly lose consciousness in a few minutes. The nitrogen of air is normally a purely inert gas. The very inertness of nitrogen may be of danger, when high pressures are reduced, since nitrogen is especially soluble in adipose and nervous tissues.[†] In all, the body normally contains about 1 litre of dissolved nitrogen, one-fifth of which can be washed out in a few minutes by breathing oxygen.[†] If a man be exposed, as in a caisson, to a pressure of three to six atmospheres, the nitrogen dissolved in the body is increased in direct proportion to the pressure. If the pressure be now suddenly released, the nitrogen, which cannot be used up by the tissues, is given off from the tissues in the form of insoluble bubbles. These bubbles, occurring in all the capillaries, obstruct the flow of blood, and therefore, if the evolution of gas is sufficiently large, the animal dies of gas-embolism in heart and nervous system. During the decompression of divers and caisson workers, or in steep high airplane climbing, a similar evolution of gas may occur, causing damage to the cord and paralysis (" caisson disease "; " bends," " divers' palsy ").[‡] In order to prevent this sudden evolution of gas, it is necessary that the decompression should be carried out gradually (best of all in oxygen), so as to give the tissues time to get rid of their excess of nitrogen without the formation of bubbles.[§] Another method is to replace the atmospheric nitrogen by helium, giving the diver a helium-oxygen atmosphere, since helium is less soluble in fat than nitrogen.[||] By this means a depth of 535 feet has been reached (=17·2 atm.).[¶]

OTHER GASES. Argon, helium, hydrogen and methane are, like nitrogen, indifferent gases, and may without harm be used, instead of nitrogen, to dilute the oxygen that we breathe.

Carbon monoxide is rapidly poisonous since it combines with hæmoglobin, forming CO-hæmoglobin. The blood is therefore deprived of its oxygen carrier, and the animal dies of asphyxia. The importance of CO poisoning lies in the fact that coal gas, motor car exhaust, breech gases from guns, etc., contain a high proportion of CO. The blood of town-dwellers usually contains 0·1—0·2 vols. p.c. of CO. Not more than 0·05 p.c. CO in air can be breathed for an hour or two without effects. Breathing air containing 0·1 per cent. of CO causes severe symptoms in thirty to sixty minutes, with per cent. saturations of the Hb with CO of the order of 15 to 20; at 30 to 40 per cent. saturation consciousness is suddenly lost, and death may follow at 50 per cent. saturation or over. In such chronic poisoning with CO, there is a great lowering of the tissue oxygen-tensions.[**] But, although the avidity of CO for hæmoglobin is about 300 times that of oxygen, we can convert the CO-hæmoglobin back into oxyhæmoglobin by increasing the mass influence of the oxygen and by adding CO_2. This may be done by giving the poisoned animal oxygen containing 5 per cent. CO_2 to breathe.

[**] Campbell. *J. Physiol.*, 1929, **68**, 81.

The curve relating CO-saturation to CO-pressures is similar in form to the oxygen dissociation curve, but, as shown by Douglas, Haldane and Haldane,* the CO-pressures required are very small, only about $\frac{1}{245}$th as great as the oxygen pressures. Thus, we get half saturation of the blood with CO at a CO-pressure of about 0·13 mm. Hg (in presence of 40 mm. CO_2), whereas for oxygen we require a pressure of about 32 mm. (with 40 mm. CO_2). When, however, oxygen and carbon monoxide are both present, the saturating power of carbon monoxide is not 245, but 310, times as great as oxygen. This is possibly due to the fact that the velocity constant for oxygenation of hæmoglobin is about 7·5 times as great as that for reduction, together with the fact that, although the rate of combination of CO with hæmoglobin is only one-tenth as great as for oxygen, the rate of dissociation of COHb is only $\frac{1}{245}$ of that of HbO_2. Hence the stability of COHb is due, not to the speed of its formation, but to the slowness of its dissociation. (Hartridge and Roughton.†)

In cases of CO poisoning there is no dyspnœa. This is because, as we have learned, the dyspnœic response to oxygen lack is a reflex from the carotid body when the oxygen *tension* of the arterial blood is lowered. But in CO poisoning the oxygen tension of the blood is normal, though its oxygen content is reduced. The other symptoms of oxygen lack are, however, more serious than the reduction of the oxygen saturation would seem to warrant. This is because CO alters the shape of the oxygen dissociation curve, removing the S-shape, and moving it to the left, so that the blood less readily gives off oxygen to the tissues.‡

Many other gases have specially poisonous properties.

Irrespirable gases are those which are so irritating that they produce spasm of the glottis. Such are ammonia, chlorine, sulphur dioxide, a high percentage (*e.g.* 20 per cent.) of CO_2, and many others.

PROTECTION OF THE LUNGS FROM DUST. Although the inhaled air contains dust particles, very few of these reach the deeper structures of the lung, and those that do so are quickly removed. Coarser dusts are normally removed from the air as this passes over the extensive nasal mucosa, which is always kept moist with sticky mucus. In mouth-breathing this line of protection is greatly weakened, but the trachea and bronchial tubes are similarly moistened and so most of the dust particles reaching them are trapped. These are then carried upwards by ciliary action in the coat of mucus, and, reaching the mouth, are swallowed. This mechanism is remarkably efficient and very few dry dust particles ever reach the alveoli. Dust particles trapped in the larger tubes are carried upwards at a speed of 1–3 c.m./min.§ It has been claimed that the removal of dust-laden mucus is expedited by peristaltic contractions of the bronchial tubes synchronising with respiratory movements.

Extremely fine and scanty particles do, in spite of these defence measures, find their way into the alveoli. These are removed by wandering cells and deposited in the lymph glands at the root of the lungs. In town-dwellers and in coal workers these glands are always found to be black and to contain many cells that have carried ingested dust particles.

VENTILATION. A point of practical importance is the securing to each individual of sufficient fresh air. It is found that a dwelling-room becomes unpleasant and stuffy when the amount of CO_2 present has reached 0·1 per cent. This stuffiness is due to exhalations from the skin, lungs and alimentary canal. As these cannot be measured, it is taken as a cardinal rule in ventilation that the amount of CO_2 should not rise above 0·1 per cent.

An adult man gives off about 0·6 c. ft. of CO_2 every hour. Hence, in that time he raises the amount of CO_2 in 1,000 c. ft. of air from 0·04 per cent. (the normal amount in the atmosphere) to 0·1 per cent. He must, therefore, be supplied with 2,000 c. ft. of air per hour, in order to keep the amount of CO_2 down to 0·07 per cent. (Ordinary air contains 0·04 per cent. CO_2, therefore 2,000 c. ft. would contain 0·8 c. ft. CO_2, which, with the 0·6 c. ft. given off by the man, would be 1·4 c. ft., which is 0·07 per cent.). In crowded rooms the CO_2 may rise to 2 per cent. or more. The maximum rise in per cent. CO_2 after a considerable period is given approximately by the formula $\frac{70}{R}$, where $R =$ ventilation rate in c. ft./hr. per person.

In order that the air may be easily renewed without giving rise to excessive draughts, a certain amount of cubic space must be allotted per person. Each adult in a room should have 1,000 c. ft. of space, and be supplied every hour with 2,000 to 3,000 c. ft. of air.

BOOK VI

THE INTAKE OF MATERIALS—NUTRITION, METABOLISM

HISTORICAL NOTE

ANCIENT and mediæval physicians, confounded by the rapidity with which food entering the alimentary canal became altered in appearance and reduced in amount, and unrestrained by any notions regarding the indestructibility of matter, did as would be expected, and cloaked their ignorance in words and doctrines. One speculation, due initially to ERASISTRATUS (*circa* 300 B.C.), and adopted with amplifications by GALEN (*circa* A.D. 180), was that the food was altered by a change called "concoction" into a principle, which, being absorbed and proceeding to the liver, was there converted into blood and endowed with "natural spirits": subsequently, as we have seen in earlier chapters, the vital spirits and animal spirits arose from it. This doctrine, being based on authority rather than on fact, died hard, or at least late.

The first approach to a realistic view of the nature of digestion was made by VAN HELMONT (1577–1644), who no doubt fancying a resemblance between the familiar phenomena of alcoholic fermentation and the vulgar facts of flatulence, saw the course of digestion as a series of fermentations, the ferment of the stomach being prepared in the spleen, and mixed with acid. Since the bile was the only then known juice poured into the alimentary canal, his guess was more astute than he knew: but we should not read too much prophecy into it, seeing that the biological, and still more the enzymic, view of fermentation lay centuries ahead. He did, however, believe that the tissues took up substances from the blood.

The notion of glands, secretions, and ducts having been put forward by STENSEN, who discovered the parotid duct in 1662, it was natural for FRANCISCUS SYLVIUS (1663) to follow up the views of Van Helmont, and to regard the changes of digestion as being what would now be termed chemical in nature, with the digestive juices, especially saliva, as active agents.

At about that time (1664) DE GRAAF performed the surprising operation of cannulating the pancreatic duct of a dog, and so collected pancreatic juice: its functions were not known, however, till long afterwards.

The science of physics was then beginning to take shape, and the new knowledge was regarded as the key to all natural phenomena. So, due to the influence of the iatro-physical school, led by BORELLI (1608–79), digestion, to be in the fashion, came to be considered as a progressively finer and finer trituration, in which the act of mastication was the first and crudest step. But the balance swung back again when the wide genius of BOERHAAVE, in 1708, found in compromise the answer which is still held as correct, viz. that both mechanical and chemical processes play their parts in reducing the food to such a state as enables it to be absorbed into the blood. In the absence of both chemical knowledge and directed experiment, however, speculation regarding the nature of the chemical changes still continued, and even the immortal HALLER (*circa* 1760) got no further than regarding them as akin to putrefaction.

Instructive experiments began with the observations of RÉAUMER (1752). He induced a tame kite to swallow perforated metal tubes containing various food materials, which were regurgitated to order after given intervals of time. Meat and bone had undergone no putrefaction, but, although protected from mechanical assault, were soaked with liquid and partly dissolved, while starchy foods were unaffected. His conclusion that the liquid had a solvent action was confirmed by SPALLANZANI (1777), who placed bits of sponge in the tubes, and showed that the liquid squeezed from them would digest meat *in vitro* if kept warm. Spallanzani, and, quite independently, STEVENS of Edinburgh (1777) applied these methods to man, and confirmed the results, but failed to note the acidity of the gastric juice, the first inkling of this being given by CARMINATI in 1785, the final identification of HCl by PROUT (1834). For a time, all the actions were attributed to the acid, although EBERLE had, in 1834, made an active artificial juice by digesting gastric mucosa with dilute HCl. A classical investigation, the first on a gastric fistula, was made by WILLIAM BEAUMONT, a United States army surgeon, between 1825 and 1833. The subject, Alexis St. Martin, a Canadian voyageur, received a gunshot wound which, after healing, left a fistulous opening into the stomach. Through this orifice Beaumont observed the secretion of gastric juice, the state of the empty stomach, its movements, etc., and noted the times taken to digest foods of various types. Distillation of the gastric juice which he collected confirmed the presence of considerable amounts of HCl. Experimental gastric fistulæ in animals were first made in 1842 by Bassow, and have since been much improved, notably by Pavlov.

Belief in the existence of specific "ferments" still existed, but the first to be named was pepsin, by Schwann in 1835. New enzymes were soon added, *e.g.* ptyalin by Miahle (1845); two enzymes of the pancreatic juice were described by Claude Bernard in 1856 and trypsin by Kühne in 1876; enterokinase was discovered by Pavlov in 1899, etc.: the generic term "enzyme" was introduced by Kühne in 1878, the catalytic nature of their action having been previously pointed out by Berzelius in 1838.

Physiologists have always tended to evolve general theories of the secretory process, and these theories have closely reflected the state of contemporary knowledge. In the 18th century, there being little knowledge of the minute structure of glands, the opinion held (Haller, 1760) was of a direct communication between the gland substance and the finest extremities of the blood-vessels, through which a kind of filtration of plasma took place. By the mid-19th century, a sound morphological knowledge existed: Johannes Müller (1830), held that the secretion was formed by the walls of the acini, the constituents passing from the blood of the encompassing capillary network, in amount and kind depending on the nature of the living acinar cells. After the enunciation of the cell theory (1838), views not unlike those now held, such as the elaboration of special substances (*e.g.* Kolliker (1850)) became current. The influence of physics also made itself felt: out of the membrane diffusion studies of Dutrochet (1827), and Graham (1850), arose the mechanical theory of Ludwig (1856), which was countered by Heidenhain (1883), who showed that physical causes alone provided an inadequate explanation.

The first indication of the means by which the secreting glands were brought into action was provided when Ludwig, in 1851, showed that the submaxillary gland secreted if the peripheral end of the chorda tympani was stimulated: secretory nerves to other glands were expected, and were, in fact, discovered later, *e.g.* the vagus to the pancreas and stomach. Bayliss and Starling, in 1902, however, showed that introduction of dilute acid into the duodenum provoked secretion of pancreatic juice by even the denervated pancreas: this led them at once to the discovery of secretin, and to the conception of humoral stimuli, to which they gave the general name of hormones.

Movements of the stomach were observed by Beaumont, and those of the intestines, familiar from ancient times, were systematically described by Ludwig in 1861. By the use of graphic methods Bayliss and Starling (1899) added considerably to our knowledge of the intestinal movements; the first use of X-rays, with opaque meals, now so extensively used in the clinic, was due to Cannon, who studied the movements of the stomach in 1898, and of the intestine in 1902.

During the latter part of the 19th century, there was considerable expansion in detail of the knowledge of the general course of digestion, of the secretion of the digestive juices, of absorption, and of the subject of physiological chemistry. For example, Kühne's work between 1876 and 1883 on the course of pancreatic digestion, of which leucine and tyrosine were recognised as products, Heidenhain's studies of the structure of the gastric mucosa, and introduction of the gastric pouch in 1879 (subsequently improved by Pavlov in 1898), and a series of important investigations by Pavlov from 1888–1900 on the work of the digestive glands.

Until 1828 the opinion was held that organic substances, which were by then being isolated in increasing numbers, could only be manufactured by living organisms, but in that year Wöhler showed that urea could be made synthetically. This paved the way for investigations on the constituents of the body, and of foods, which was crowned by the classical work of Fischer on the carbohydrates, purine bodies, and proteins. The idea of chemical material alterations in the body, now called metabolism, was introduced about 1836, and an attempt to make up a material balance sheet for the body was first made by Boussingault in 1836. The development of thermodynamics in the mid-19th century opened up the possibility of studying an energy balance sheet; the introduction of a respiration apparatus by Regnault and Reiset in 1849, its improvement by Voit in 1861, and the classical studies on heat values and the calorific balance sheet by Rubner about 1891, and by Atwater and Benedict from 1897 onwards, placed that subject in the catalogue of accepted scientific facts. The indispensability of protein in the diet was shown by Majendie (1819), and the conception of nitrogenous equilibrium was due to Voit (1857).

Lavoisier (1789) believed that in the lungs, oxygen directly oxidised carbon and hydrogen: Liebig (1842) taught that it was protein, carbohydrate and fat that were oxidised, the protein being only oxidisable in muscle, and during its contraction. Out of these various researches there grew the opinion that appropriate amounts of protein, carbohydrate, fat, salts and water were all that were needed to constitute a complete diet. The accessory food factors came to be recognised as a result of the work of Lunin (1880), Eijkman (1897), Holst and Fröhloch (1907), Hopkins (1912), and Funk (1911), the name "vitamin" being proposed by the last-named. The constitution of most of the known vitamins has been worked out since 1930, and several of them have been made synthetically.

The unfolding of the problems of intermediary metabolism has been largely linked up with the recent rapid development of biochemistry. One of the most important studies was that of Knoop (1910) who traced the oxidation products of amino-acids by linking them with a benzene ring. Recent developments which have proved fruitful are the use of the tissue slice method, conjoined with respirometric and microchemical technique, and the employment of compounds containing isotopic elements as a means of tracing intermediary products in metabolism. The development of rapid and accurate methods of microchemical analysis has also provided biochemists with most valuable tools, and to these has been added the employment of chemical substances having specific effects on particular tissues, or on particular enzymes : drugs, *e.g.* like atropine, acetyl choline, iodoacetate, etc. Probably no drug has played a larger part in the history of the metabolism of carbohydrate, and, incidentally, that of other materials, than has phlorrhizin (v. MERING, 1885). The relation of the pancreas to diabetes mellitus was discovered by v. MERING and MINKOWSKI (1889), the presence of sugar in diabetic urine and blood having been long known. The then hypothetical anti-diabetic hormone of the pancreas was named insulin by SHARPEY-SCHAFER in 1916, and, after being sought by many, was finally extracted from pancreas, and isolated, by BANTING and BEST in 1922.

The nature of the chemical changes by which the ultimate oxidation of the food materials was effected has been a fruitful source of experiment and of speculation. Before about 1920, oxidation was believed to be due to a direct combination between oxygen and the compound to be oxidised, though it was doubtful as to how this might be brought about in animal tissues. About that time however, WIELAND and THUNBERG showed that certain substances, such as succinic acid, could be oxidised in complete absence of free oxygen, by transfer of two hydrogen atoms to a reducible substance under the influence of tissue enzymes called dehydrogenases. Almost simultaneously Warburg put forward the view that oxidation can be brought about by iron-containing catalysts that activate free oxygen. By about 1935 it was realised from KEILIN'S work that both mechanisms were employed by the tissues, dehydrogenation reactions, often in many stages, leading finally to oxygen activation by cytochrome oxidase at the end of the chain.

The means by which carbon dioxide is finally produced as an end-result of oxidative metabolism, and in which the tricarboxylic acid cycle plays an important role, began to be realised about 1940 from the work of KREBS, SZENT-GYORGYI and others.

CHAPTER XLI

THE EXCHANGES OF MATTER AND ENERGY IN THE BODY

All the energy which leaves the body as heat or work is derived from processes of oxidation, the carbon, hydrogen, nitrogen and sulphur of the foodstuffs being oxidised and eliminated in the form of carbon dioxide, water, urea, sulphates, etc. In a starving animal this is associated with a loss of body substance. The necessity for taking food is determined by the need of replacing this loss. Most food-stuffs cannot be utilised directly as a source of energy, but must be altered and built up into the living protoplasm. The total amount of living material in the body, though fairly constant in the adult, may yet undergo alterations under some conditions, and especially in the growing animal. We have in this chapter to inquire into :

(1) The relation between the total amount of material taken up by the body and the total amount given out—the *material balance sheet ;*

(2) The relation between the potential energy available to the body and the amount of energy set free as heat or work—the *energy balance sheet ;*

(3) The nature and amounts of the foodstuffs necessary for maintaining the weight of the body constant or providing for its growth and health ; and

(4) The significance of the various classes of foodstuffs as sources of energy and in the replacing of tissue waste.

1. THE MATERIAL BALANCE SHEET

METHODS EMPLOYED

Income. The determination of the material exchanges of the body involves comparison of its income and output. The income consists of the foodstuffs and oxygen. The foodstuffs may be divided into two classes, namely (1) the organic foodstuffs, which on oxidation may serve as sources of energy, and (2) the inorganic foodstuffs, such as salts and water.

The latter class neither add to nor subtract from the total energy of the organism, but their presence is essential ; and as they are contained in the various excreta, a corresponding amount must be present in the food to make good this loss.

In spite of the variety of foods, their essential organic constituents can be assigned to the three classes, proteins, fats and carbohydrates ; and analyses of the food must give the relative amounts present in digestible form of these three proximate principles.

In the proximate analysis of the foodstuffs the water is determined by drying at 105° C., the inorganic constituents by ashing the dried remainder. The nitrogen (Kjeldahl's method), multiplied by 6·25, gives approximately the total protein. The fat is determined by extracting the dried food in a Soxhlet apparatus with ether. Carbohydrates may be determined by boiling the food with dilute acids in order to convert all carbohydrate into hexoses, which are then estimated as glucose. The carbon and hydrogen content of the food can easily be calculated.

In order to attain greater accuracy, some observers have made a complete food, which is prepared in large quantities at the beginning of the experiment and used as the sole diet throughout. The monotony of such a diet tends to interfere with the success of the experiment, since the subject loses his appetite.

For approximate calculations, especially of dietaries of whole communities, the labour of analyses is lightened by the fact that nearly all the ordinary foodstuffs have been analysed and their average composition published.*

---

* R. H. A. Plimmer, "Analysis and Energy Values of Foods," H.M. Stationery Office, 1921. Atwater and Bryant, *Bull.* 28, U.S. Dept. Agricult., 1906. McCance and Widdowson, "Chemical Composition of Foods" (M.R.C., Rep. No. 235, 1940).

Output. The material output of the body is turned out by the kidneys, the alimentary canal, the lungs and the skin. These excreta must therefore be collected and analysed. In most cases the losses by the shedding of the cuticle, hairs and nails, and so on, are so small that they may be disregarded.

The nitrogen of the food, and that derived from the disintegration of the tissues of the body, is excreted almost exclusively in the urine, but a small amount is thrown out by the alimentary canal. The total nitrogen must therefore be determined both in the fæces and in the urine. The nitrogen in the fæces is derived from two sources. Part represents those nitrogenous constituents of the diet which have resisted digestion, and a certain amount is derived from the intestine itself. Even during complete starvation fæcal matter is formed in the intestine, and it has been calculated that normally about 1 g. of nitrogen a day is excreted in the secretions entering the gut and contributes to the formation of the fæces. It is usual, therefore, to regard 1 g. of the nitrogen of the fæces as belonging to the *output* of the body, while the balance belonging to undigested foodstuffs is subtracted from the total nitrogen of the latter in reckoning the real *income* of the body. A small amount of nitrogen is also lost by sweat, but this can usually be disregarded.

If an animal is kept on a sufficient diet which contains a regular amount of nitrogen, after a few days a condition known as *nitrogenous equilibrium* is set up, *i.e.* the total nitrogen of fæces and urine is exactly equal to the total nitrogen of the food. The same applies to the sulphur, as shown in the following Table (quoted by Tigerstedt):

Days of experiment.	Nitrogen of food.	Nitrogen excreted.	Per cent. difference.	Sulphur ingested.	Sulphur excreted.
1–7	154·81	153·02	— 0·51	—	—
8–17	213·72	213·26	— 0·21	12·77	12·79

In order to express the nitrogenous metabolism in terms of protein, we multiply the total nitrogen of the excreta by 6·25. This will give the total protein which has been broken down during the period of the experiment.

Respiratory Exchange. This gives us the oxygen intake and the carbon dioxide output. The estimation of these involves the use of some form of respiration apparatus. Water output in the breath can be calculated, or determined directly.

The methods which have been used for this purpose are very numerous, but are of two main types, the closed or re-breathing type and the open or expired-air-analysis type. In the closed type, the subject breathes an atmosphere which circulates in a closed apparatus; the carbon dioxide produced is absorbed, and can be weighed, and oxygen is added in measured amount to keep the volume of the enclosed atmosphere constant: the nitrogen is breathed over and over again. In the open type fresh air is inspired, and the expired air is subjected to measurement and analysis in one of several ways. The Benedict apparatus is on the closed principle; Haldane's and Douglas' methods are on the open principle.

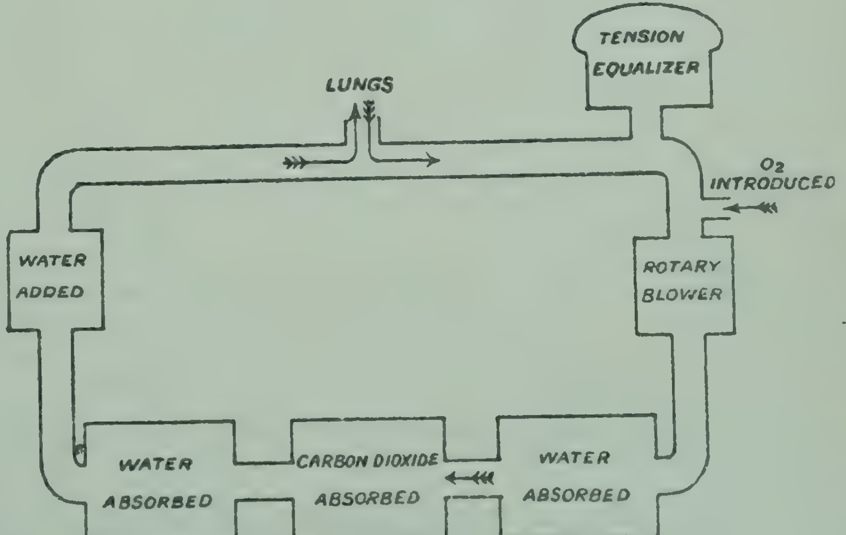

Fig. 522. Air Circuit in Benedict's Respiration Apparatus.

I. The Method of Benedict. The subject of investigation is placed in a closed chamber containing a given volume of air. The carbon dioxide produced is absorbed in caustic alkali, and the oxygen consumed is made good by allowing oxygen in measured amount to flow into the chamber. The inflow of oxygen is regulated so as to keep the pressure of air in the chamber constant. At the end of the experiment, the alkali is weighed to find the amount of carbon dioxide absorbed ; or the CO_2 can be expelled by acid and its volume measured direct. The air in the chamber is also analysed at the end, to correct for any change.

The Atwater-Benedict Respiration Calorimeter (Fig. 526, p. 792) is on a similar principle.

In a modification of this method * applicable to clinical purposes, the subject breathes through a nose-piece into a wide metal tube, the mouth being kept closed. The metal tube forms part of a closed system through which a current of air is maintained by means of a blower. In the course of the current of air are interposed vessels for the absorption of carbon dioxide and of water, and the volume of gas in the system is maintained constant by admitting oxygen to it as the oxygen is used up in respiration. The tension equaliser (Fig. 522) consists of a pan closed by a loose rubber bag. The whole circuit to commence with

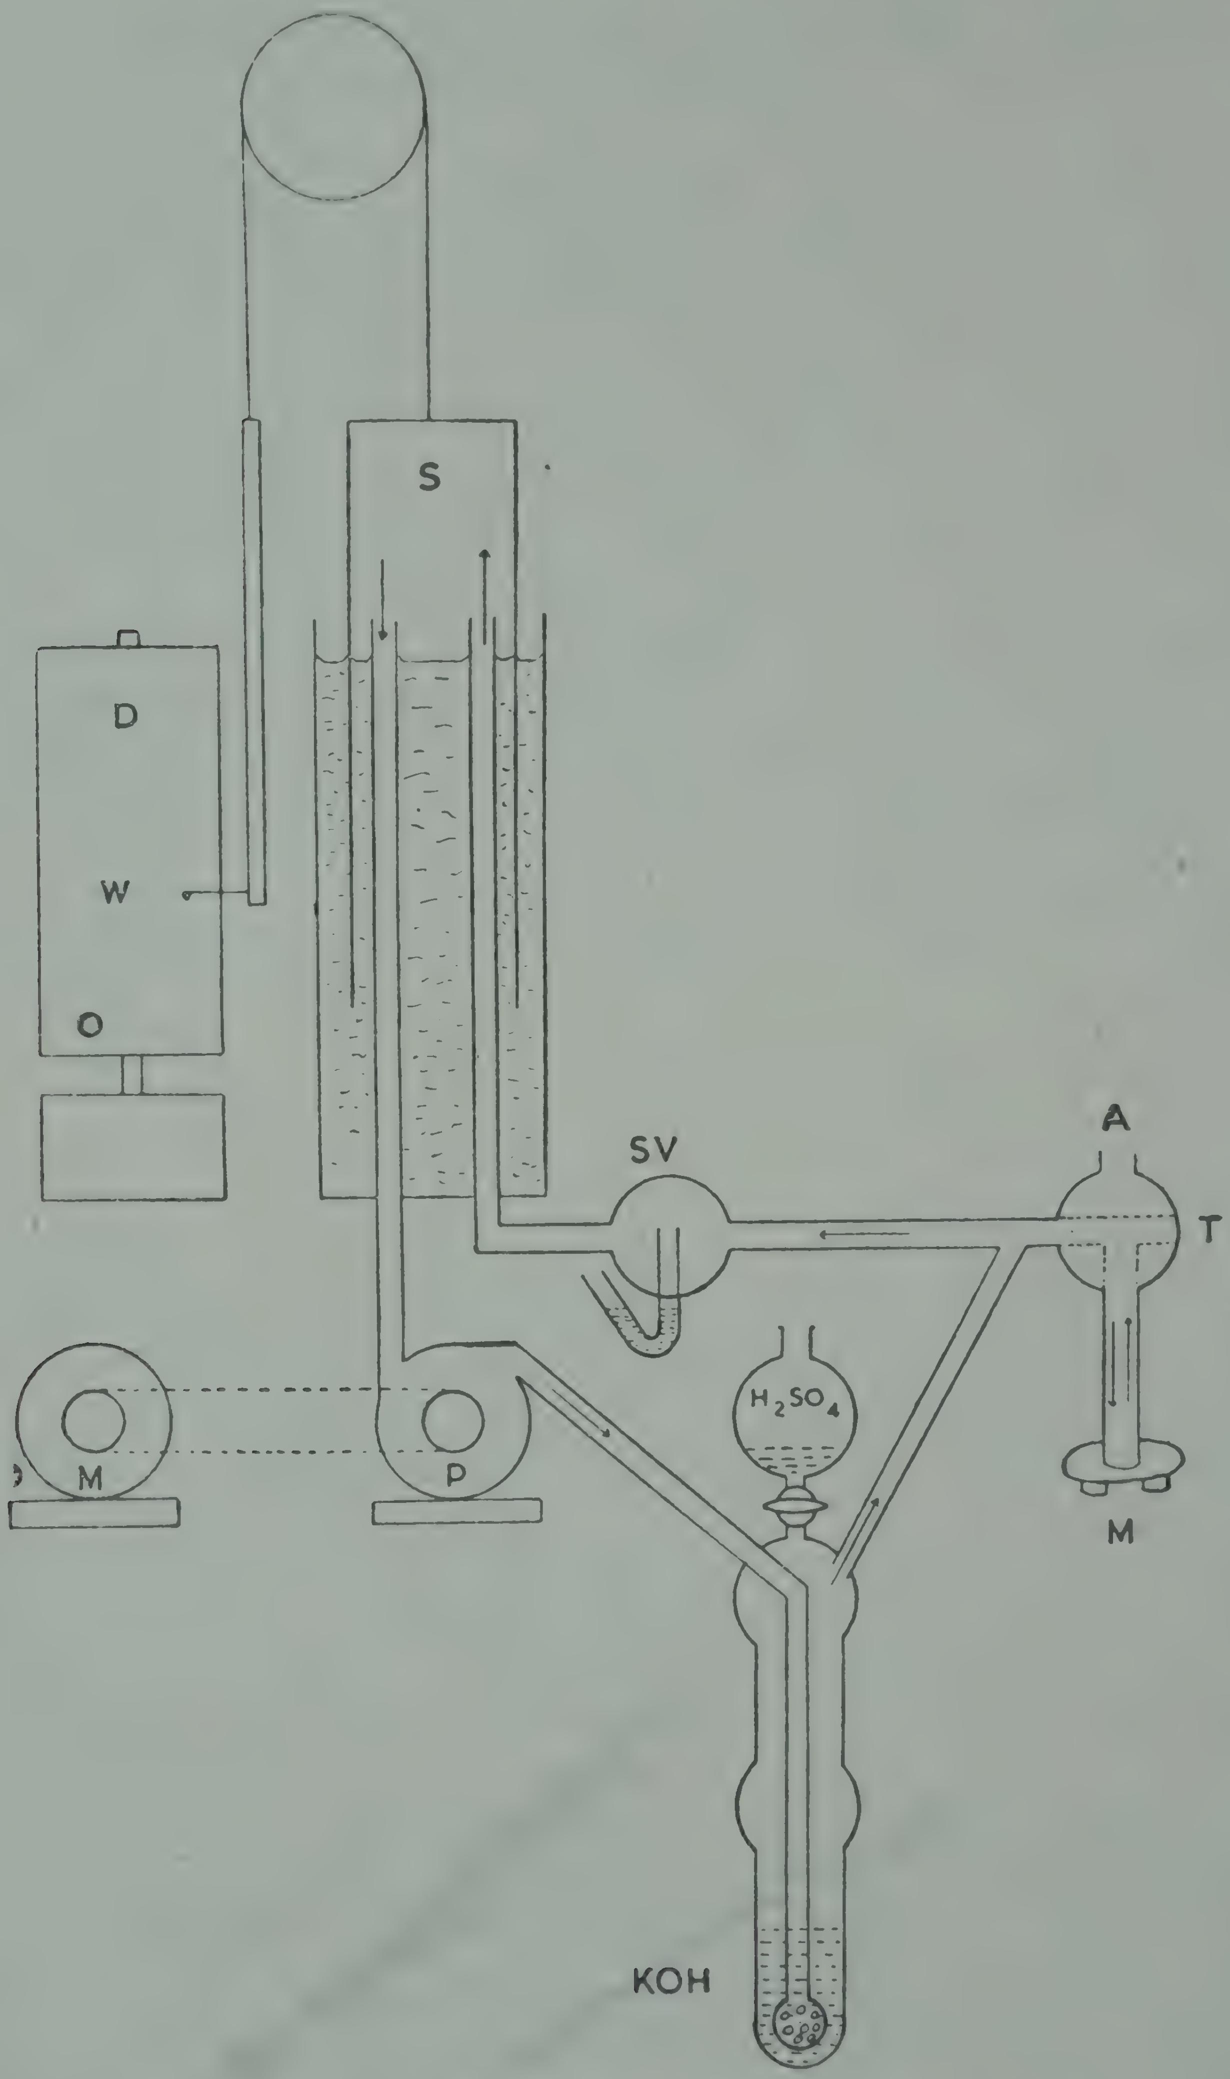

FIG. 523. Knipping Recording Spirometer. (C. F. Palmer & Co.)

---

* BENEDICT. *Boston Med. & Surg. J.*, 1918, **178**, 667 ; 1920, **183**, 449.

is filled with oxygen-enriched air, slightly filling out the rubber bag. As air is drawn into the lungs the rubber diaphragm sinks, to rise again with expiration. The respiratory movements can thus proceed without appreciably altering the pressure within the closed system of tubes. By the admission of oxygen (measured through a meter) the volume is adjusted so as to keep the bag from becoming either too distended or too flattened. As air leaves the lungs and is swept along by the blower, it flows through bottles containing sulphuric acid for the removal of water vapour and then through a cylinder, filled with soda lime for the absorption of carbon dioxide. From here it passes again through sulphuric acid for the absorption of water given off by the soda lime. Since the dry air would be uncomfortable to breathe, it is then carried through another bottle containing water with a trace of sodium carbonate for the neutralisation of any acid fumes given off by the sulphuric acid. It then passes back to the tube from which the subject is breathing. In this way it is possible to determine very accurately the amount of oxygen used up, and the amount of carbon dioxide given off, in the course of an experiment lasting one to three hours, or longer.

II. The Recording Spirometer. The Knipping apparatus (Fig. 523) is a form which enables CO_2 production also to be measured. The air is circulated by a blower P; the subject breathes through the mouthpiece M and the CO_2 is absorbed in KOH solution. The descent of the spirometer bell S gives a measure of the oxygen usage. As oxygen is used, the respiratory record is written on a sloping line; more oxygen is added through a gas meter from time to time to restore the respiratory base line. The rate of oxygen usage at any time is given by the slope of the respiratory tracing. After the oxygen usage has been determined the tap T is closed and the CO_2 liberated from the KOH by adding acid from the tap-funnel. After cooling, the volume increase represents the CO_2 liberated.

III. The Method of Haldane.* This method is convenient when dealing with the gaseous exchanges of small animals, such as mice, rats, or frogs. The animal is placed in the chamber C (Fig. 524). On the inlet side of the bottle is a series of bottles of sulphuric acid and soda lime. On the outlet side is a corresponding series of vessels for the absorption of water and of carbon dioxide. Air is sucked through the whole apparatus by means of a water pump. The animal is thus supplied with dry air freed from carbon dioxide. All water or carbon dioxide produced by the animal is absorbed by the vessels interposed on the course of the outgoing air. These vessels are weighed at the beginning and at the end of the experiment, and the difference in weights will therefore give the amounts of carbon dioxide and water which have been discharged by the animal.

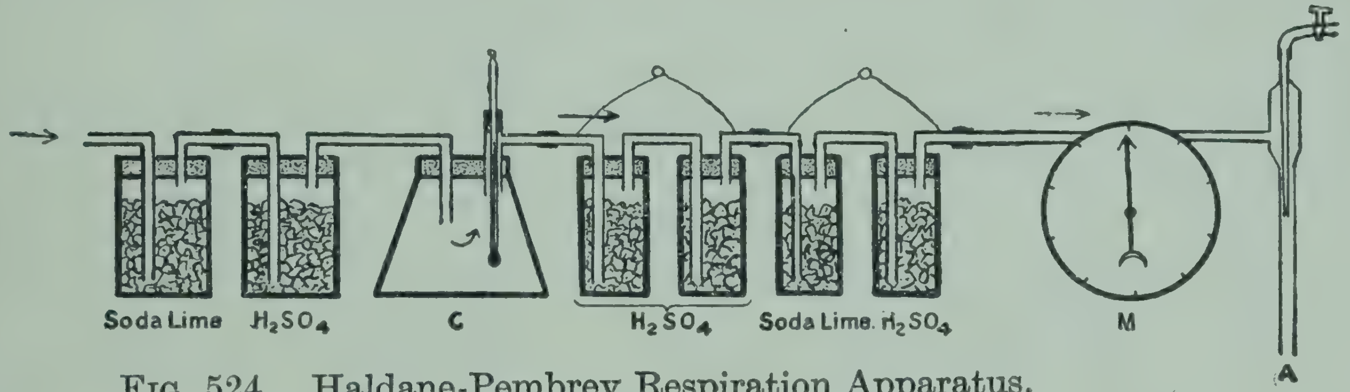

FIG. 524. Haldane-Pembrey Respiration Apparatus.
C. Chamber for animal. M. Gas meter.

The intake of oxygen is determined indirectly. Since it gives off only carbon dioxide and water, and absorbs only oxygen during its stay in the chamber, the loss of weight of the animal during its stay in the chamber, subtracted from the total weight of carbon dioxide plus water it gives off, will represent the weight of oxygen absorbed.

IV. The Douglas Bag. A convenient method for estimating the respiratory exchanges of man is by the use of the Douglas Bag, by which the expired air is collected (*v.* p. 723). When a sufficient volume of air has been collected, the bag is removed, the time taken in collecting being accurately noted. The amount of air expired during this time is measured by emptying the bag through a gas meter. A sample of its contents is analysed and the oxygen and CO_2 in it determined. From the analysis and measurement of the expired air we can calculate the respiratory metabolism during the time of the observation. This method has been used for determining the metabolism of soldiers in training, of industrial workers, athletes, etc.

Calculation of Results. In the closed circuit methods, the weight or volume of oxygen used and carbon dioxide produced are given directly, and any necessary corrections, *e.g.* of volumes to dry volumes at N.T.P., are obvious. With the open methods, some explanation is necessary. The subject inspires ordinary air which contains 20·96 volumes per cent. of oxygen, 79 per cent. N_2, and 0·04 per cent. CO_2, and it is the volume and composition of his expired air during a given interval which is actually determined. As regards CO_2, let us suppose that the expired air contains 4·10 per cent., *i.e.* an increase of 4·06 per cent.; then, if his volume of expired air is 8·5 l. per min., the volume of CO_2 expired is $85 \times 4{\cdot}06 = 345$ c.c. per minute. The oxygen is less direct because, as explained in Chapter XL., the expired air has generally a different, mostly a smaller, volume than the inspired, the *percentage* of nitrogen being raised owing to utilisation of oxygen which is not replaced by CO_2. The *total amount* of nitrogen breathed out is, however, equal to that inspired. Hence, if the expired air contains, say, 79·5 per cent. N_2 and 16·4 per cent. oxygen, then each 100 c.c. expired air corresponds to $\frac{100 \times 79\cdot5}{79} = 100\cdot6$ c.c. inspired air and this contained $\frac{20\cdot96 \times 100\cdot6}{100} = 21\cdot09$ c.c. oxygen, so that the oxygen utilised per minute was (21·09 − 16·4) × 85 = 398 c.c.

---

* HALDANE. *J. Physiol.*, 1892, **13**, 419.

The Respiratory Quotient is obtained, when required, from the respiratory exchange. It is the ratio of the volume of carbon dioxide produced during a given time to the volume of oxygen utilised during the same time. (Both gases should, of course, be measured at the same temperature and pressure.) In the above example it is $\frac{345}{398} = 0\cdot87$.

If the R.Q. is exactly 1·0, the percentage of nitrogen is unaltered. When the R.Q. is greater than unity, the percentage of nitrogen in the expired air is less than that in the inspired air, but the same type of calculation as that given above can be applied.

By these methods we may arrive at a correct idea of the total income and output of an individual for periods up to many days. The following details by Atwater and Benedict may serve as an example of the results obtained in such experiments :

SUMMARY OF INCOME AND OUTPUT OF NITROGEN, CARBON AND HYDROGEN IN MAN (ATWATER AND BENEDICT *)

State.	Total No. of Days.	Average Daily Income. (Grams.)	Average Daily Output. (Grams.)					Gain or Loss. (Grams).
		Food.	Fæces.	Urine.	Water.	Respn.	Total.	
Rest	42	NITROGEN. 18·5	1·1	17·8	—	—	18.9	−0·4
		CARBON. 253·3	9·9	12·4	—	217·9	240·2	+13·1
		HYDROGEN. 39·2	1·4	3·5	41·8	—	46·7	−7·5
		(Protein lost by body = 2·4 grams) (Calc. from N. loss)		(Fat gained by body = 19·2 grams) (Calc. from C. gain)				
Fast of 1 or 2 days	5	NITROGEN. 0·0 .	0·0	13·1	—	—	13·1	−13·1
		CARBON. 0·0 .	0·0	9·9	—	184·4	194·3	−194·3
		HYDROGEN. 0·0 .	0·0	2·7	98·3	—	101·0	−101·0
		(Protein lost = 82·0 grams) (Fat lost = 198·3 grams)						

In the resting experiments, in which the subject was on an ordinary diet, it is seen that the intake and output almost balance ; there was, however, a slight loss of 0·4 gramme of nitrogen, which means that about 2·4 grammes of protein from the body had been lost. Some fat had, however, been laid on, as shown by the gain of 13·1 grammes of carbon. In the fasting experiment the body, of course, lost considerably.

Growth. In growing individuals, materials from the food are converted into body substances. But the proximate constituents of the diet are not retained in the same proportions as they occur in the diet. The following table shows that carbohydrate, though the most abundant constituent of the diet, hardly accumulates at all.

---

* ATWATER and BENEDICT, 1903. *U.S. Dept. Agric. Bull.*, 1903, *No.* **136**, p. 120.

AVERAGE COMPOSITION OF HUMAN BEINGS (YOUNG *)

	Weight of Material (kg.).			Percentage of Total.		
Material.	New Born.	Adult.	Added during Growth.	New Born.	Adult.	Added during Growth.
Total mass	2·9	70·0	67·1	—	—	—
Water	2·1	41·0	38·9	72	59	58
Dry matter	0·8	29·0	28·2	28	41	42
Carbohydrate	0·01	0·40	0·39	0·35	0·57	0·58
Fat	0·35	12·60	12·25	12·1	18·0	18·2
Protein	0·34	13·10	12·76	11·7	18·7	19·0
Salts	0·10	3·00	2·90	3·5	4·3	4·3

This must mean that carbohydrate is either burnt as fuel, or is converted into some other constituent, such as fat.

Of the total food taken during the years of growth, it will be seen from the following table, that only 0·02 per cent. of carbohydrate can be regarded as being retained, whereas the amounts of protein and fat respectively retained amount to over a hundred times that amount.

RATE OF ADDITION OF MATERIAL ADDED TO HUMAN BODY DURING 7,000 DAYS (APPROX. 19 YEARS) OF GROWTH (YOUNG *)

Material.	Weight of Material in Adult Body (kg.).	Weight of Material added during Growth (kg.).	Rate of Addition of Tissue (g./day).	Approx. Percentage of Ingested Food retained in Body during Growth.†
Total mass	70·0	67·1	9·6	0·32
Water	41·0	38·9	5·6	0·22
Dry matter	29·0	28·2	4·0	0·85
Carbohydrate	0·40	0·39	0·06	0·02
Fat	12·60	12·25	1·7	2·27
Protein	13·10	12·76	1·8	2·40
Salts	3·00	2·90	0·4	2·00

These figures indicate that growing children require, for their size, more protein and fat than adults, but that increased amounts of carbohydrate, except in so far as it can form fat, are less urgently needed.

2. THE ENERGY BALANCE SHEET OF THE BODY

Income. The energy income of the body is measured by the potential energy of the foodstuffs, *i.e.* the amount of energy which can be evolved, either as heat, work, or in any other form, by the oxidation of the foodstuffs to the end products which occur in the body. We express the total potential energy of a foodstuff in *Calories*. The heat value of any given food is the number of Calories ‡ which it evolves on complete combustion with oxygen, and is determined by burning a weighed quantity of the dried foodstuff in oxygen in a bomb calorimeter.

Instead of using the bomb calorimeter, the heat of combustion can be determined *indirectly* by finding how much oxygen is needed to burn the foodstuff. As seen from the table on p. 791, for common foodstuffs the Calories

* YOUNG. *Sci. Prog.* 1948,, **141,** 13.

† Based on mean daily food intake for 0–19 years of 300 g. carbohydrate, 75 g. fat, 75 g. protein, 20 g. salts, 2600 ml. water (including water formed by oxidation).

‡ A calorie is the amount of heat necessary to raise a gramme of water from 15° C. to 16° C. A kilocalorie, or large Calorie (printed with a capital C) is equal to 1000 calories and is the unit employed in most physiological work.

yielded per litre of oxygen used is roughly 4·8. The determination is carried out in a modified closed-circuit apparatus, called an oxy-calorimeter, in which the substance is burned in a circulating current of oxygen. A suitable apparatus is shown in Fig. 525.

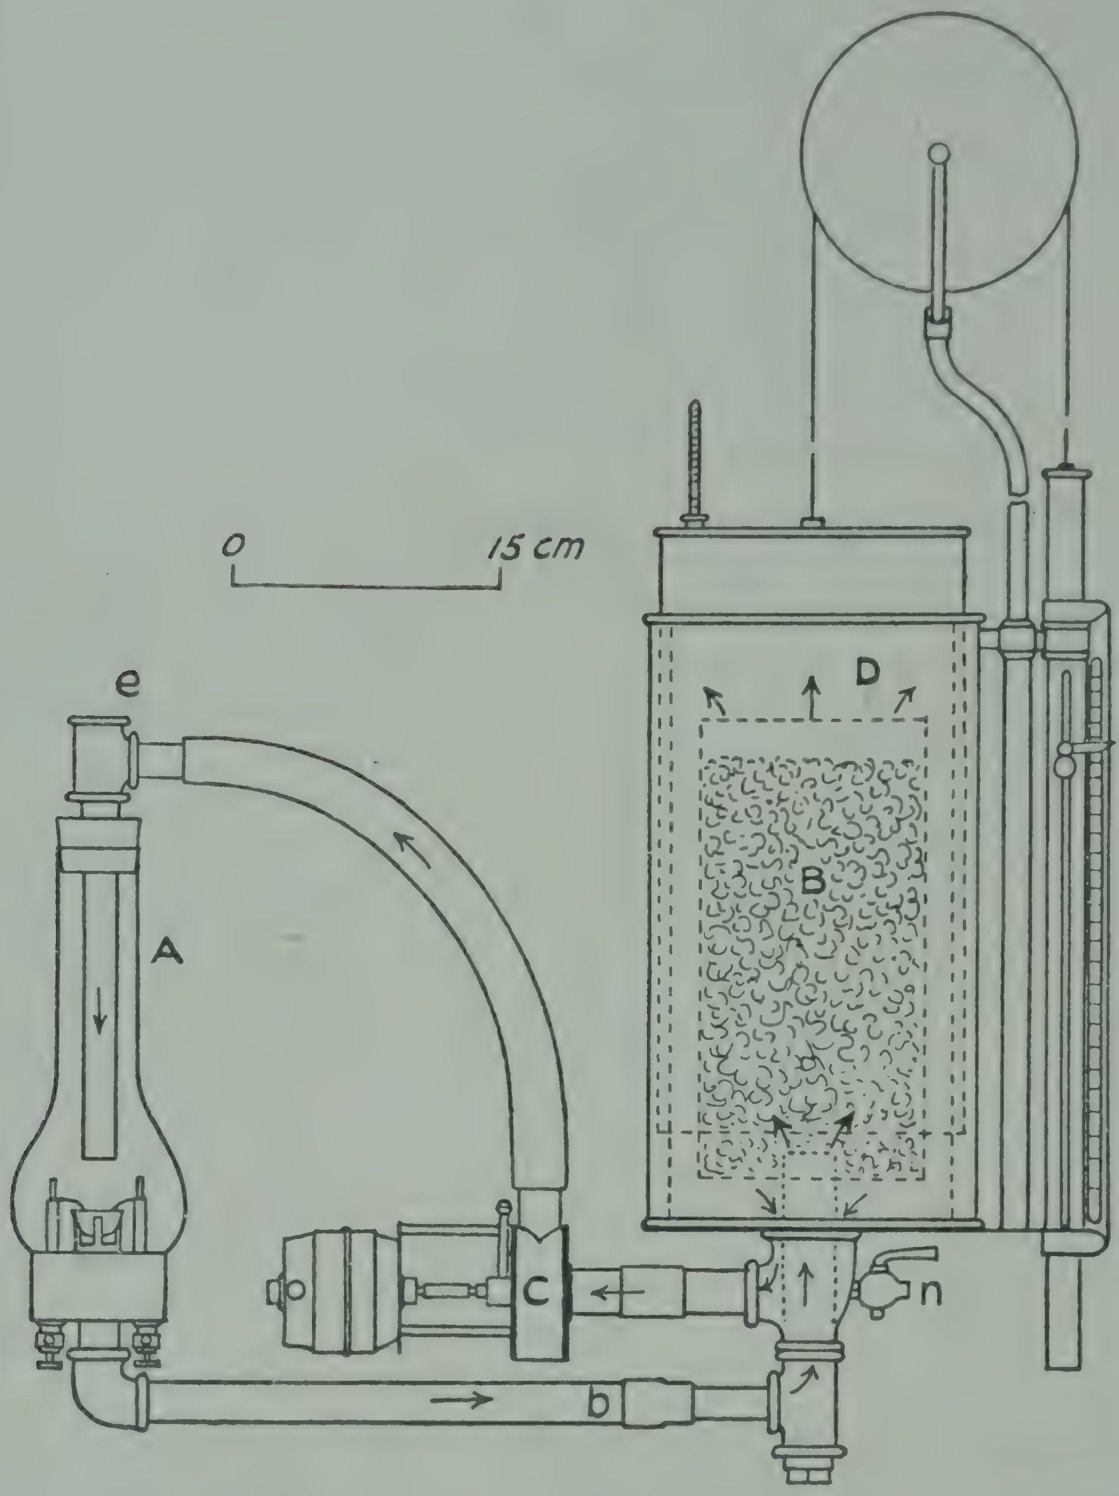

FIG. 525. Simplified oxy-calorimeter for determining energy values of foods, foodstuffs and excreta. (BENEDICT and FOX, *Journ. Biol. Chem.*, 1925, **66,** 783.)

The substance to be tested is dried and weighed into a small nickel crucible, inside the lamp-glass A. The apparatus is filled with oxygen, circulated by the rotatory blower C. The spirometer bell D gives the variation in volume, and is filled with soda lime to absorb CO_2. Combustion is started by electrical heating of the substance, and, after completion and cooling, the oxygen used is read off. Except when very accurate results are needed, an exact analysis of the substance is not necessary; the average calorific values of oxygen may be taken to be: for nitrogen-rich substances, 4·68 Calories per litre of oxygen; for fats, 4·7 Calories; for carbohydrate-rich foods, 5·0 Calories; for a mixed diet of carbohydrates and fats, 4·825 Calories; and for fæces, 5·0 Calories.

In the case of proteins it is necessary to draw a distinction between the heat value on combustion, and the physiological heat value. Since carbohydrates and fats undergo complete oxidation in the body to carbon dioxide and water the values of these foodstuffs to the organism are identical with their absolute heat values. When proteins are burnt, however, the nitrogen is converted into various gases. In the animal body, no nitrogen is eliminated in the gaseous form, but it is excreted as urea and allied substances still endowed with potential energy, which can be set free when their oxidation is completed by burning.

The following heat values have been obtained for different foodstuffs :

GASEOUS AND ENERGY RELATIONSHIP IN THE COMBUSTION OF SOME COMMONLY METABOLISED COMPOUNDS. (BENEDICT and FOX, *Journ. Biol. Chem.*, 1925, **66**, 783.)

Substance.	Oxygen required to oxidise 1 g.	Produced in the oxidation of 1 g.		Calories per litre of oxygen.
		Carbon dioxide.	Heat.	
	c.c.	c.c.	cals.	
Starch	829·3	829·3	4·20	5·06
Cane sugar	785·5	785·5	3·96	5·04
Glucose	746·2	746·2	3·74	5·01
Lactic acid	745·9	746·0	3·62	4·85
Animal fat	2013·2	1431·1	9·50	4·72
Human fat	1990·8	1420·4	9·54	4·79
Protein	956·9	773·8	4·40	4·60
Acetone	1542·9	1157·2	7·43	4·82
β-Oxybutyric acid	968·2	860·7	4·69	4·85
Ethyl alcohol	1459·5	972·9	7·08	4·85

In order to determine the physiological heat value of protein, we must subtract from its absolute heat value the heat value of the excretory products as they leave the body. The physiological heat value of proteins was determined by Rubner in this way : A dog was fed with a protein of absolute heat value, of 5·345 Cal./g., and its urine was collected, dried, and its heat value determined by combustion. It was found that, for each g. of protein which had undergone disintegration in the body, urine was passed of a heat value of 1·0945 Calories. The heat value of the fæces formed under the same diet was 0·1845 Calorie per g. protein. Rubner further reckoned the heat required for the solution of the proteins and of the urea, at 0·05 Calorie. The reduced or physiological heat value of protein is therefore equal to $5{\cdot}345 - (1{\cdot}0945 + 0{\cdot}1854 + 0{\cdot}05) = 4{\cdot}015$ Calories.

It is usually unnecessary to reckon out accurately the relative values of the different kinds of protein, carbohydrate, etc., contained in each diet, and Rubner calculated the *average* physiological heat values of the three classes of foodstuffs, and found them as follows :

1 grm. protein = 4·1 Calories
1 grm. fat = 9·3 ,,
1 grm. carbohydrate = 4·1 ,,

These figures are accurate only for a diet containing the normal proportion of vegetable to animal foods—60 to 40. The heat value of vegetable protein is as a rule less than that of animal protein.

Output. The energy expenditure of the body is measured in Calories and can be determined either directly by placing the subject in a suitable calorimeter, or indirectly from the oxygen consumption.

THE RESPIRATION CALORIMETER. The Atwater-Benedict * respiration calorimeter consists of a room or chamber with double non-conducting walls. All round the inner wall of the room are fitted coils of pipes through which a stream of water flows. The pipes are fitted with discs in order rapidly to take up heat produced in the room. The current of water is accurately adjusted so as to maintain the temperature of the inner wall constant. As the inner wall and outer wall are kept at the same temperature, no heat is lost to the exterior, the whole of the heat produced by the animal or individual in the chamber being communicated to the water passing through the chamber. The temperatures of the entering and leaving water are taken by thermometers readin to a thousandth of a degree Centigrade. Knowing the amount of water tha has passed through in a given time and the difference in temperature durin the same time, it is easy to calculate the amount of heat given off by the anima under investigation. It is generally convenient to maintain a constant difference of temperature between the entering and leaving water, by appropriat adjustment of the amount of water passing through the apparatus. Th equality of temperature between the inner and outer casing is recorded b electric thermo-couples, any difference of temperature being at once compensated by electrically warming the cooler part. The chamber contains a

bicycle or other arrangement for the performance of mechanical work. It is adequately ventilated by a current of air passing through an apparatus similar to that of Benedict, described on p. 785. Any work done is measured and can be calculated in terms of heat, since 1 kg. m. = ·0024 Cal. It is thus possible to estimate simultaneously the total heat production of an individual as well as the respiratory exchange, including both carbon dioxide output and oxygen intake. The general principle of the calorimeter is shown in the diagram (Fig. 526). The calorimeter is also supplied with bed, table, chair, etc., and food can be introduced through a double window so that an experiment may be continued over several days on one and the same individual.

INDIRECT CALORIMETRY. From the equation

$$\underset{(180\text{ g.})}{C_6H_{12}O_6} + \underset{(134\text{ l.})}{6O_2} = \underset{(134\text{ l.})}{6CO_2} + 6H_2O$$

and from the observation that 1 g. of glucose on combustion yield 3·7 Calories of heat, we can deduce that when carbohydrate is being burnt in the body (*i.e.* when the R.Q. = 1·0), the utilisation of each litre of oxygen generates about 5·05 Calories of heat. Similar calculations can be made for the combustion of proteins (4·6) or fats (4·74), so that in all cases the calorific value of oxygen is in the neighbourhood of 5 Calories per l., the exact value of the non-protein part varying according to the respiratory quotient, as shown in the following Table (Cathcart and Cuthbertson) (*v.* also p. 805).

Non-protein R.Q.	Cal. per litre oxygen.
1.00	5·047
0·90	4·936
0·80	4·827
0·718	4·735

These figures have been obtained by actual comparison between respiratory exchange and calorimeter experiments on man. It is therefore now quite easy, when the oxygen usage and R.Q. are known, to calculate the total energy liberation of the body.

Careful experiments have shown that the sum of the energies put out by the body is equal to the sum of the energy obtained by the oxidation of the tissues and of the foodstuffs in the body during the same time. Here are the figures from one such experiment by Atwater on man :

	(a) Heat of combustion of food eaten.	(b) Heat of combustion of fæces.	(c) Heat of combustion of urine.	(d) Estimated heat of combustion of protein gained (+) or lost (−).	(e) Estimated heat of combustion of fat gained (+) or lost (−).	(f) Estimated energy of material oxidised in the body; a − (b + c + d + e)	(g) Heat determined.	(h) Heat determined greater (+) or less (−) than estimated; g − f.	(i) Heat determined greater (+) or less (−) than estimated: h ÷ f.

Basal Metabolism. During fasting the energy output of the body is determined (*a*) by the amount necessary to keep the body alive—*i.e.* to maintain its warmth and to furnish the energy for respiratory movements, contractions of the heart, etc. ; (*b*) the energy necessary to carry out any external work that is performed.

The energy requirements under (*a*) represent the " Basal Metabolic Rate " (B.M.R.) of the body. It may be defined as the energy expenditure of the body in the resting state, a few hours after the absorption of the last meal and under comfortable conditions of temperature, etc. The basal metabolism, of course, varies with the size of the individual ; but if a number of different animals are compared, the smaller the animal, the greater their metabolism per kilo. is found to be.

This is due to the fact that the chief expenditure of energy is devoted to maintaining the temperature of the body, and the smaller the animal the larger is its surface, and therewith its heat loss, relatively to its weight. The basal metabolism, therefore, is more nearly a function of the surface of the body. The surface area, S, of an animal can be found approximately by the Meeh formula * : $S = k\sqrt[3]{W^2}$, where W is the weight and k a constant for the species, *e.g.* for cat, 0·099 ; rabbit, 0·125 ; rat, 0·091 ; dog, 0·107 ; man, 0·123. (Probably 0·11 is more nearly correct for man.) A comparison of the metabolism in different warm-blooded animals shows that it is of the same order in all cases, viz., a daily expenditure of about 700 to 1,000 Calories per square metre body surface, in order to maintain its temperature and carry out such motor processes as are essential to life.

---

* Meeh. *Zeit. f. Biol.*, 1879, **15**, 425. For dogs, Cowgill and Drabkin's formula (modified) is better : A (in m²) = $0{\cdot}2864\ W^{0.367}\ L$, where W = weight in kg. and L = body length in m. from nose to anus (*Am. J. Physiol.*, 1927, **81**, 36).

The same thing applies to man. If we desire to predict the normal basal metabolism of any given individual we must find his surface. This depends

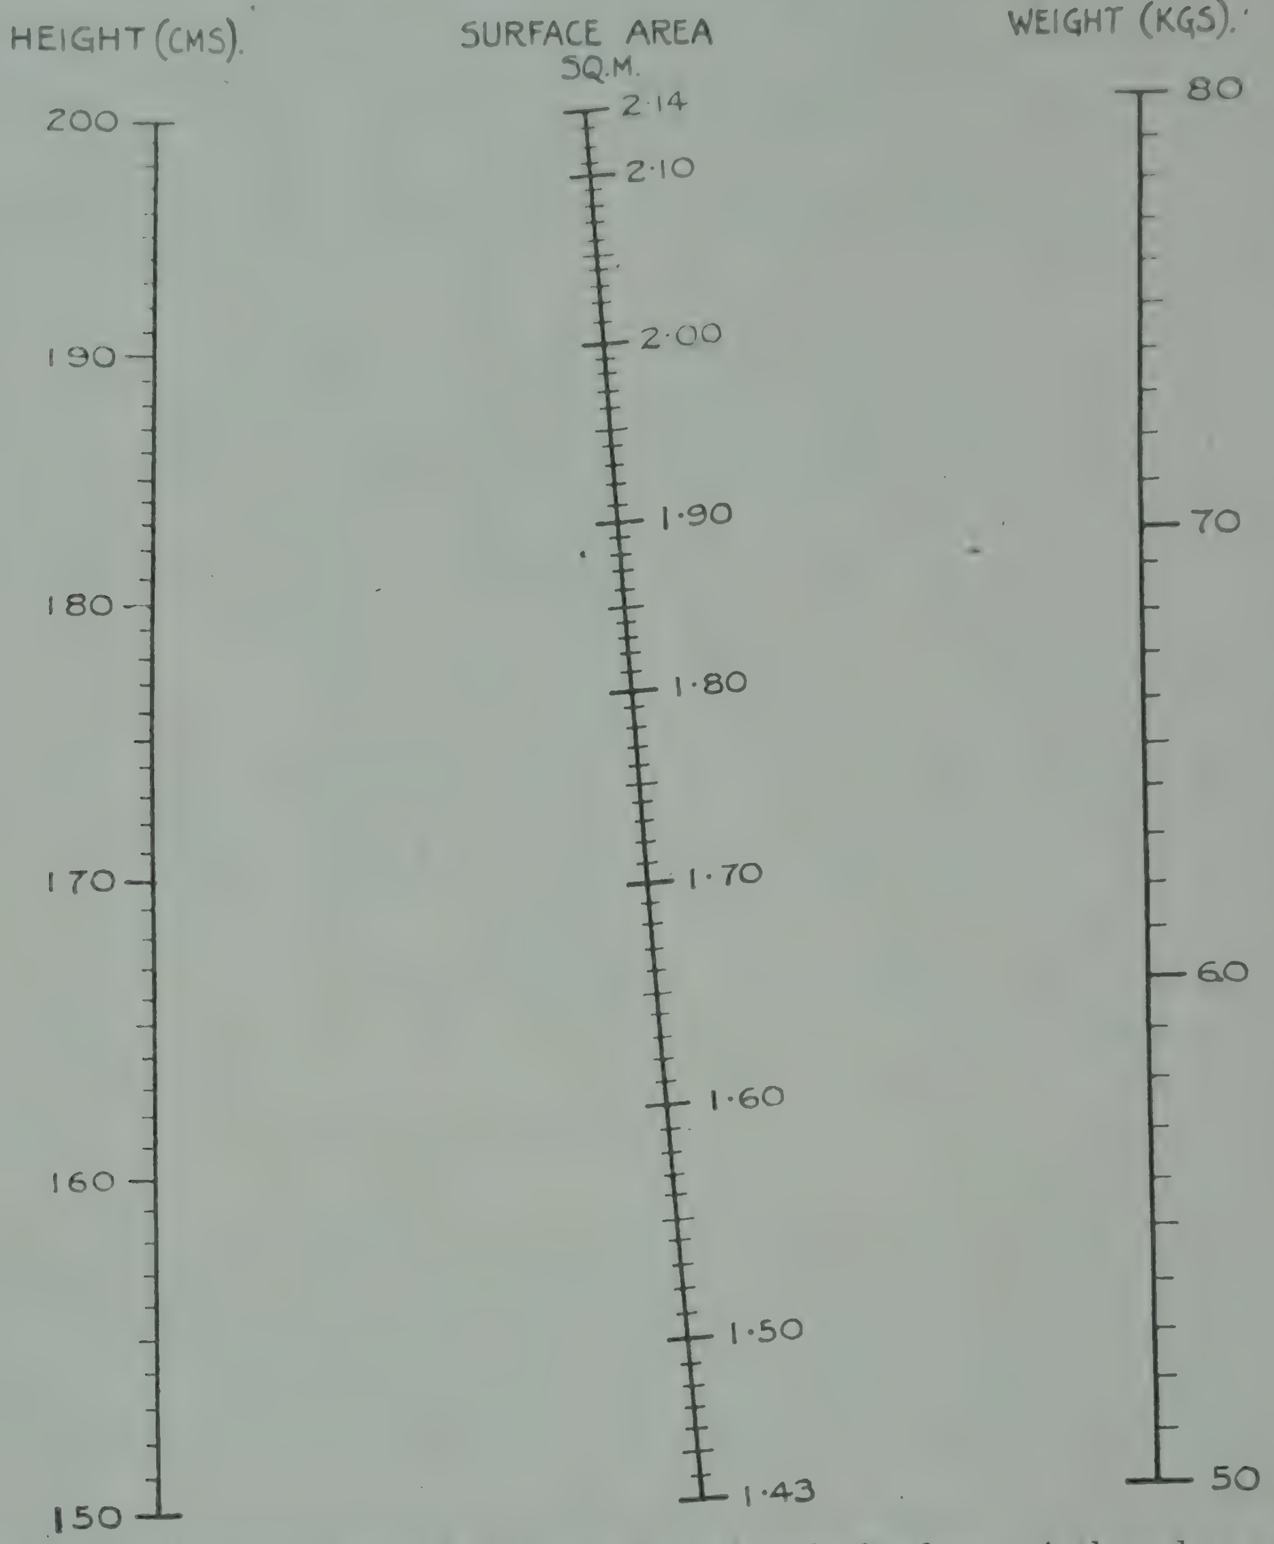

FIG. 527. Alignment chart for Calculation of Body Surface. A thread or ruler, placed so as to lie on the points for weight and height, cuts the line for surface at the correct value. (W. A. M. SMART.)

on height as well as on weight. If we know the height and weight, the surfac can be calculated by the following formula (Du Bois *):

$$S = \cdot 007184 \times W^{0.425} \times H^{0.725}.$$

where S is the surface in square metres, W the weight in kilogrammes, H th height in centimetres ; or, more conveniently, by the use of a nomogram suc as is shown in Fig. 527.

In young adult white men the basal metabolism is about 40 *Calories pe square metre per hour*. It is about 2·5 Calories less for women. From the age o forty onwards there is a reduction, the formula † being 39·138 — 0·0678 × age Cal./sq. m./hr., *e.g.* at fifty it would be about 36 Cal./sq. m./hr.

In the new-born infant, however, it is low (25 Calories per square metr per hour), and is even lower in premature infants. It rises rapidly in the firs year of life, and at five years is about 52 Calories per square metre per hour

† LEWIS. *Am. J. Physiol.*, 1938, **121**, 502.

There are racial variations, due partly to varying diet and in part to different extents of muscular relaxation.

It is usual to determine basal metabolism indirectly by estimating the oxygen usage of the resting, fasting individual, and calculating from the calorific value of oxygen at the observed respiratory quotient. The observed value can then be compared with the value predicted from the body surface. The results are usually given in percentages of the normal predicted basal metabolism. In certain diseases the normal is departed from, a divergence of 10 per cent. being considered significant. Thus in fevers there is an increase during the febrile state, which may amount to 50 per cent. In diseases associated with over-action of the thyroid there is also an increase to 20 to 50 per cent. above normal, while in the converse condition of subthyroidism there is a reduction of 10 to 30 per cent.

Injection of adrenaline, or mental excitement increases the basal metabolism.

Since the cardiac minute volume varies directly with the oxygen usage of the body observations of pulse rate and pulse pressure often give a clue to the B.M.R.* If, for example, we suppose that the stroke volume of the heart (S.V) is proportional to pulse pressure (P.P.) and to surface area (S.A.), and since minute volume = pulse rate (P.R.) × S.V., then the O_2 used, $\propto$ P.R. × S.V. $\propto$ P.R. × P.P. × S.A.

3. INFLUENCE OF STATE OF NUTRITION ON METABOLISM

The basal metabolism depends on the state of nutrition of the animal. Thus in fattening an animal, the basal metabolism increases steadily as the animal gets fatter. It requires much more food to keep a fat animal fat, than to maintain it in a lean condition. The figure 40 Cal./sq. m./hr. applies to a well-nourished individual. If the food supplied to the individual be diminished, he can go on working as before, obtaining his energy at the expense of the fat and muscular tissues of his own body. But when, under this régime, the weight has fallen about 12 per cent. it is found that the basal metabolism is also largely reduced. During the War of 1914–18, Zuntz and Loewi † found their own basal metabolisms lowered by 15 and 12 per cent. In a squad of men investigated by Benedict,‡ the food normally taken ranged from 3,200 to 3,600 Calories per day. After these men had by restriction of diet to 1,400 Calories suffered a loss of 12 per cent. in their body weight, the basal metabolism was 18 per cent. below normal. They could maintain themselves at this reduced weight on a diet of 1,950 Calories and could carry out the same work as before on a diet of 2,300 Calories. With further deprivation, when the body weight has been reduced by 20 per cent., there may be a return of the basal metabolic rate up to or even above the normal level.

How great a reduction of calorie intake over long periods is compatible with life is uncertain. In World War I, during four years, the average daily Calorie intake of the Belgians fell from 2,850 to 2,250 ; in World War II it had nominally fallen to 950 in 1943 § ; in France, in 1943, it was about 1,000 ; in German prison and extermination camps it must have been much less. During the siege of Madrid in 1936–39 also, the caloric intake fell to about 1,000, with 66 g. protein, of which animal protein was about 5 g. daily.*

Starvation. During starvation the whole energy expenditure is derived from the animal's own tissues. Even if all the tissue components could be used up, the store of available carbohydrate, chiefly as glycogen, would only supply one day's need, whereas fat and protein reserves are much greater, as shown below :—

Storage of Energy in the Adult Human Body (Young †)

Material.	Weight of Material ingested Daily as Food (g.).	Weight of Material in Adult Human Body (g.).	Number of Days' Supply stored in the Adult Body (approx.).
Carbohydrate . .	400	400	1
Fat	100	12,600	126
Protein . . .	100	13,100	131
Salts	27	3,000	111

According to the evidence of fasting men, this is not painful, provided water is available. During the first day or two there is a craving for food at meal-times. This often passes off, and later even the desire for food may be absent. The essential characteristic of inanition is an ever-increasing weakness, accompanied by a strong disinclination to undertake any mental or physical exertion. The time is passed in a state of semi-stupor. The pulse rate and the body temperature remain nearly normal until a few days before death, which is ushered in by an increase in the somnolent condition of the animal and by a gradual slowing of respiration and fall of temperature. The urine is reduced with diminution in the output of urea and in the amount of water consumed. Some fæces are formed, and may be voided during or at the close of the starvation period. Especially instructive in this connection are the cases of the professional "fasting men," several of whom have been subjected to metabolic investigation. In the case of Succi, who fasted for thirty days, considerable muscular exertion was, by an effort of will, undertaken on the twelfth and on the twenty-third day of starvation without any appreciable ill-effects. In Succi fæces varied from 9·5 to 22 g. a day and contained from 0·3 to 1·0 g. nitrogen per day.

During the whole of the period there is a steady loss of body weight, *e.g.* during the first ten days, the daily loss is between 1 and 1·5 per cent. of the original total weight. This loss of weight does not affect all parts of the body alike. It might be imagined that those organs which are most active should show also the greatest loss of weight. The very reverse of this is the case, as will be seen from the Table on p. 797.

Those organs which are most necessary for the maintenance of life, the brain, the heart, the respiratory muscles, undergo very little loss of weight. Of the other tissues the fat, which is a mere reserve to provide for such contingencies, is drawn upon first, and during starvation 97 per cent. of the total fat of the body may be consumed. The nitrogen needs of the body seem to be supplied chiefly at the expense of the muscles and glands. Hence it is easy to understand the muscular inactivity. We may suppose that during starvation, all tissues undergo a process of slow autolysis, giving up the products of this process to the blood and that the active tissues take up the material set free from all the other cells of the body and so maintain their weight at the expense of all other parts.

The animal organism, in starvation, deals with the resources of its tissues

with the utmost possible economy. The total metabolism sinks rapidly during the first two days of starvation, and then more slowly, but the metabolism per kilo. body weight till within a day or two before death is not changed so much. This is shown in the following Table of the output of energy in man during a five days' period of starvation (Tigerstedt):

METABOLISM DURING STARVATION (MAN)

Day of experiment.	Nitrogen output.	Fat oxidised.	Total Calories.	Calories per kilo. body weight.
1	12·16	204·8	2231	33·3
2	12·85	190·3	2112	32·1
3	13·62	179·9	2032	31·3
4	13·67	176·4	2003	31·3
5	11·44	180·0	1979	31·4

THE METABOLISM OF CARBOHYDRATE, FAT, AND PROTEIN DURING STARVATION. During the first phase of inanition the carbohydrate stores in the body rapidly diminish. This stage lasts for one or two days at most, after which energy is derived mainly (80–90 per cent.) from fat and slightly (10–20 per cent.) from protein. In the final stages, as fat becomes scarce, the energy is derived to an increasing extent from oxidation of protein. After prolonged undernutrition there is a lowering of the plasma albumin.

The relative parts played by protein, carbohydrate and fat respectively in the chemical exchanges of a starving animal may be determined in the following way: The amount of protein utilised is given by estimating the total nitrogen of the excreta. The oxygen intake and carbon dioxide output by the lungs must also be determined. Now we know that for each gramme of urinary nitrogen there has been used 5·923 l. of oxygen to oxidise the protein, and 4·754 l. of CO_2 have been produced thereby. The amounts of oxygen and CO_2 which represent protein combustion can thus be calculated, and these quantities are now deducted from the total exchanges, and the remainders expressed as a quotient, $\frac{CO_2}{O_2}$ and called the *non-protein respiratory quotient*. By a simple calculation, the amounts of carbohydrate and fat burned can then be found; more usually a table is used, such as the following:

VALUE OF 1 L. OF OXYGEN IN NON-PROTEIN RESPIRATORY QUOTIENT
(After MCCLENDON)*
One litre of oxygen is equivalent to

Non-protein. R.Q.	Grams.		Calories.
	Carbohydrate.	Fat.	
1·00	1·232	0·000	5·047
0·95	1·010	0·091	4·985
0·90	0·793	0·180	4·924
0·85	0·580	0·267	4·862
0·80	0·375	0·350	4·801
0·75	0·173	0·433	4·739
0·707	0·000	0·502	4·686

For example, suppose that a man in twenty-four hours excretes 10 g. N, uses 426 l. of oxygen, and produces 322·5 l. of CO_2.

Then the oxygen and CO_2 corresponding to the nitrogen output would be 59·23 l. and 47·54 l. respectively. Deducting these from the respiratory exchanges we have a non-protein exchange of:

$$322{\cdot}5 - 47{\cdot}5 = 275 \text{ l. } CO_2 \text{ and } 426 - 59 = 367 \text{ l. } O_2$$

with a non-protein R.Q. of $\frac{275}{367} = 0{\cdot}75$

and for this each l. of oxygen = 0·173 g. carbohydrate and 0·433 g. fat. Hence the material used is:

10 × 6·25 g. = 62·5 g. protein,	which = 62·5 × 4·1 =	256 Cal.
367 × 0·173 g. = 63·5 g. carbohydrate,	which = 63·5 × 4·1 =	260 Cal.
367 × 0·433 g. = 159 g. fat,	which = 159 × 9·3 =	1,480 Cal.
	Total Calories =	1,996

If, as we suppose, the subject is fasting, the carbohydrate used would be glycogen.

A check on this calculation is furnished if the individual can be placed at the same time in a calorimeter.

The influence of glycogen breakdown on that of protein during the first and second days of fasting is shown in the experiments given below:

	First day.			Second day.		
	Glycogen metabolised.		N. eliminated.	Glycogen metabolised.		N. eliminated.
	Total.	Per kilo.		Total.	Per kilo.	
S.A.B.	181·6	3·15	5·84	29·7	0·52	11·04
S.A.B.	135·3	2·31	10·29	18·1	0·31	11·97
S.A.B.	64·9	1·09	12·24	23·1	0·39	12·45
H.C.K.	165·6	2·33	9·39	44·7	0·64	14·36
H.R.D.	32·8	0·59	13·25	41·6	0·76	13·53

The relative part taken in the production of the total energy by fats and proteins respectively may vary according to the amount of fat available in the body. If the subject previous to the experiment has been receiving a diet rich in protein, the excretion of nitrogen and urea in the urine diminishes rapidly during the first days of starvation. During the first two days, therefore, a considerable proportion of the necessary energy is obtained at the expense of protein. Between the third and fifth day the nitrogenous excretion reaches a minimum, at which point it remains approximately constant until a day or two before death. If the previous diet was very poor in protein, the excretion of nitrogen may be low throughout the whole course of the experiment. These facts are illustrated by the curves in Fig. 528, which show the output of urea in three experiments on a dog on high, medium and low previous diets of protein. These experiments indicate that it is not possible, by giving extra protein in the diet, to provide any large store of body protein. The potassium excretion in starvation runs parallel to that of nitrogen, and corresponds to the potassium content of the lost muscular tissue.*

---

* MCCLENDON and MEDES. "Physical Chemistry in Biology and Medicine."

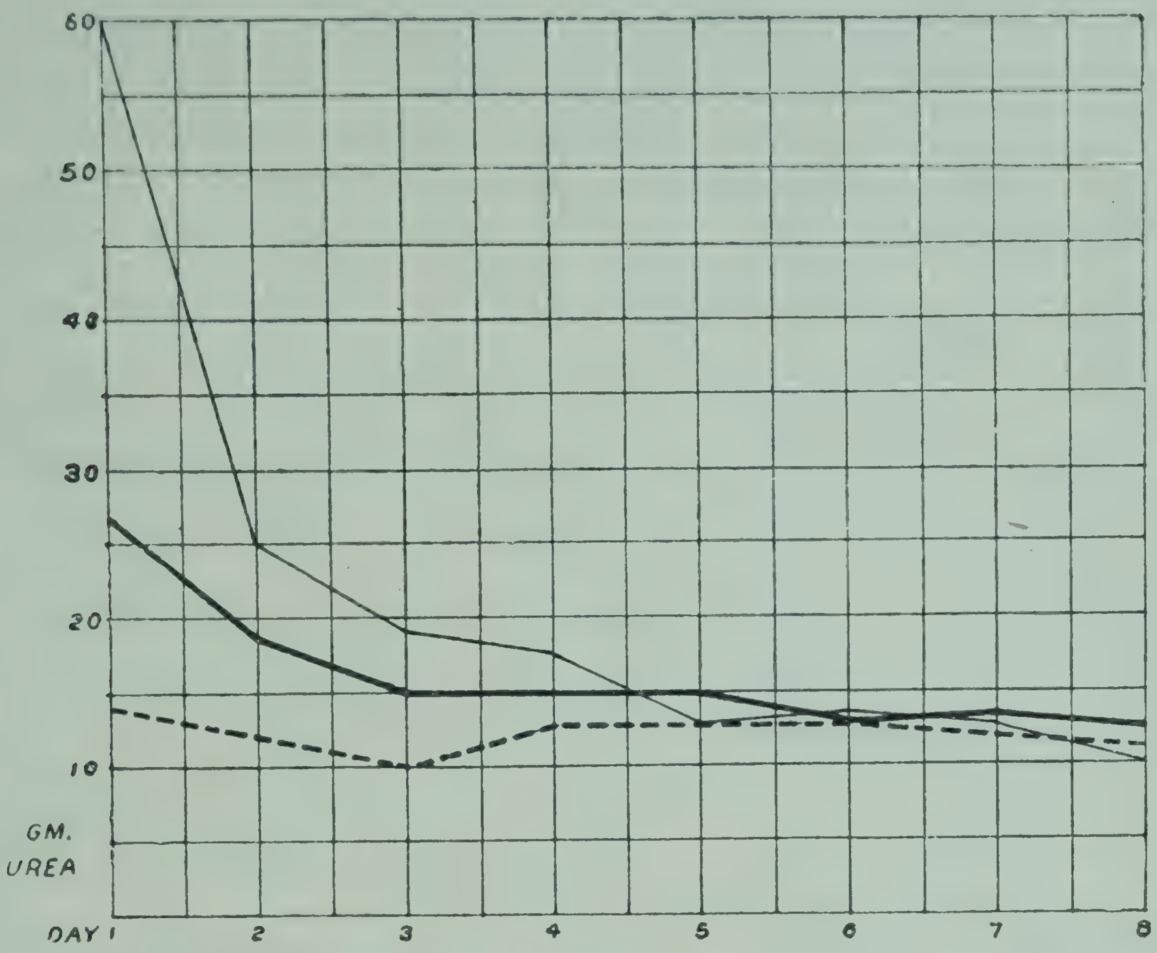

Fig. 528. Three Experiments on the Output of Urea during Starvation (dog). (Tigerstedt, after Voit.)

In (1) (thin line), the dog received 2,500 grammes meat per day before the experiment; in (2) (thick line), the diet was 1,500 grammes meat; and in the third experiment (dotted line), the meat was reduced to a minimum.

In prolonged fasting the nitrogen output falls gradually to a low level as is shown below.

Daily Nitrogen Excretion of Succi in Starvation

Day.	N.	Day.	N.	Day.	N.
1	17·0	8	9·74	15	5·05
2	11·2	9	10·05	16	4·32
3	10·55	10	7·12	17	5·4
4	10·8	11	6·23	18	3·6
5	11·19	12	6·84	19	5·7
6	11·01	13	5·14	20	3·3
7	8·79	14	4·66	21	2·82

Often just before death there is a rise of protein metabolism, synchronous with a practically complete disappearance of fat from the body. The animal now has to supply all its requirements at the expense of protein, which accounts for the increased excretion of nitrogen. This is shown in the following experiment of Rubner on a rabbit:

Days.	Average daily output of nitrogen.	Average amount of fat oxidised daily.
1–3	1·67 g.	10·3 g.
4–5	1·46 ,,	10·3 ,,
6–8	3·21 ,,	2·4 ,,

We see therefore that during starvation, apart from the first day or two, the animal derives the main portion of its necessary energy from the combustion of fats, provided that there is a sufficient store of these substances in the body. Since protein comes from the working tissues of the body, these are spared so far as possible, and it is only when the stored fat is used up that any large call is made on the tissue protein.

---

* Gamble, Ross and Tisdall. *J. Biol. Chem.*, 1923, **57**, 633.

It is probable that part at least of the protein that becomes available in food deprivation comes from the liver. Some also comes from blood plasma, which shows a fall in serum albumin. Hunger œdema, which is especially associated with chronic protein shortage, appears to be a result of this.

In starvation the ability to metabolise carbohydrate is depressed, so that if glucose is administered, there is an abnormally high blood sugar, and glucose is excreted in the urine—so-called hunger diabetes.

4. EFFECT OF THE FOODSTUFFS ON METABOLISM

Food not only supplies energy, but also serves to replace the wear and tear of the body. So far as the latter function is concerned the proteins of the food take a position apart. Every working cell of the body consists largely of proteins ; to repair the wear and tear of the machine of the body, therefore, proteins are absolutely necessary. To supply the energy requirements any or all of the three classes of foodstuffs can be utilised.

The Influence of Proteins. A starving man is putting out energy and diminishes in weight as a result. In the example cited on p. 798 the man was losing about 13 g. of nitrogen a day and was putting out about 2,000 Calories, derived partly from the combustion of protein and partly from the oxidation of the fat. It would manifestly be useless to try to stay the loss from the body by giving merely 13 g. of nitrogen in the food in the form of protein, since this would give him only 320 Calories towards his basal requirements of 2,000. We should find in fact that the effect of such an administration would be practically to double the output of nitrogen from the body and to increase slightly the total output of energy. In the dog, it would be possible to stop the loss of body weight by giving an amount of protein equal to five times the loss during starvation. In man, such an amount would be too great for his assimilating powers and it would be necessary to give fats and carbohydrates in addition to the protein.

Nitrogenous Equilibrium. A subject is said to be in a state of nitrogenous equilibrium when the amount of nitrogen excreted during a given period is equal to that ingested. The protein taken in with the food has a twofold function to perform. One of the functions is the replacement of tissue. When, however, we are feeding an animal on a pure protein diet, by far the larger portion of the food is utilised for meeting the energy requirements of the body. In this function protein presents no apparent advantages over the other two classes of foodstuffs. Its value to the animal, represented numerically by its physiological heat value as 4·1, is equivalent to the value of the same weight of carbohydrate and is far inferior to that of fat. If, instead of giving to the starving animal a pure protein diet, we administer a mixed diet containing fat or carbohydrate, or both substances, sufficient to meet the normal energy requirements of the body, we can restrict the utilisation of protein more nearly to the replacement of tissue waste in the body, and are therefore able to attain nitrogenous equilibrium with a much smaller proportion of protein than is possible when this substance furnishes the whole diet. In omnivora, such as man, it is easy to attain nitrogenous equilibrium on a mixed diet with a smaller nitrogen turnover than is found during starvation. In the experiment given on p. 798 the average nitrogen output during fasting was about 13 g., and in prolonged starvation it may fall to 5 g. per day or less.

Chittenden * found that in man apparently normal nutrition may be maintained on a mixed diet containing only 7 g. of nitrogen daily. If the amount of fat and carbohydrate be very largely increased, it is possible to maintain nitrogenous equilibrium on even smaller quantities of protein. Thus Kon and Klein † kept a man and a woman, each of about 63 kg. body weight, for 167 days in good health and nitrogenous equilibrium on an average daily nitrogen intake of 5·7 and 3·8 g. respectively.

Most of the experiments on the influence of variations in the quantity of protein food have been made on carnivora, such as the dog and cat. Within very wide limits, the output of nitrogen is proportional to the intake. This is shown in the Tables by Voit ‡ given below, representing two experiments on dogs.

In Experiment I. the animal had been fed for some days before with 500 g. of meat (17 g. N) per diem. The fact that he was excreting 18·6 g. nitrogen daily shows that he was not yet in a condition of nitrogenous equilibrium. Each day he was using up 1·6 g. of his body nitrogen, in addition to the 17 g. supplied in the food. On increasing his food threefold to 1,500 g. (= 51 g. N) the nitrogenous output was considerably increased, but now some nitrogen was retained in the body; the output of N continued to rise, and the amount retained to fall, until on the eighth day of the experiment nitrogenous equilibrium was reached. During the six days intervening 26·4 g. N had been retained in the body, *i.e.* there had been a retention of protein, probably in the form of increased muscular substance.

EXPERIMENT I.				EXPERIMENT II.			
Day.	Daily N. intake. g.	Daily N. output. g.	N-balance. g.	Day.	Daily N. intake. g.	Daily N. output. g.	N-balance. g.
1	17·0	18·6	− 1·6	1	51·0	51·0	0
2	51·0	41·6	+ 9·4	2	34·0	39·2	− 5·2
3	51·0	44·5	+ 6·5	3	34·0	36·9	− 2·9
4	51·0	47·3	+ 3·7	4	34·0	37·0	− 3·0
5	51·0	47·9	+ 3·1	5	34·0	36·7	− 2·7
6	51·0	49·0	+ 2·0	6	34·0	34·9	− 0·9
7	51·0	49·3	+ 1·7				
8	51·0	51·0	0				
		Total	+ 26·4			Total	− 14·7

In Experiment II. diminution of the food (from 1,500 g. to 1,000 g.) was followed by a loss of N. from the body, the output being greater than the income. The excess, however, was rapidly diminishing and equilibrium had been practically attained on the last day of the experiment. During this time the animal had excreted 14·7 g. more nitrogen than it had received in its food. Many such experiments have agreed in showing that in carnivora an appreciable storage of nitrogen can take place in the body, probably by a growth of muscle substance. However much protein is given, the limit is finally arrived at where no further laying on of protein tissues of the body is possible, and the animal then enters into a state of nitrogenous equilibrium. This equivalence of income and output signifies that the *total energy output* of the body rises and falls with the quantity of protein in the food. This is shown in the Table on p. 802 by Pettenkofer and Voit,§ in which the figures were recalculated by Pflüger.

We see, therefore, that *carnivorous animals* can satisfy their total energy requirements at the expense of protein. When the protein income is in excess of their requirements, a small amount is laid on, probably as increased muscular tissue. The most marked effect, however, is an increased metabolism, which rises in proportion to the nitrogenous income. The limit to this increase is set by the powers of the alimentary canal to digest the protein. The rise in metabolism consequent on protein food is very rapid and affects the gaseous exchanges as well as the output of nitrogen. Magnus Levy and Falk found that a large protein meal might increase the respiratory exchange 40 per cent., during seven hours.

Period.	Nitrogen in food.	Nitrogen output.	Fat gain or loss.	Total Calories.
1	0	5·6	−98	1072
2	17	20·4	−59	1094
3	34	36·7	−38	1328
4	51	51·2	−22	1554
5	61	59·7	−30	1851
6	68	69·5	+22	1600
7	85	85·4	+12	2128

The nitrogenous output also rises immediately after a protein meal, so that 50 per cent. of the nitrogen of the ingesta may appear in the urine within seven hours after the meal.

These results cannot be strictly applied to man, in whom it is impossible to supply all the energy requirements of the body on a pure protein diet. Even if a man eats as much meat as he can, he will be unable to obtain sufficient energy for his daily needs. Whereas the average daily requirements of a man amount to about 3,000 Calories, 1 lb. of lean meat (*i.e.* entirely devoid of fat) would yield only about 400 Calories, and even if he took 4 lb. of meat daily, an amount which is impossible for most individuals, he would be obtaining only about 1,600 Calories. The cures for obesity, in which a large protein diet plays an important part, are in all cases practically equivalent to a state of semi-starvation.

Many experiments have been made on the influence of variations in the quantity of protein in a mixed diet. Within wide limits the output of nitrogen is equal to the intake. A normal adult man seems able to store little, if any, protein. The only way in which protein can be laid on in the body is by furnishing a physiological stimulus to the growth of muscle, *i.e.* by constant exercise. The conditions, however, are different when dealing with an individual in whom, from some cause or other, the muscular tissues are not at their full development. Thus in growing individuals a certain amount of the protein of the food is always retained and laid on as tissue protein. Weight for weight, a boy of sixteen to eighteen requires about 50 per cent. more protein than an adult man. In convalescence after great wasting of the muscles has taken place, feeding with large amounts of protein has been found to give rise to a considerable retention of protein in the body. This process goes on only until the muscles have attained their normal condition of development.

Specific Dynamic Action. Protein food has in man, as in animals, a specific stimulating effect on the metabolism, so that the respiratory exchange is largely increased as a result of a heavy protein meal. The rise is about 30 per cent. of the basal value ; *i.e.* if for each 100 Calories basal metabolism we give protein equal to 100 Calories, then the metabolism, instead of remaining at 100, rises to 130 Calories. This effect was named by Rubner the "*specific dynamic action*" of protein.

If either fats or carbohydrates be given to a starving animal, a certain sparing of the fat of the body takes place, but this effect is accompanied by a distinct specific dynamic action, viz. from a basal value of 100 Calories the metabolism is increased to 106 Calories by 100 Calories glucose, or to 104 by 100 Calories fat. In undernourished individuals the effects are greater than these, and tend to bring the metabolism up to what it would be if the basal level were normal. As regards the protein metabolism, Cathcart found that while administration of fat increases the nitrogen output during starvation, carbohydrate food causes a diminution in the nitrogen output, and thus exercises a marked sparing effect on the proteins of the body.

The stimulating influence of carbohydrate on metabolism, although much less than that observed on the administration of protein, is easily demonstrable after administration of moderate amounts of soluble carbohydrate to a fasting subject. If carbohydrate be given in excess of the daily energy requirements, the greater proportion of it remains in the body, being stored up provisionally as glycogen, but eventually in the form of fat.

If excess calories be given in the form of carbohydrate, there is a sparing of protein, and N. and S. are stored. Conversely, if the protein and carbohydrate portions of a diet are consumed at different times, there is a loss of the order of 2 g. N. daily. It is clear, therefore, that the metabolism of carbohydrate and of protein are linked in some way: it may be that intermediaries of carbohydrate take the place of amino-acids in being oxidised.*

Cause of Specific Dynamic Action. The metabolic rate during the absorption of a meal is always greater than that under otherwise comparable conditions in the fasting subject. We have seen that the specific dynamic action of the various foodstuffs results in the augmentation of the basal, *i.e.* fasting, rate of metabolism by the following percentage amounts :—

Protein	30 per cent.
Carbohydrate . . .	6 ,,
Fat	4 ,,

The augmentation is not so constant as these figures suggest, however. With protein it varies according to the amount given, first decreasing, then reaching a level and finally increasing as the total caloric contribution from protein is raised.

The explanation of specific dynamic action is not entirely clear and the effect may be due to various causes, but in general it may be said to be a consequence of the energy expenditure involved in processes of intermediary metabolism. Since protein has the most striking effect it has received most attention. The effect is also produced by some of the amino-acids, *e.g.* glycine, alanine, tyrosine and phenyl-alanine and to a smaller extent by leucine and glutamic acid : it has its seat mainly in the liver, and seems largely to represent heat set free in the conversion of the amino-acids to urea. Two stages of this conversion involve energy expenditure, first the liberation of ammonia by an oxidative change, and second, the coupled oxidative reactions associated with conversion of the ammonia to urea. If the amino-acids are not broken down, but are built into the tissues, as in rapidly growing young animals, no specific dynamic action is seen. It is abolished by removal of the liver, because it is there that the changes occur.

The specific dynamic action of protein results only in the production of heat, and since in cold surroundings a large proportion of the food must always be applied to maintain the body temperature, the excess heat involved in the consumption of protein, and to a less extent of other foods, can be, and is, utilised. Hence it comes about that in order to exhibit this specific dynamic action, the animal must have a temperature above 33° Centigrade. Below this temperature the specific dynamic action of the foodstuffs becomes less and less apparent, and is finally merged in the heat production necessary, whether food is taken or not, to keep up the temperature of the body.

The effect of carbohydrate probably represents the energy expenditure needed to convert it into glycogen, or into fat. The latter involves the greater energy expenditure : if conversion to fat is encouraged by giving vitamin B_1 with the glucose, the S.D.A. is increased.† It is not abolished by liver removal.

The effect of fat is unexplained, and is supposed to be due to increased fat combustion.

5. THE EFFECT OF MUSCULAR WORK ON METABOLISM

The energy for muscular work is immediately derived from the oxidation of glycogen, but ultimately of the foodstuffs. The following Table (Benedict and Cathcart) represents the respiratory exchanges in a trained muscular subject during complete rest and while riding a stationary bicycle. The "severe work" in this Table was carried to exhaustion, so that the respiratory exchanges represent the maximal for that type of exercise.

Condition.	c.c. CO_2 eliminated per minute.	c.c. Oxygen absorbed per minute.	Respiratory quotient.	Pulse rate.	Respiration. Rate.
Lying . .	200	243	0·83	56	20
Moderate work .	1720	1834	0·94	150	32
Severe work .	3227	3265	0·98	166	38

We can determine the relation between work done and energy expended by either direct or indirect colorimetry, as explained on p. 792. In the Table below are given the results of an experiment by Atwater by the direct method. The work was done by the man on a bicycle ergometer.

In these experiments, the difference in the mean expenditure of energy on the work days and on the rest days (with food) was 2,723 Calories. This *excess metabolism* over resting requirements took place in order that the body might perform work equal to 546 Calories. The fraction $\frac{\text{work}}{\text{energy of excess metabolism}}$ is spoken of as the "mechanical efficiency" of the body. In the above case it equals one-fifth, and the body is said to have a 20 per cent. efficiency. Of course a certain proportion of this excess of energy used over work done is accounted for by the increase in the work which must be performed by the respiratory muscles and heart. Even if we neglect these factors altogether, the efficiency of the body as a machine corresponds to between 16 and 25 per cent., an efficiency which exceeds that of the best of our steam engines and is only equalled by certain internal combustion engines.

ENERGY PER DAY.

Nature of experiment.	Heat eliminated.			External work in Calories.	Total in Calories.
	By radiation and conduction.	In urine and fæces.	In water vaporised from lungs and skin.		
Rest with food (average of four days) . . .	1850	26	521	—	2397
Rest, fasting (four experiments) (average of five days)	1605	21	561	—	2187
Work (fourteen experiments) (average of forty-six days)	3802	29	743	546	5120

We have already seen in Book II that the results of metabolism experiments during work may throw light on the nature of the constituents of the body which undergo oxidation to furnish the energy of muscular work. In the experiment already quoted, the oxidation of carbon was increased more than threefold during a six-hour period of work. This carbon might form part of the molecule of protein, fat or carbohydrate ; but it has long been known that muscular exercise causes no considerable increase in the nitrogen excretion.* The above experiments illustrate this fact. The basal output of nitrogen per day corresponded to the destruction of 82 g. of protein. During rest and with food, the average daily consumption of protein was 98·8 g. During a work day, in which the individual received protein and a somewhat insufficient quantity of carbohydrates and fats, the consumption of protein was 109·4 g. Thus there was a three- to four-fold increase of the carbon metabolism of the body, but only a 10 per cent. increase in the protein metabolism.

The study of the respiratory quotient over periods of several hours might be expected to give us some idea of the nature of the material which is furnishing by its oxidation the energy for muscular work. If the whole of the energy requirements were furnished by the oxidation of carbohydrates, $C_6H_{13}O_6 + 6O_2 = 6H_2O + 6CO_2$, the *respiratory quotient* of the animal, namely $\frac{CO_2 \text{ expired}}{O_2 \text{ inspired}}$, would be equal to unity. From the formula of a fat it is evident that it will require a relatively larger amount of oxygen to oxidise it than is necessary in the case of the carbohydrate. The respiratory quotients for protein, fats and carbohydrates are given in the following Table :

Material.	Respiratory quotient $\frac{CO_2}{O_2}$ (volumes).
Carbohydrate	1·0
Protein	0·81
Human fat	0·718

Since the carbon dioxide excreted during exercise may result from the oxidation of protein, fat or carbohydrate, we cannot exactly deduce the total energy set free in the body by an estimation of the O_2 intake alone. The respiratory quotient must also be determined, and the output of nitrogen in the urine measured. Then the non-protein R.Q. is calculated as already explained on p. 797, and from this the relative contribution of the various foodstuffs can be deduced by reference to a table such as the one following, which gives the relative oxygen usage for combustion of carbohydrate and fat for a given non-protein respiratory quotient in man † :

Non-protein R.Q.	Carbohydrate.	Fat.	Calories for one litre oxygen.
1·00	100 per cent.	0 per cent.	5·047
0·95	82·3 ,,	17·7 ,,	4·992
0·90	65·5 ,,	35·5 ,,	4·936
0·85	46·8 ,,	53·2 ,,	4·881
0·80	20·1 ,,	70·9 ,,	4·827
0·75	11·4 ,,	88·7 ,,	4·770
0·718	0 ,,	100 ,,	4·735

The number of Calories set free in the body for every litre of oxygen taken in are also given in the above Table.

The respiratory quotient of an animal is a net result determined by the average nature of the substances which are undergoing oxidation in its body. If the performance of muscular work involved special chemical processes, *e.g.* a metabolism of one of the main constituents of the body in preference to either of the others, this sudden change in the quality of the metabolism should show itself in the respiratory quotient. It must be borne in mind that the respiratory quotient gives only the final result of the oxidative changes, and tells us nothing regarding the intermediate stages by which that end result is reached. For instance, if fat were converted to carbohydrate and the carbohydrate all burned, the respiratory quotient would be the same as if the fat had been burned directly.

Prolonged moderate exercise, although attended by a large increase in the CO_2 output and oxygen intake of the body, does not alter the respiratory quotient.* The respiratory quotient over a long period, such as a day, must depend on the material which is combusted, irrespective of the amount of muscular work which is done in the time. Ultimately there is no doubt that the energy for muscular exercise can be derived from any of the three classes of food. Such experiments, however, do not answer the question as to the immediate origin of the energy involved in muscular contraction. When dealing with this we saw that the ultimate source of the energy of contraction was the glycogen of the muscle. We shall see later on that the body has the power of converting carbohydrates into fats ; and proteins, and perhaps fats, into carbohydrates. The respiratory quotient in the course of a day is affected by these intermediate changes as well as by the foodstuffs oxidised.

* Fick and Wislicenus. *Vierteljahrs. d. zürch. Naturf. Gesselsch.*, 1865, **10**, 317.

† Cathcart and Cuthbertson. *Journ. Physiol.*, 1931, **72**, 249. The slightly different values from those on p. 792 is due to the fact that the composition here taken for fat is that of human fat.

As the result of a series of experiments Krogh and Lindhard † came to the conclusion that the cost of work in man, when it is performed at the ultimate expense of fat, is 10 per cent. more than when it is performed at the expense of the carbohydrate of the body. This extra expenditure of energy they regard as, so to speak, wasted in the chemical conversion of fats into carbohydrates. This great difference does not arise in the case of proteins, which form carbohydrates in the body with extreme ease. But whereas proteins form, for the most part, the working tissues of the body, fats are stored as a reserve food, so that under normal conditions, in default of an excessive diet of proteins, fats must often be utilised for the carrying out of muscular work. For this to take place, it is probable that they are first converted into carbohydrates and stored in the muscles as glycogen.

It will be noticed that, in contradiction to popular opinion, the proteins do not play any special part in relation to muscular exercise.‡ The special value of protein is for building up the body and for repairing wear and tear. As a source of energy it presents no advantages over carbohydrate and fat ; in fact it may be in some respects inferior to these substances, or at any rate less economical, owing to the specific dynamic action, the whole of which appears in the form of heat. If an animal after a protein meal be made to work, the increased metabolism due to the specific dynamic action of the protein is still observed over and above that due to the performance of work. On the other hand, in training there is some reason for a plentiful supply of protein in the diet. When, however, a man has arrived at the full development of his muscular system, there is no need to attempt to supply the energy for his movements at the expense of protein. In many cases the beneficial effects of meat are due to its content of fat.

6. THE SIGNIFICANCE OF THE FOODSTUFFS

Isodynamic Replacement. A primary requirement of a diet is that it provide an appropriate source of energy. For supplying this energy any of the three classes of foodstuffs may be utilised. Thus carbohydrates and proteins are *isodynamic—i.e.* give rise to the same amount of energy in the body for a unit weight—1 g. of each giving out 4·1 Calories. Within limits, carbohydrate can be replaced by the isodynamic amount of fat, and within narrower limits all three classes are isodynamically interchangeable. This isodynamic equivalence of the foodstuffs is, however, interfered with to a certain extent by the specific dynamic action. On account of this, an average mixed diet, in order to maintain the body in a state of equilibrium, must have a Calorie value about 15 per cent. higher than the basal requirement. Thus, supposing a man while fasting and in bed gives off 1,800 Calories a day, he would under the same circumstances give off about 2,000 Calories if he received a minimum mixed diet just sufficient to maintain his body weight constant.

Protein. Proteins are distinguished from carbohydrates and fats by the fact that no means are provided for the storage of proteins in the body, except by the growth of muscular and other tissues, and perhaps, to a certain extent, by actual storage of protein in the liver.* Arrived at its maximum state of growth, the body cannot add to its protein store, and therefore all the protein that is ingested and absorbed is at once broken down in the body. If we examine the curve of nitrogenous excretion in the urine, we find that practically all the nitrogen taken in as protein in the food is turned out within twelve to sixteen hours. Thus, if a man is on a mixed diet sufficient for his daily needs, a doubling of the protein in the diet, leaving the other constituents unchanged, will result in a doubling of the nitrogenous excretion. On the other hand, an increase of the fats or carbohydrates will not increase the carbon output of the body, but any excess above the daily needs, if absorbed, is stored up in the body in the form of fat. To increase the protein metabolism, therefore, all that is necessary is to increase the protein intake; to increase the carbohydrate and fat metabolism it is necessary to increase the metabolism as a whole, *e.g.* by muscular exercise or by exposure to cold.

Protein is essential for the repair of the wear and tear of the tissues. We may thus speak of the protein of the food as having a twofold destiny. The amino-acids into which it is resolved circulate in the blood, and there is a continual exchange of amino-acids between the blood and the proteins of the living cells. These proteins are thus maintained by constant intra-molecular repair, or are increased in amount, if growth is in progress, by synthesis anew from the blood amino-acids.

Surplus molecules of amino-acids not used up in these ways are broken down, the nitrogen being converted to urea and excreted, and the remainder of the molecule, after further intermediary changes, being oxidised to CO_2 and water. These aspects of the subject will be dealt with in Chapter XLVI.

Action of the Products of Protein Digestion. Since the proteins of the body differ in their composition from those of the food, it is evident that each protein molecule has to be disintegrated and reconstructed before it can take its place in the body fabric; and it is therefore immaterial, so far as metabolism is concerned, whether we feed the animal with the ordinary food-protein or with the products of its hydrolysis, provided all the essential amino-acids, including threonine, are present; the mixed amino-acids can be given either by mouth or by slow intravenous injection.

The Biological Value of Proteins. Different diets containing the same amounts of protein are not necessarily of equal food value. One reason for this is that the proteins in different foodstuffs show different digestibilities: *e.g.* meat and milk 100 per cent., egg 85, legumes 70–80 per cent., and apple very indigestible. The reason for indigestibility is partly that the proteins are enclosed in indigestible cell walls. Pure proteins show smaller differences. The digestibility of proteins is expressed as the per cent. of consumed N. that does not appear as fæcal N. In consequence of the variation in the composition of the proteins contained in the different tissues of the body, it is necessary that the food shall include certain of the amino-acids in proper quantities. The indispensable amino-acids, ten in number, are called *essential*: the remainder can be synthesised in the body and are hence *non-essential*. Hence it follows that all proteins are not equivalent as regards their capacity for replacing tissue waste or serving for growth. Those in which nearly all the amino-acids are represented and which contain these in proportions approximating the average of those found in the chief tissue proteins are called *first-class proteins*. Most animal proteins belong to this group, though gelatin is an exception; some vegetable proteins such as edestin, glutenin of wheat, or glutelin of maize, are also included.

In the remaining, or second-class proteins, either (1) one or more of the essential amino-acids are absent, or (2) there is a large preponderance of one or more of the amino-acids which are required only in small proportions. As an example of the first type we may instance collagen and gelatin, and zein, the chief protein of maize. As an example of the second type we may instance the protein of wheat flour. Whereas caseinogen contains 22 per cent. of glutamic acid and serum albumin only 8 per cent., gliadin, the chief protein of flour, contains as much as 36 per cent. If wheat flour is the main or sole source of protein to the body, it is evident that a large amount of glutamic acid will be in excess of that required. It is also deficient in lysine.

---

* Foster and Whipple. *Amer. J. Physiol.*, 1922, **58**, 393, 407; Stübel, *Pflüger's Arch.*,1920, **185**, 74.

One of the methods of studying the subject is to feed young animals, *e.g.* rats, on a diet in which the protein lacks certain amino-acids, and to follow the rate of growth. This is reduced if the lacking amino-acid is essential. Gelatin is lacking in cystine, valine, phenylalanine, histidine, methionine, threonine, leucine, isoleucine, tyrosine, tryptophan and hydroxyglutamic acid, and it has long been known that it cannot entirely replace the proteins of the food. Its capacity for yielding energy to the body equals that of any other protein, but it can only replace body protein when the missing amino-acids are also supplied. In the same way zein, which is deficient in lysine and tryptophan, is incapable by itself of supporting life, though this can be accomplished if tryptophan is administered at the same time. Growth does not occur, however, until lysine is also added (Fig. 529).

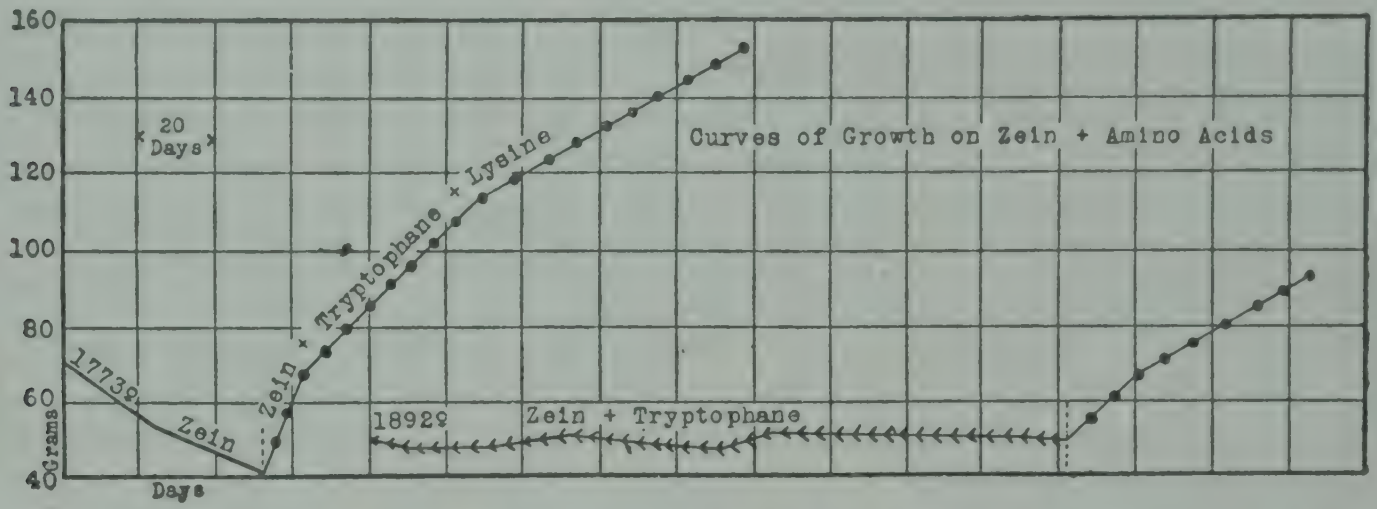

Fig. 529. Growth curves of young rats fed on a diet in which the protein is given as zein. No. 1773 received zein and lost in weight; when tryptophan and lysine were added to the zein it gained weight. No. 1892 received zein and tryptophan for six months; its weight remained stationary, but showed rapid increase when lysine was also given. (Mendel. Courtesy of the *J. Amer. Med. Assoc.*)

Certain proteins are also deficient in the sulphur-containing amino-acid methionine, some in phenylalanine, and some in histidine. All these, together with lysine and tryptophan, are essential, and cannot be made in the body. It is noteworthy that cystine can be replaced by methionine, and tyrosine by phenylalanine; but histidine cannot be replaced by arginine.

Undoubtedly the best method of finding which amino-acids are essential and which are not is to feed young animals on a diet in which protein is replaced by mixtures of pure amino-acids, one of which is omitted. This method has been used with remarkable success by Rose, and threonine was actually discovered in this way, as it was observed that mixtures of all previously known amino-acids were inadequate to promote growth. One of the consequences of lack of essential amino-acids is failure of growth; another is lack of appetite. Lack of valine produces curious rotatory movements in rats. Methionine (or cysteine plus choline, from which methionine can be formed) appears to be essential for the well-being of the liver. Complete lack of methionine causes, in the rat, liver changes ranging from fatal acute yellow atrophy to chronic hepatic cirrhosis.* Liver damage following chloroform anæsthesia, arsphenamine dosage, etc., can be averted by administration of methionine, or of proteins such as casein, which are rich in it.

---

* Himsworth and Glynn. *Lancet*, 1944 i., 457.

The following Table shows the essential and non-essential amino-acids (for rats), according to Rose.*

Essential.	*Non-essential.*
Arginine.	Alanine.
d- or *l*-Histidine.	Aspartic acid.
d-Isoleucine.	Citrulline.
l-Leucine.	Cystine.
d-Lysine.	Glutamic acid.
l-Methionine.	Glycine.
d- or *l*-Phenylalanine.	Hydroxyglutamic acid.
d-Threonine.	Hydroxyproline.
d- or *l*-Tryptophan.	Norleucine.
d-Valine.	Proline.
	Serine.
	Tyrosine.

The original experiments on essential amino-acids were carried out on rats. It has now been shown that most of the amino-acids listed above as essential for rats, are also needed to maintain N. equilibrium in man, so probably there is no great species difference. Lack of valine causes an immediate loss of nitrogen.

These differences in chemical composition between the proteins are of greatest significance when the protein of the food is reduced to the minimal amount required to replace tissue waste, and under such circumstances marked differences are observed between the biological values of proteins. The biological value of a given protein decreases as the amount of that protein is increased.

It is evident that when there is scarcity of protein, animal protein is more economical than vegetable protein; and that if it is necessary to live on a largely vegetable diet this should be mixed, so that all the amino-acids required in the body may be represented in the diet. Thus, the diets at R.A.F. stations in 1941, though only containing about 40 per cent. of the total protein in the form of animal protein, had the high biological value of about 80.†

For the estimation of the biological value of proteins various methods have been used. In one method the nutritive value for growth is expressed in grammes of body weight increase per gramme of protein consumed, when the diet contains that amount of protein at which the maximal growth occurs.‡

The *nutritional biological value* of a protein can be practically assessed by the method of Mitchell.§ It is too involved to be adequately discussed here; its principle is to determine, on rats, what fraction of the absorbed nitrogen escapes excretion in the urine, during the feeding period, *e.g.*

Estimation of N. absorbed and retained.

		Daily. mg. N.
N. in food of diet . . .		=56·9
Fæcal N. on diet . .	=27·6	
„ „ on N.-free diet .	=21·7	
∴ indigestible N. . .	= 5·9	5·9
N. absorbed		=**51·0**
N. wasted		=10·9
N. retained		=**40·1**

Estimation of N. escaping metabolism.

	Daily. mg. N.
Urine N. on test diet . . .	= 48·6
Tissue catabolism, *i.e.* urine N. on N.-free diet	= 37·7
N. wasted in metabolism . .	= **10·9**

$$\text{Biological value} = \frac{40\cdot1}{51\cdot0} \times 100 = \underline{\underline{79}}$$

---

Fats. Besides their high calorific value and their frequent content of vitamins, there is evidence that fats are essential constituents of diet. In the form of lecithins they are indispensable components of most living cells, and although certain fats are readily synthesised in the body, it is doubtless more economical for them to be supplied in the diet. Moreover, there seems good ground for regarding small amounts of unsaturated fatty acids such as linolenic and linoleic acids, or their esters, as being quite indispensable for proper nutrition. Rats fed on entirely fat-free but otherwise complete diets developed a deficiency disease affecting the skin, and their growth and reproduction were impaired. Addition of small amounts of the acids or fats named effected cure, or prevented the disease.

7. THE INORGANIC FOODSTUFFS

The Water Balance. Some 72 per cent. of the body weight consists of water, about 5·5 per cent. in the blood, a variable amount, around 25 per cent., in extracellular fluid, and the remainder within the cells : all this water is interchangeable—as is shown by studying the dissemination of injected D_2O—in rabbits that of blood and extracellular fluid speedily (within 30 secs.), and that between blood and the whole of the remainder more slowly (within 30 mins.).† The water content of the tissues is maintained reasonably constant by equalisation of the loss and gain of water.

The water of the blood plasma, lymph and extracellular fluid may be called "free water," because its molecules can freely interchange and travel, and so can carry dissolved substances without appreciable hindrance from place to place. Its amount can be determined by injecting into the blood a known amount of some diffusible non-metabolisable substance, such as sodium thiocyanate, and, after a short interval to allow of its uniform dispersal, finding its concentration in the plasma. From such experiments the "thiocyanate space" is found to be about 17 l. for a normal adult, or about 25 per cent. of the body weight.

The remaining water is held within the cells, by reason of its being bound to colloids and confined by cell membranes ; diffusion of dissolved substances between the extracellular fluid and the intracellular water is not entirely free, but is conditioned by the properties of the plasma membrane and cytoplasm.

The osmotic pressures of the blood, tissue fluid, and of the various secretions into the alimentary canal are identical. Even when very large amounts of water are drunk there is no considerable dilution of the blood ; nor is there measurable concentration of it on deprivation, except in extreme thirst.‡ By delicate methods, however, changes can be shown to occur.§

The income of water is derived from two sources, viz. water taken in as such with food or drink, and water formed by the oxidation of foodstuffs. The output of water is by the lungs, skin, urine and fæces.

‡ HALDANE and PRIESTLEY. *J. Physiol.*, 1915, **50**, 296.

§ PRIESTLEY. *J. Physiol.*, 1915, **50**, 304. MARGARIA. *J. Physiol.*, 1930, **70**, 417.

The water formed by oxidation of foodstuffs can be calculated since we know that, from 100 g. protein we get 41 g., from 100 g. fat 108 g., and from 100 g. carbohydrate 55 g. water, and so we deduce that with average sedentary diets about 350 c.c. of water per day is formed by oxidation.

The total exchange of water per day is approximately as follows for average conditions for a sedentary adult in a temperate climate :

Income.		Output.	
Drink	1,450 c.c.	Urine	1,500 c.c.
Food	800 ,,	Skin	600 ,,
Oxidation	350 ,,	Lungs	400 ,,
		Fæces	100 ,,
	2,600 c.c.		2,600 c.c.

The proportion of the water lost by the respective channels of kidneys, skin, lungs or bowel will naturally vary with conditions. In diuresis relatively more will pass out by the urine, in sweating more by the skin, when dry air is breathed more by the lungs, in diarrhœa more by the bowel; when more passes out by one channel, there will be less to be eliminated by the other routes. The biggest variables are the volume of fluid drunk and the amount lost by sweating: when the former is increased the urine output increases to keep the balance, when the latter increases urine output is reduced and the fluid drunk increased. The specific gravity of the urine is the best objective indication as to adequacy of water intake, since the kidneys must excrete at least about 300–500 c.c. daily in order to remove the necessary substances in solution; if the salt intake is raised, however, the minimum obligatory urine volume is increased.*

In a person at rest and not visibly perspiring, the loss of water by lungs and skin can be estimated by weighing the subject at intervals; the loss of weight is mostly due to water loss, but allowance can be made for the small loss due to the difference in weight between oxygen intake and CO_2 output. Proceeding in this manner, it has been found † that the rate of loss from "insensible perspiration" is proportional to the basal metabolism, and in an average man is about 40 grammes per hour, of which 18 grammes represents water lost by the lungs, 18 grammes water lost by skin, and 4 grammes the balance between weights of O_2 intake and CO_2 loss.‡

With alterations of body weight there is usually a proportional loss of water and of solid constituents, but in some cases there is a proportionally greater loss or gain of water, which it is important to take into account. A loss greater than 20 per cent. of the body water is not usually compatible with life.

Regulation of the water intake is principally effected through the agency of thirst (Chapter XLIV.; for the conditions regulating urine secretion *v.* Chapter XLVII. and for sweating, Chapters XLVIII. and XLIX.).

Excessive water intake, if uncompensated, causes a serious condition, by lowering the osmotic pressure of the tissue fluid, which causes the cells to swell: it can prove fatal.

In abnormal states the distribution of body water is often altered. Thus, in conditions of shock, there is loss of plasma into the tissue fluid, so that "hæmoconcentration" occurs, and is shown by a rise in the hæmoglobin content of the blood. This can often be set right by intravenous injections of blood plasma: saline solutions are useless, because they do not increase the colloid osmotic pressure of the blood which is needed to enable it to retain its fluid. If for any reason a patient cannot drink, it is again wrong to give saline solution, as this only throws extra work on the kidneys in eliminating the salt, and water goes out with it: in this case 5 per cent. aqueous glucose should be given intravenously. But if there has been dehydration due to loss of secretions and tissue fluid, as in diarrhœa or vomiting, then the administration of intravenous saline would be correct.

Dehydration occurs much more readily in infants than in adults, because, whereas in adults the daily water exchange only amounts to about one-eighth of the bulk of extracellular fluid, in infants it is as high as one half.

Van Slyke (1926). Factors affecting the Distribution of Electrolytes, Water and Gases in the Animal Body. (Philadelphia and London : Lippincott & Co.)

Saline Constituents. Mineral salts are essential to life. If an animal be fed with a diet from which all the salts have been removed, it loses appetite, becomes ill, and dies sooner than if completely starved. An animal in a state of salt-hunger becomes very weak, and shows signs of paralysis ; food, still undigested after prolonged periods in the stomach, is vomited up, and it is clear that the functions of the entire body are profoundly upset.

In salt-hunger the body is continually giving off inorganic constituents in the urine. The amount of these is smallest when the animal is supplied richly with organic foodstuffs. It seems that certain inorganic ions are held in a state of combination with the tissue constituents.* If the food supplied is insufficient, the animal lives on its own tissues, thus setting free salts which appear in the urine. An interesting condition is miner's cramp, met with in workers who drink water and perspire freely. So much sodium chloride is lost in the sweat that the urine, though small in bulk, is sometimes quite free from chloride. (Normal urinary Cl = 7 — 10 g./l. as NaCl.) † The cramp is due to excess of water in the tissues, and can be avoided by the subject drinking water containing 10 grains of salt per gallon (0·105 per cent.).

A large number of elements are probably needed for the maintenance of health and normal growth, and these are required by the body in very different amounts. The daily adult intake for some of the more important may be put approximately at :

Calcium	0·7 g.
Sodium	6·0 ,,
Potassium	4·0 ,,
Iron	12 mg.
Phosphorus	1·25 g.
Iodine	0·05 mg.
Chlorine	20·0 g.
Zinc	12 mg.

Most of these elements are taken in excess of the minimal requirements, any excess over this being excreted, and it is often uncertain what the minimal requirement actually is. Usually a state of balance is maintained, as in the following example for Ca, Mg and Fe :

Balance Sheet for Calcium, Magnesium and Iron.

(Amounts for six subjects over fourteen days (McCance and Widdowson.‡))

	Intake from Food, g.	*Output, g.*			*Balance, g.*
		Urine.	*Fæces.*	*Total.*	
Calcium	61·68	13·69	48·99	62·68	— 1·00
Magnesium	22·80	9·28	13·30	22·58	+ 0·22
Iron	0·6033	0·0078	0·607	0·6148	— 0·0115

‡ McCance and Widdowson. *J. Physiol.*, 1938, **94**, 148 ; *Bioch. J.*, 1939, **33**, 523.

Sodium, chiefly in the form of chloride, plays an important part in the maintenance of the proper osmotic pressure of the body fluids, and the sodium ion is also essential in proper concentrations in those fluids. Sodium deficiency is rare in Europe, but is seen after removal or disease of the suprarenal cortex.

Potassium is an essential ion in all cells, and deficiency of it is very rare.

Iron is essential for the formation of hæmoglobin and of the various hæmatin-like compounds, such as cytochrome, which play a very important part in carrying on the oxidative processes in the body. Much of the iron taken by the mouth is unabsorbed. Milk is poor in iron (about 1 mg./l.), but the infant is born with a store of iron in the liver sufficient to last it for several months. Good sources of iron are meat, potatoes, liver, kidney, watercress and most vegetables. Iron compounds are probably reduced to the ferrous state in the alimentary canal, and unabsorbed iron is excreted as ferrous sulphide. Deficiency of iron leads to anæmia, but the taking of excess of iron does not lead to formation of larger amounts of hæmoglobin than normal.

Very little iron is excreted per day, the iron store of the body being kept up by conservation of iron. When the hæmoglobin of the red cells is disintegrated on their destruction, the iron is stored for a time as a ferric hydroxide complex with protein, known as *hæmosiderin*, in the liver, and is re-utilised as demand arises for the construction of fresh hæmoglobin.

Copper in a very small amount appears to be necessary for the assimilation of iron and formation of hæmoglobin.

Cobalt is a constituent of the hæmopoietic principle of the liver.

Manganese is another element which must be supplied in minute amounts. In its absence the processes of reproduction are disturbed.

Magnesium is also essential. It is chiefly present in the body in the bones, as a phosphate. A rat requires not less than 5 mg. of Mg per 100 g. food. The human requirement is about 0·6 g./day. In magnesium deprivation there are vascular disturbances, hyperexcitability, convulsions and death.* The effects of Mg. deficiency are intensified if the diet is very rich in Ca.† The Mg. ion acts antagonistically to the Ca ion with regard to the excitability of tissues.

Chloride is the chief anion of the body, but especially of the interstitial fluid: it is readily absorbed as soluble chlorides. In shortage of chloride the ion is tenaciously retained in the body, and the urine, which normally carries the excess of ingested chloride over the requirements, may then become totally chloride-free.

Iodine is a constituent of thyroxin, the hormone of the thyroid. About half of the body iodine is present in the thyroid. Iodides are rapidly absorbed and are excreted unchanged.

Bromide is also quickly absorbed, and is normally present in traces in the body, where it mingles with the chlorides.

Calcium ‡ is most abundant in milk and cheese; eggs and green vegetables contain some, but meats, fish and bread are poor in calcium. Some of the calcium requirement can be obtained by drinking hard water. Much of the calcium of the diet is not absorbed, the fraction so remaining depending on the other constituents of the diet, and on the extent to which the duodenal contents retain an acid reaction. Bile salts and sugars aid in the absorption of calcium, while alkalies or large amounts of phosphates retard it by formation of the insoluble calcium phosphate. Fats also retard it. Growing children and pregnant women and nursing mothers need more calcium than other persons, and about 1·6 g./day is suggested for them.

Calcium is essential for the formation of the bones and teeth, for blood clotting, and for the maintenance of the normal excitability and permeability of different types of cells.

The calcium of the blood is practically all in the plasma (or serum); its amount varies with the amount of plasma protein and usually is about 10 mg./100 c.c. Not all of it is diffusible or ionisable but usually only about half of the total amount. Practically all that is dialysable is fully ionised. The fraction that is non-dialysable is attached to protein and in fact the calcium ion concentration of the plasma can be calculated from the formula of McLean and Hastings :—

$$\frac{[Ca^{\cdot\cdot}] \times [\text{Protein}]}{[\text{Ca Proteinate}]} = 10^{-2.22} \text{ at } 25° \text{ and } pH\ 7{\cdot}35.$$

A nomogram for finding the serum calcium from the total Ca and total protein is given in Fig. 530.

The ionic calcium also varies in the opposite direction to the *p*H of the plasma, but no strict relationship between them seems to have been yet discovered. The Ca of the cerebro-spinal fluid is all in the ionic state, and as a rule equals that of the ionic calcium of the blood plasma.

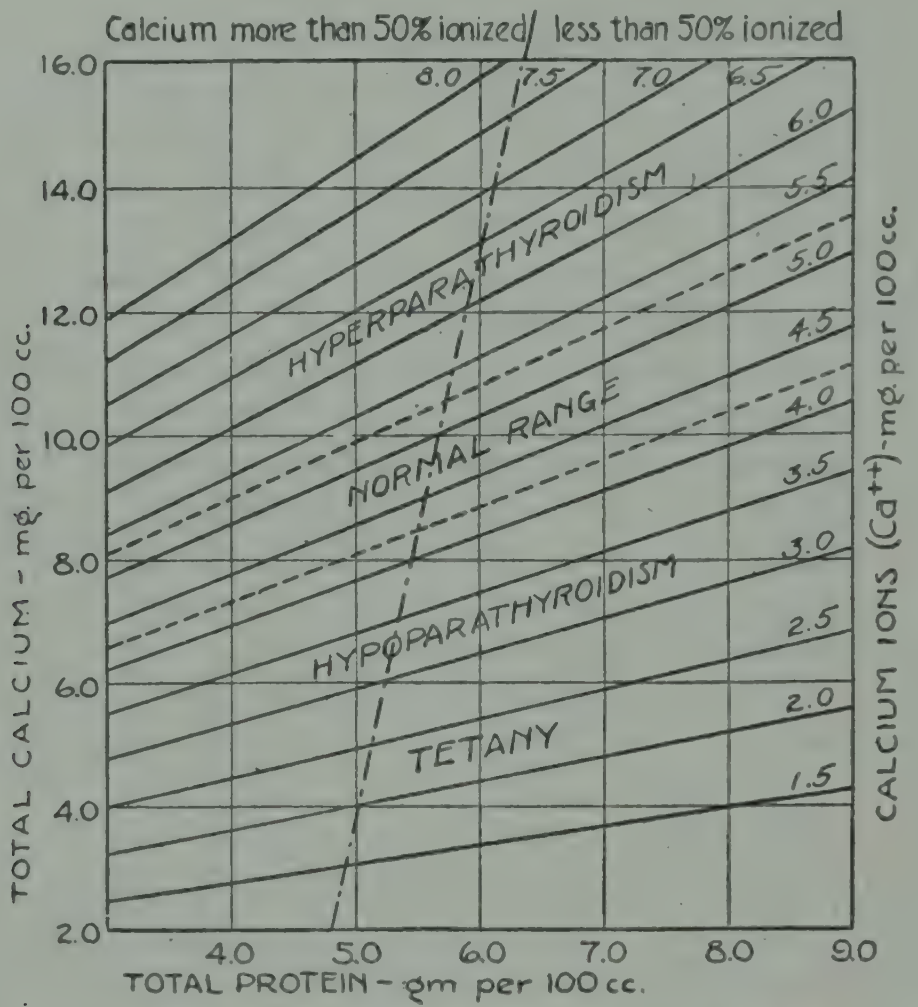

FIG. 530. Nomogram for finding $Ca^{\cdot\cdot}$ of serum from total Ca and protein. The position of the point of intersection of any pair of rectangular co-ordinates with respect to the more horizontal oblique lines gives the $Ca^{\cdot\cdot}$ of the serum, *e.g.* at 8 per cent. protein and 12 mg. Ca/100 c.c., the $Ca^{\cdot\cdot}$ is 5 mg./100 c.c. (McLEAN and HASTINGS, *Amer. J. Med. Sci.*, 1935, **189**, 601.)

Soluble calcium salts, such as chloride, lactate or gluconate, given by mouth, cause an increase in the calcium of the plasma in an hour or two ; a few hours later this returns to normal again. Amounts varying from 10 to 50 per cent. of the intake of calcium by the mouth are excreted in the urine, and from 50 to 90 per cent. are excreted in the fæces and probably represent unabsorbed calcium salts. But some state that when calcium salts are given by mouth there is no increase in the calcium of the fæces ; on the other hand, it is claimed that in fasting the calcium content of the fæces is but little reduced.

Phosphorus is obtained partly in the form of phosphates of inorganic cations, but largely as organic phosphorus compounds. In the course of their metabolism in the body, these liberate phosphoric acid. Thus various phosphatides, nucleic acid derivatives, etc., all ultimately yield phosphoric acid. Part of the phosphorus present in cereals is in the form of phytin (inositol hexaphosphate), and this source of phosphorus is not utilisable in the body. Sources of available phosphorus are similar to those of calcium, but meat and fish, though poor in calcium, contain plenty of phosphorus.

Phosphorus, in the form of various derivatives of phosphoric acid, plays an important part in the processes of intermediary metabolism. Thus sugars and fats are metabolised through the intermediation of phosphorylated derivatives.

Phosphorus and calcium should be provided in a proper ratio, which in most human diets is about 2 P to 1 Ca. In bone the ratio is 2 Ca : 1 P, and that ratio is favourable for growing animals. Since both are principal constituents of bone and teeth, they must often be considered together.

8. BONE AND BONE FORMATION

Bone is a living tissue which consists of 25 per cent. water and 30 per cent. of an organic matrix impregnated with inorganic material. When a bone is soaked in dilute acid the inorganic material is dissolved away, and the remaining organic matrix is elastic and flexible. Calcination, by removing the organic matrix, leaves only the inorganic material as a friable residue of bone ash, forming some 45 per cent. of the weight of the original bone. The chief organic constituent is a collagenous protein called ossein. The inorganic material consists chiefly of calcium phosphate and carbonate, with some magnesium phosphate. Examination of the X-ray spectrum of bone shows it to be crystalline in structure, and to correspond to one of the minerals known as apatite or hydroxyapatite, *i.e.* either

$$3\ Ca_3(PO_4)_2.CaCO_3 \text{ or } Ca_3(PO_4)_2.CaOH_2.$$

It is not proposed to describe here the histological features of bone formation and in Chap. XLII. we shall deal with some features of bone formation in relation to vitamins. That the cartilaginous basis and the growing bone are formed by the osteogenic cells of the periosteum and endosteum has been shown by the direct method of tissue culture. Cartilage cells, or bone cells, when once formed, however, multiply as such, though the osteogenic layer of the periosteum can produce either cartilage cells or bone cells.

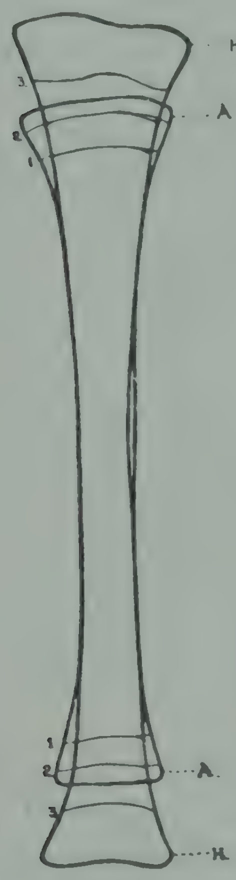
The foundation of cartilage on which a long bone is subsequently laid serves to determine roughly what the shape of the finished bone will be. It is, in fact, possible to cultivate *in vitro* a portion of undifferentiated mesenchyme from the thigh region, and to witness the emergence of a roughly formed femur in tissue quite removed from its usual surroundings. The final detail of the architecture of the bones and of the joints is, however, the result of the operation of various extrinsic factors. Among these, some are mechanical, *e.g.* due to local stresses and strains, and others are chemical. Thus, the growth and quality of the skeleton is largely influenced by such endocrine organs as the anterior pituitary, thyroid, parathyroid and sex organs, the hormones of the latter in particular being responsible for the difference in form and growth of the skeleton in the two sexes.

In the development of the long bones, the primary spongy bone which at first replaces the scaffolding of cartilage is itself only provisional, and is reabsorbed by the activity of " osteoclasts," the while new bone is being laid down to replace it. This simultaneous absorption and formation of bone is not confined to fœtal life or even to childhood, but continues, though at a slower tempo, throughout life, so that bones are far from being the static and finished structures they are commonly believed to be.

As a bone grows it increases in thickness by absorption from within the marrow cavity while sub-periosteal bone is being laid down on the outside. Hence, a layer of bone which at an early stage lies just beneath the periosteum comes at later stages to appear to sink into the underlying bone, until it finally reaches the layer adjoining the medullary cavity, after which it disappears. This can be shown by feeding a growing animal for a time on madder. This colours the new bone red, and on cross section of the shaft of a long bone from the animal, the new bone deposited during the period of madder feeding stands out clearly as a coloured ring. If the animal is killed at or shortly after the period of madder feeding, the coloured ring is at the surface of the shaft, but as the interval between feeding and killing is lengthened, so the position of the coloured ring is found to lie further and further away from the surface. This method of growth explains why it is possible to put a fœtal femur inside the medullary cavity of an adult femur, although we know that one has developed by a process of continuous growth from the other.

Long bones grow in length by progressive growth and ossification of the cartilaginous epiphyseal plate. During certain illnesses the rate of growth is greatly slowed, and the lamina of bone then laid down is more dense than normal, and remains so, as a permanent record visible in an X-ray of the bone. As this lengthening occurs it is accompanied by a good deal of re-moulding of the outer surface of the epiphysis by sub-periosteal reabsorption (Fig. 531).

Since the bones and teeth stand out from other tissues by reason of their high content of calcium salts, much attention has been directed to finding how this calcification has been brought about. It seems probable that the essential feature of the process consists in the construction, first of an organic matrix by the osteogenic cells, and then the calcification of this matrix by the formation in it of a precipitate of calcium phosphate. The precipitated calcium phosphate then appears to adsorb ions of $Ca^{\bullet\bullet}$, OH', and CO_3' to form the apatite-like bone salt.*



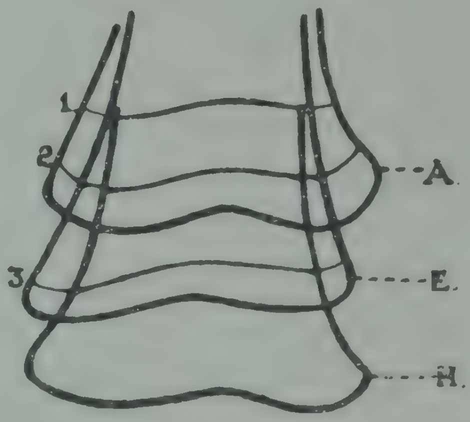


Fig. 531. Superimposed radiographs of bones of a child taken at intervals over a period of 106 weeks. (Radiographs by H. A. Harris.) On right, outlines of three pictures of lower end of the femur. Between A and E, 63 weeks elapsed, and between E and H, 43 weeks. The lines of growth retardation corresponding to periods of illness are at 1, 2 and 3. On left, A and H with 106 weeks' interval, are of tibia of same child. Note how much bone has been re-absorbed to form the final shape of H in both cases. (Brash, *Edin. Med. Journ.*, 1934, **41**, 305.)

Processes of calcification and of decalcification are apparently always going on in bone—sometimes, as in growing bone, calcification greatly exceeds decalcification, and sometimes, as when there is present an excess of the hormone of the parathyroid, decalcification is in excess of calcification. The two processes are probably independent, and occur locally as a result of cell activity, and in the normal adult a state of equilibrium between the two processes occurs. That continuous replacement of the inorganic material of bone goes on is shown by the fact that when salts of radio-active calcium, or phosphates containing radio-active P are administered, the radio-active element can be detected in all the bones in a few hours or days.

The deposition of calcium phosphate in the formation of bone is probably bound up with the fact that the formation of a precipitate of an ionisable substance from a solution depends on the concentration of the constituent ions reaching a value at which their product exceeds the "solubility product" of the substance concerned. In this case, when the solution is in equilibrium with a small amount of solid calcium phosphate, *i.e.* when the solution is saturated, then $[Ca^{\bullet\bullet}] \times [PO_4{}''']= K$. Protein, by forming unionised Ca proteinate, decreases the amount of Ca in solution and, as we have seen (p. 814), the concentration of Ca ions in plasma can be calculated if the total Ca and total protein are known. If the concentration of either the $Ca^{\bullet\bullet}$ or the $PO_4{}'''$ in the saturated solution is increased, then calcium phosphate is precipitated until the product $[Ca^{\bullet\bullet}] \times [PO_4{}''']$ falls to the solubility product value. Precipitation of calcium phosphate from a saturated solution can thus be brought about by adding a soluble phosphate (in just the same way as we can throw down sodium chloride from its saturated solution by the addition of HCl), or alternatively by the addition of excess Ca ions in the form of a soluble calcium salt.

---

* Logan and Taylor. *J. Biol. Chem.*, 1937, **119**, 293.

Now the product of the $Ca^{\bullet\bullet}$ and $PO_4{}'''$ ions in normal blood plasma is about equal to the solubility product of Ca phosphate, and therefore an increase in say, $PO_4{}'''$ ions will throw down calcium phosphate ; moreover, the calcium phosphate thrown down will not be redissolved unless the ionic product falls far below the solubility product.

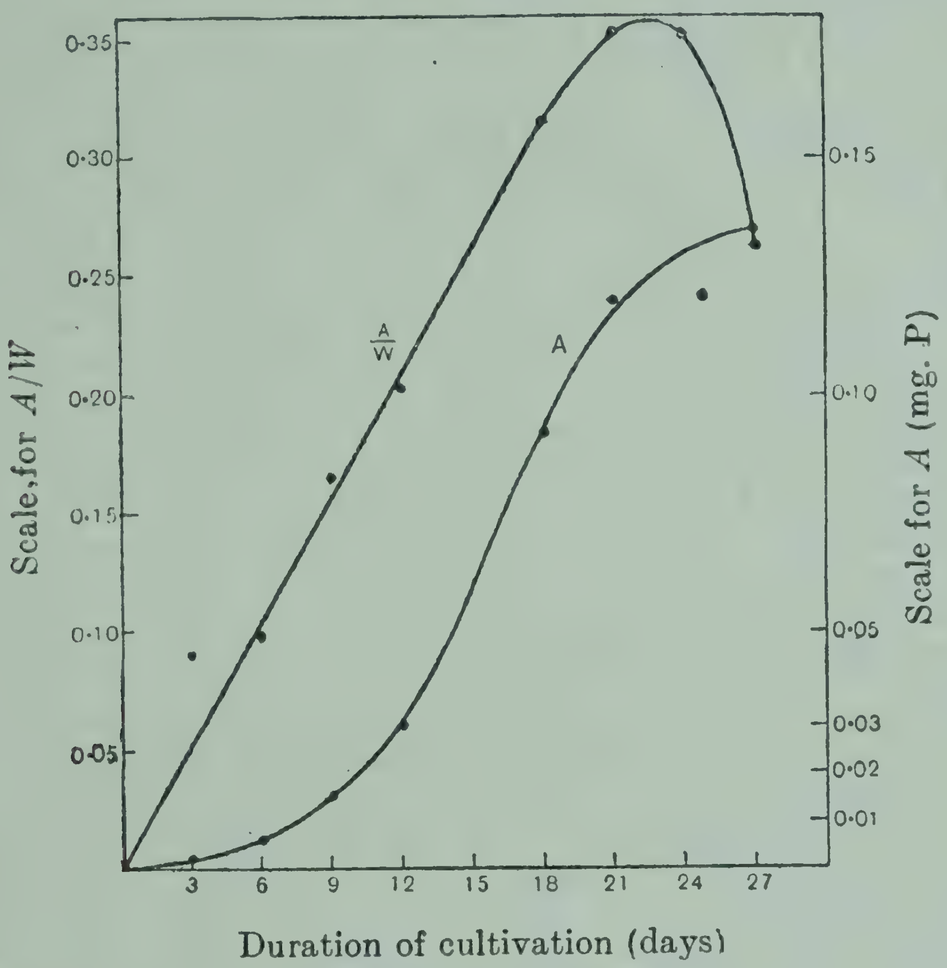

Fig. 532. Production of phosphatase during development of femora of fowl embryos excised at sixth day.

A = Phosphatase per femur (mg. P hydrolysed from glycerophosphate).
A/W = Phosphatase per mg. dry weight of femur (after Fell and Robison. *Bioch. J.*, 1929, **23**, 767).

It was shown by Robison that in the process of calcification an important part is played by an enzyme called *bone phosphatase*, which is produced by the osteoblasts. This enzyme can decompose phosphoric acid esters (such as glycerophosphate or hexose monophosphate), which are unionised, with liberation of $PO_4{}'''$ ions, and so lead to such a local increase in the ionic product as to exceed the solubility product of calcium phosphate, which is therefore deposited from the blood plasma. The enzyme is present in ossifying (but not in non-ossifying) cartilage : similar phosphatases also occur in other tissues, especially in the small intestine and kidney ; we cannot here discuss the interesting question as to why these last two tissues do not ossify, except to state that the bone matrix evidently has something to do with the deposition which occurs in bone. Bone salts are deposited on a piece of boiled ossifying cartilage placed in the abdominal cavity.

Phosphatase is not originally present in the cells of the mesenchyme from which the bone is to be formed, and the appearance and increase of phosphatase in a developing bone can be followed by making estimations of phosphatase on portions of a bone growing *in vitro* (Fig. 532).

It is perhaps significant that magnesium, which is also an invariable constituent of bone, greatly accelerates the action of phosphatase.

JOINTS

A joint is a tissue space lined by modified connective tissue cells. The articular surfaces are covered by hyaline cartilage and are kept in contact mainly by the supporting structures of the joint, such as the ligaments. The joint capsule is entirely of mesenchyme origin, and the inner layer of the synovial membrane is provided with blood vessels, lymphatics and nerves, and lined by large modified connective tissue cells which simulate an epithelium. The intermittent pressure to which a joint is subjected is important in keeping the articular surfaces in normal condition, and no doubt also in facilitating exchanges between the blood and the synovial fluid. The synovial membrane, unlike the articular cartilage, has high powers of regeneration if damaged, and is difficult to stretch.

THE SYNOVIAL FLUID is normally small in amount, *e.g.*, about 0·5 c.c. in a normal human knee-joint. It is a clear, pale yellow fluid, viscous and slippery to the feel, owing to the presence of mucin, and is subjected when *in situ* to slight if any positive pressure when the joint is at rest. It contains a number of cells, in man about 60 per c.mm., though the number and type of cells varies considerably, no doubt as a result of the occurrence of slight degrees of trauma to the joint. Of the cells present in normal fluid about half are monocytes and a quarter lymphocytes ; the rest are polymorphs, and other cells similar to those of blood.

In composition, the fluid is distinguished by the presence of mucin, about 0·14 per cent., and it contains about 2 per cent. of other proteins. Inorganic ions are nearly the same as in the plasma, such difference as exists being what would be expected from the Donnan equilibrium if we regard the synovial fluid as being in equilibrium with the blood. The high Ca content is at variance with this, however. Other constituents, such as urea, uric acid, etc., are at the same concentration as in the plasma. The relatively low protein content, as compared with the plasma content of 8 to 9 per cent., together with the fact that the albumin/globulin ratio is 3·9 as compared with 1·1 in the serum, means that, as in other body fluids, the passage of proteins from the blood stream is relatively difficult. It contains no fibrinogen and so does not clot.

There have been many suggestions as to how the synovial fluid is formed, but little experimental work. The most likely view is that the fluid is the liquid matrix of connective tissue, that the mucin originates therein, and that the fluid in this tissue space is in diffusion equilibrium with the blood. It has been abundantly demonstrated that substances of small molecular size pass readily from blood to synovial fluid, or *vice versâ*, and it is easy to show that acid dyes of high diffusibility pass freely from the blood into the joint.* Particulate matter, such as carbon particles, introduced into a joint, are slowly phagocytosed and removed by the lymphatics.

CHAPTER XLII

THE VITAMINS

If we feed an animal on a mixed diet containing proteins, fats, carbohydrates and salts in the proper proportions, but in a state of purity, *e.g.* a mixture of caseinogen, starch, sugar, salts and lard, we find that the animal becomes ill, ceases to grow if young, and finally dies. This had already been pointed out in 1880 by Lunin, but the matter was taken up again by Hopkins,* who worked on young growing animals. He found that in the case of rats it was sufficient to add 3 c.c. of milk daily to the artificially compounded diet for growth to take place normally (Fig. 533). Three cubic centimetres of milk contain only 0·08 g. total solids, of which the greater part consists of substances already present in the artificial diet; yet this small amount of fresh milk enabled the rats to add 0·5 g. a day to their weight. These observations were the beginning of numerous series of experiments by many different observers. It has been found that practically all fresh foods contain extremely small traces of essential organic substances to which the name "vitamins" has been given. Each of them is a catalyst indispensable for the occurrence of some metabolic reaction, but is not found in the body and must therefore be provided in the diet. They are essential for the utilisation of the food, for the maintenance of health and for growth. Fifteen or more vitamins have been clearly distinguished according to their different properties and mode of action. It should be stressed, however, that "except in infancy and childhood, there are but few instances where good health cannot be maintained by eating properly

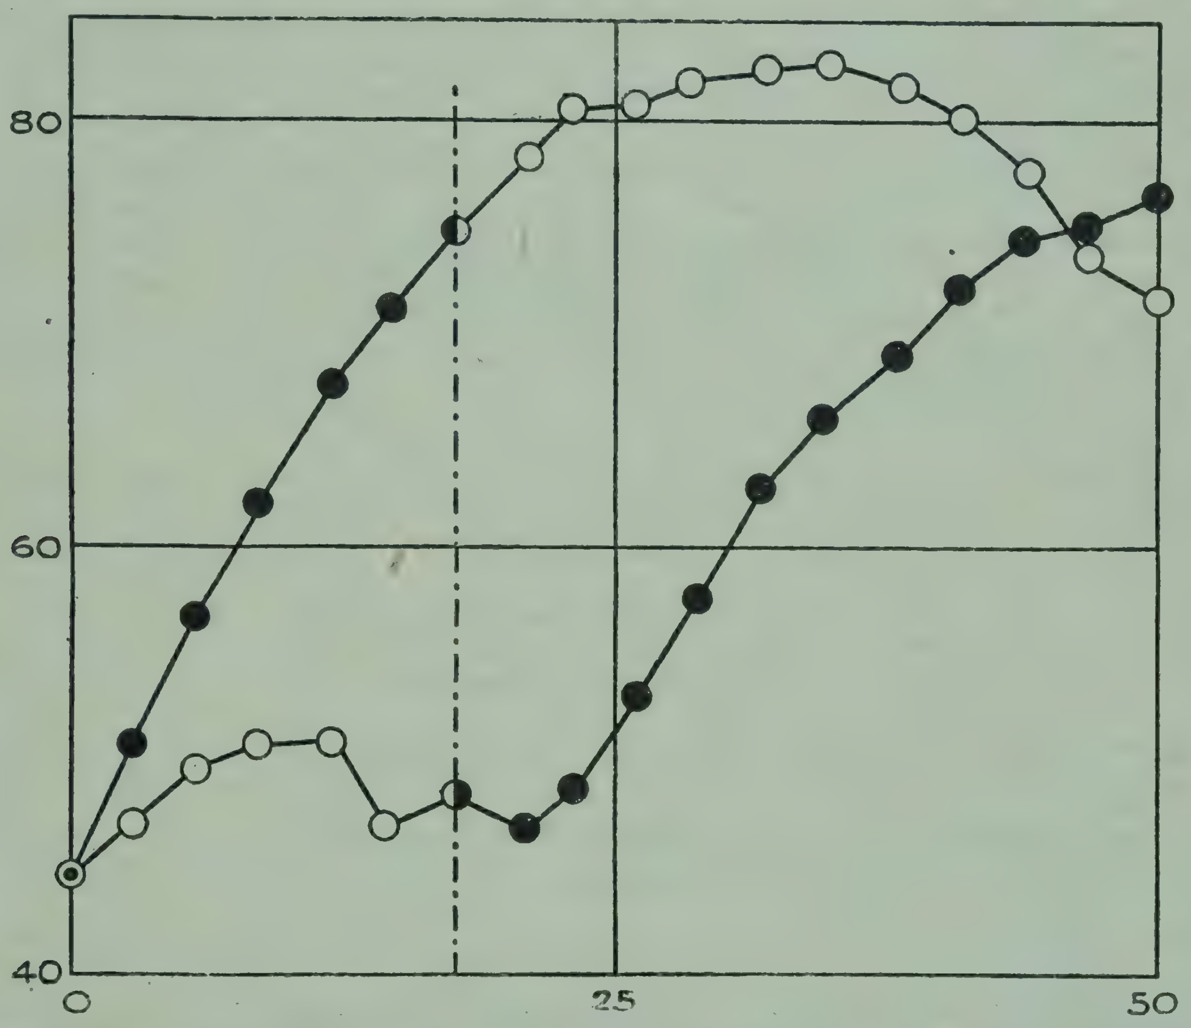

Fig. 533. Two Curves showing Growth of Rats with and without "vitamin A."

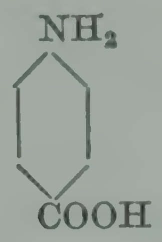
* Hopkins. *J. Physiol.*, 1912, **44**, 425.

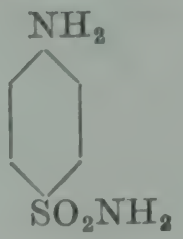
chosen food without the constant administration of vitamin preparations" (E. Mellanby).

Several vitamins have been proved to play a definite rôle as catalysts in connection with enzyme actions concerned in intermediary metabolism.

In carrying out this rôle they enter into transitory combination with some part of the reacting enzymes, and an important consequence of this arises in the phenomenon of *competition* by analogous substances. As an example of this we may take a classical instance concerned with the processes of intermediary metabolism of certain bacteria, for which the substance *p*-aminobenzoic acid is an indispensable substance. Now it would be thought that the rather similar substance sulphanilamide might do instead, but far from this being the case its presence has the same effect as *absence* of the essential *p*-aminobenzoic acid : this is because it enters into combination with the enzyme with which *p*-aminobenzoic acid should combine, and so excludes the latter from its essential functions in intermediary metabolism, by competition.



p-*aminobenzoic acid*



Sulphanilamide

The amounts of the various vitamins needed can be only approximately stated, because they vary with the total Calorie needs. Hence, for example, vitamins A, B and C are needed in greater amount in hyperthyroidism, or when heavy work is done. In experiments on the vitamins, animals are fed for several weeks on a diet deficient only in the vitamin concerned, and are compared with controls fed with the diet, but containing the vitamin. It is important to remember, however, that certain vitamins can be produced in the intestine by the activity of bacteria.*

The vitamins are often distinguished by letters. Some are soluble in fats and occur naturally together in association with them, while others are water-soluble.

Some Important Vitamins

Fat-Soluble Vitamins

A $\begin{cases} A_1 \text{ Also termed Axerophthol, the anti-xerophthalmic or anti-infective factor.} \\ A_2 \text{ Closely related to } A_1\text{, but of small importance.} \end{cases}$
D_2 (Calciferol) or irradiated ergosterol.
D_3 Natural vitamin D.
E (Tocopherol). Anti-sterility factor.
K Essential for formation of prothrombin of blood.

Water-Soluble Vitamins

B_1 (Thiamin ; aneurin). Anti-neuritic. Beri-beri preventive : forms co-enzyme of pyruvate carboxylase.
B_2 complex, comprising :—
    Riboflavin. Component of oxidising systems.
    Nicotinamide (Niacin). Anti-pellagra factor.
    Folic acid (vitamin M). Hæmopoietic factor.
    † Biotin (vitamin H).
    † Choline.
    ‡ Pyridoxin (vitamin B_6). Rat anti-dermatitis factor.
    ‡ Pantothenic acid.
    ‡ Inositol.
    ‡ *p*-aminobenzoic acid.
B_{12}, the hæmopoietic factor of liver.

---

* Elvehjem. *Feder. Proc.*, 1948, **7**, 410.
† = significance for man doubtful.
‡ = action only demonstrated on lower species.

C (Ascorbic acid). Anti-scorbutic factor.
P Citrin or Hesperidin. A factor associated with ascorbic acid and believed to supplement its action.

FAT-SOLUBLE VITAMINS

Vitamin A_1: its absence leads to failure of growth (Fig. 533), excessive keratinisation of the skin, including an affection of the cornea called xerophthalmia, a general lowering of resistance to infection and ultimately to death. Prolonged deficiency of this vitamin during growth also causes extensive degeneration in the central nervous system, especially in the afferent nerves and tracts * due to excessive bone growth in certain positions. Whereas vitamin D controls the calcification of bone, vitamin A co-ordinates the activity of the osteoblasts and osteoclasts, so that in its absence there is loss of normal bone shape and also of co-ordination of its growth in relation to that of the central nervous system. For instance, the growth of the basi-occipital bone is abnormal, because whereas normally there is a layer of active osteoclasts at surface 1 (Fig. 534) which absorbs bone, and a layer of active osteoblasts at surface 2 laying down bone, in vitamin A deficiency the state of affairs is reversed, while at surfaces 3 and 4 normal growth proceeds. Hence the bone becomes thickened and the marrow cavity enlarged.

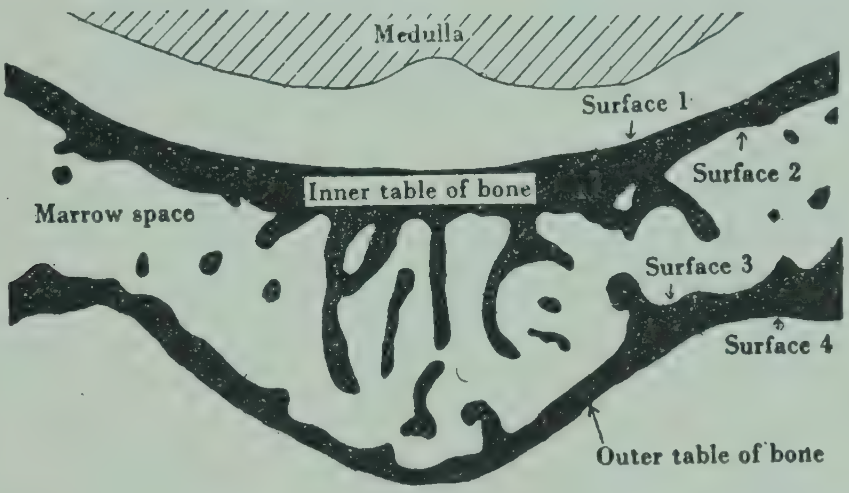


FIG. 534. Diagram of the basi-occipital bone, showing surfaces at which osteoclasis and bone formation occur. (MELLANBY. *J. Physiol.*, 1947, **105**, 382.)

On restoring vitamin A there is a return to the normal distribution of the responsible cell elements, and hence, if not too late, a reversal of the effects of the deprivation. Many other abnormalities of the nervous system may result from the same cause, including deformity of the cerebellum and medulla, increased intracranial pressure, internal hydrocephalus, and the squeezing of the whole of the central nervous system in its bony covering. Another effect of vitamin A deficiency is night-blindness, *i.e.* the inability to see in dim light. This is a consequence of reduction of visual purple in the retina owing to structural changes in the rods,† and also perhaps to a chemical relationship between visual purple and vitamin A. The occurrence of night-blindness is a convenient and early symptom of A_1 deficiency.

Vitamin A circulates in the blood, the plasma of which normally contains about 120 I.U. per 100 ml. It can be stored in the body, so that the effects of its absence from the food are not perceptible in adults till after many weeks. The normal human liver contains about 500,000 I.U., or enough to supply requirements for up to 400 days. In isolating it, the fats can be removed by saponification in the absence of oxygen.‡ The residue can be freed from cholesterol and the vitamin persists in the fraction consisting of unsaturated alcohols and hydrocarbons, but in very minute quantities.

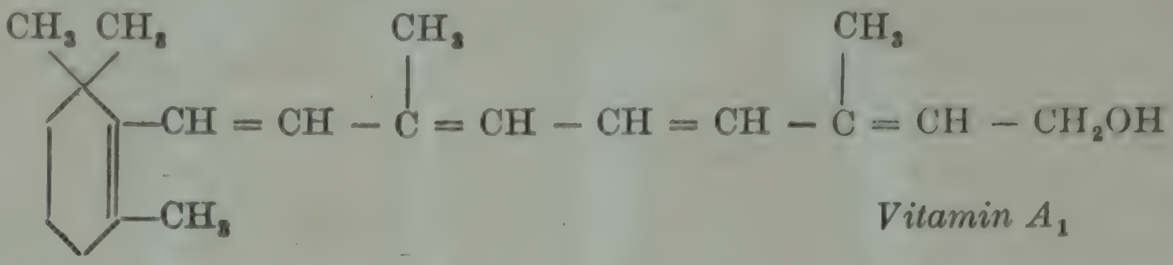
Vitamin A_1 is a viscid colourless oil of the elementary composition $C_{20}H_{30}O$. Its structure * is :



Vitamin A_1

It is insoluble in water but soluble in all organic solvents, and related to the unsaturated hydrocarbon carotene, $C_{40}H_{56}$. This is a crystalline pigment which gives a yellowish colour to certain natural fats and oils. Both carotene and vitamin A give a blue colour when treated with antimony trichloride in chloroform, and may be estimated colorimetrically by this means. Another method is by the determination of the coefficient of absorption in the ultraviolet (325 $m\mu$).

It would seem that, although animals cannot synthesise vitamin A, they can partially convert carotene into it. The amount of the purest vitamin A which is required to keep a rat from developing symptoms of vitamin A lack is only about 0·5μg. daily, whereas about 1μg. of carotene is needed. Carotene is thus to be regarded as the pro-vitamin of A. Probably the change into vitamin A occurs in the liver, in which the greater part of it is then stored.

The international unit of vitamin A is now 0·344 μg. of a specified crystalline vitamin A acetate, dissolved in a vegetable oil to make 0·1 mg. of solution. The former standard is discarded. The standard requirement for human beings is 3,000 I.U. daily. A prolonged and extensive investigation by the M.R.C. indicates 2,500 I.U. of vitamin A or 7,500 I.U. of carotene as the daily requirement in young healthy males.† Probably many diets only supply about 1,000. Milk contains about 3–5 units per c.c. ; butter about 20–50, egg yolk about 80, spinach 100, carrots 20 units per g., and other vegetables usually much less.

Vitamin A is originally formed in the growing green plant, and it is doubtful whether any higher animals have the power of forming it *de novo* in their bodies. The cow, for instance, obtains its A vitamin from grass : after ingestion it is absorbed into the fat of the body and of the milk, so that it is taken by man largely in the form of butter or milk. The organs richest in vitamin A are liver and kidneys. It is contained in large quantities in cod liver oil, and in even larger amounts in the oils from mammalian liver. Its origin in the sea is especially in the green diatoms which serve as food for the small plankton, organisms which are the basis of the food supply of the larger fish. It is not destroyed by heat, though easily oxidised. It is absent from most specimens of lard and from many vegetable oils, such as olive oil. If, however, pigs are fed on green food, pig fat contains the vitamin. It is much more abundant in the milk of cows in summer, out at grass, than when these animals are kept in byres and fed on oil-cake, etc.

Vitamins D. The absence of growth in vitamin lack is associated with abnormal formation of bones, which gives rise to the disease of *rickets* (Figs. 535, 536), and this can be prevented by giving cod-liver oil, but not by linseed oil.‡ The substance which is present in cod-liver oil was subsequently shown to remain in the non-saponifiable fraction, and this anti-rachitic substance was called vitamin D ; unlike vitamin A it resisted the action of oxidising agents. Vitamin D also produces growth effects to a minor extent, but its chief effect

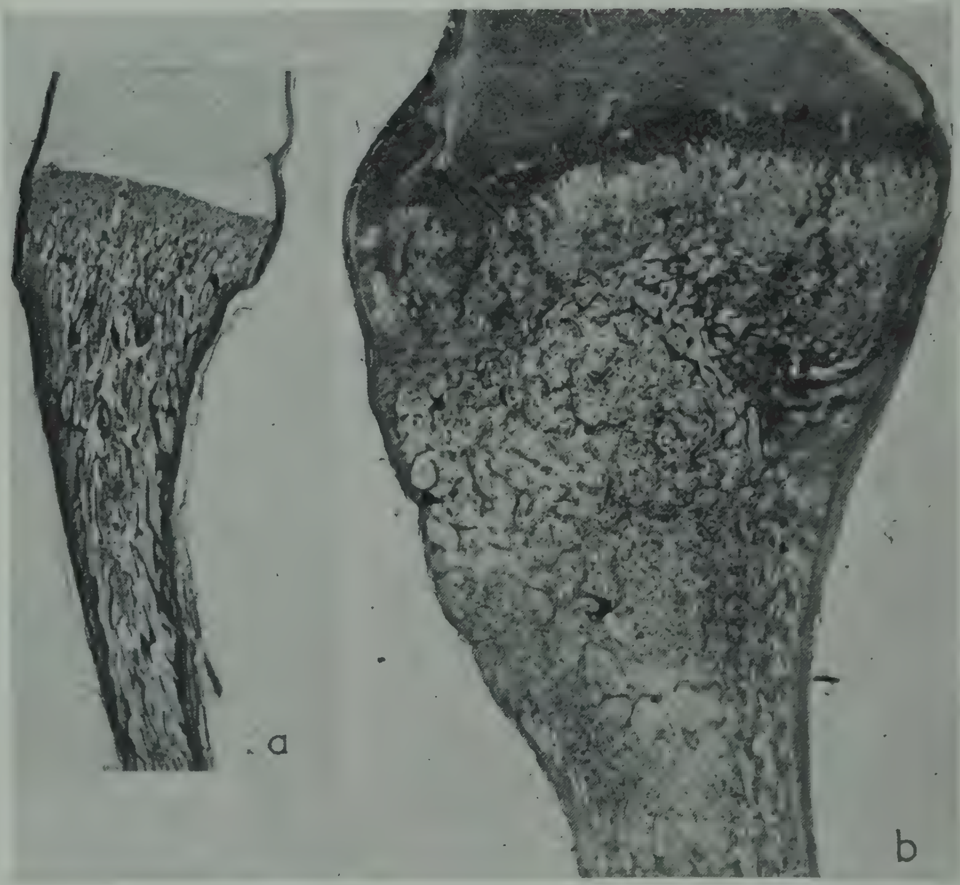
FIG. 538. Costo-chondral junctions of normal (*a*), and rickety (*b*) dogs.

The diets of the two dogs contained a large amount of oatmeal, which is rickets-provoking, but that of (*a*) contained cod-liver oil, while that of (*b*) contained olive oil.

(E. MELLANBY. "Nutrition and Disease." Oliver and Boyd, 1934.)



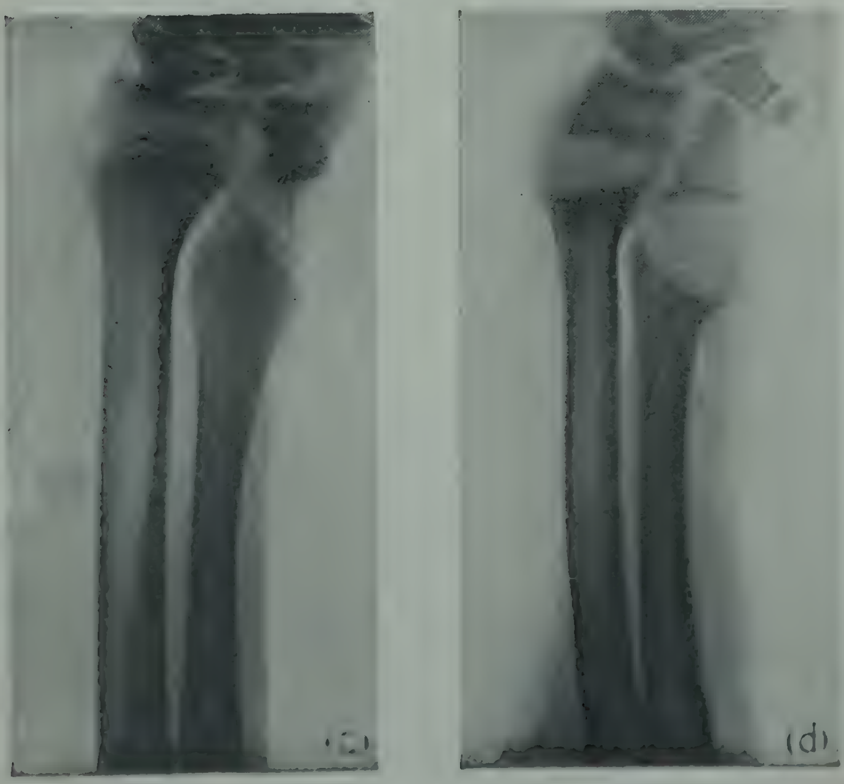


FIG. 539. Radiographs of wrists of dogs as in previous fig. (*c*) = wrist of dog (*a*) : normal. (*d*) = wrist of dog (*b*) : rickets.

(E. MELLANBY. "Nutrition and Disease." Oliver and Boyd, 1934.)

seems to be in controlling the balance of calcium and phosphorus. In normal plasma the product of the total Ca and P (inorganic) in mg./100 c.c. is over 50; in rickets both fall, the P first, and the product is below 40. The reason for this seems to be a loss of phosphate and ultimately of calcium by way of the fæces.

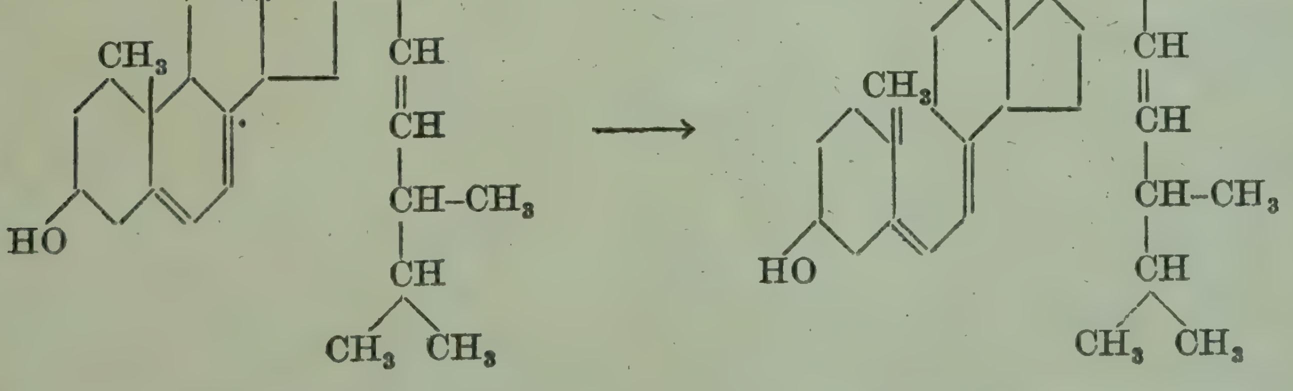
It has also been demonstrated by May Mellanby that vitamin D plays an important part in the formation of the teeth (Fig. 537). Once the dentine has been formed, however, administration of vitamin D cannot alter it either in structure or composition.[*]

The constantly growing incisor tooth of the rat is a delicate indicator of the conditions for tooth formation, the effect of replacement of vitamin D sometimes being detectable in twenty-four hours.[†]

The most marked change in rickets is a defect in bone formation normally occurring at the epiphyseal line (Figs. 538–539); the new bone at the epiphysis is inadequately calcified, soft and increased in breadth. Hence the bones show swellings at the epiphyseal junctions, and are easily deformed, resulting in bow-legs, knock-knees, etc. Ossification in cartilage consists of the following stages: (1) multiplication of cartilage cells; (2) calcification of the cartilage; (3) absorption of the calcified cartilage; (4) deposition of true bone, around cells —osteoblasts—which have invaded the calcified cartilage from the marrow. In rickets there is an accelerated multiplication of cartilage cells and a retardation in the deposition of true bone, from a failure in the process of deposition of calcium salts. If an anti-rachitic vitamin is added to the diet of a previously deprived and rachitic rat, a line of calcification soon appears transversely right across the cartilage near the epiphyseal line. This "line test" is a delicate detector of anti-rachitic property.[‡] It is evident that in the causation of rickets, or for the growth of normal bone, many factors are involved. In the first place, the presence of vitamin D is necessary. This may, however, be replaced to a certain extent by exposure to the sun's rays. Then it is necessary that calcium and phosphorus shall be present in proper amounts. An unsuitable ratio of Ca : P in the diet may also hinder the formation of bone. Thus Ca : P = 4 or 0·2 would be unfavourable; for some growing animals 2 is a good ratio. Cereals have a rickets-promoting effect owing to the fact that, calcium phytate being insoluble, and its phosphorus being present in a non-assimilable form as phytin, absorption of both $Ca^{\cdot\cdot}$ and PO_4''' are diminished.[§] It has been shown by Robison that, in the carriage of calcium salts to the bone, a part may be played by organic phosphoric esters which form soluble salts with calcium, and which have been detected in blood. Under the action of alkaline phosphatase which is present in ossifying cartilage, and which is *also present in rachitic bone*, this calcium salt is hydrolysed, and calcium phosphate is precipitated in the matrix round the osteoblasts.

The manner of action of vitamin D is unsettled, but it is probable that it primarily attacks the lipides of the tissues, with liberation of phosphoric acid,[||] the lack of which in the blood is a notable feature of rickets. It prevents loss of calcium by the bowel. As a net result, vitamin D acts by allowing an increased net absorption of calcium and phosphate, so raising their levels in the blood.[¶]

Exposure of animals to sunlight, or to ultra-violet light, can replace to a certain extent the necessity for the presence of vitamin D in the food. Investiga-



Ergosterol *Calciferol* (*vitamin* D_2).

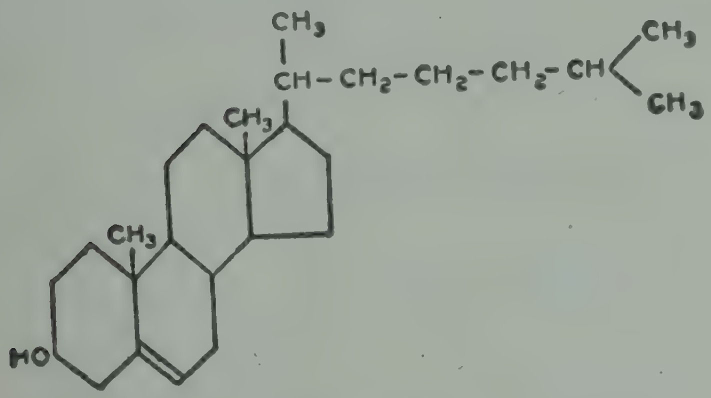
[§] Harrison and Mellanby. *Bioch. J.*, 1939, **33**, 1660.
[||] McGowan *et al.* *Bioch. J.*, 1931, **25**, 1295.
[¶] Nicolaysen. *Bioch. J.*, 1937, **31**, 107, 122, 323.

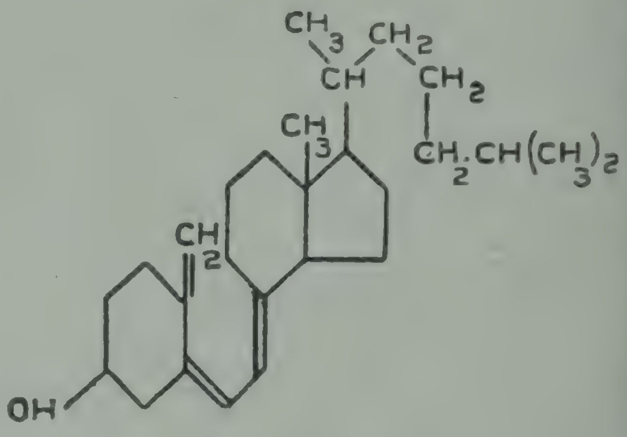
tion of the cause of the similarity between the effect of addition of vitamin D to the diet and exposure of the animal to ultra-violet light, led Steenbock to the discovery that vitamin D activity is produced by the action of ultra-violet light (250–300 mμ.) on a precursor which is present in the tissues, including the skin. It was further found* that this precursor is a sterol called *ergosterol*, $C_{27}H_{42}O$. Irradiated ergosterol has many of the properties of vitamin D.

By distillation of irradiated ergosterol in high vacuum, a crystalline isomer of double its activity was obtained; this was called "calciferol,"† or vitamin D_2. In large doses it causes loss of weight, reduced excretion of Ca and P, hypercalcæmia, toxic symptoms and death; extensive deposits of calcium salts are found in the heart, great arteries and kidneys. The anti-rachitic activity of calciferol is 40,000 international units per mg. The international unit for vitamin D activity is 0·025 μg. of a standard preperation of crystalline vitamin D_3.

It now appears that there are various natural vitamins D, the chief of which, D_3, is a very close isomer of cholesterol. It can be made by irradiation of 7-dehydrocholesterol. Its actions are similar with those of D_2.



Cholesterol.



Vitamin D_3.

The human daily requirements of vitamin D are not precisely known, but it is probable that growing children need more (*e.g.*, 2,000–5,000 units) than adults (200–500 units). Expectant mothers probably need 1,000–2,000 I.U. daily to allow of the increased Ca and P needs of fœtus and milk formation. It is essential that adequate amounts of calcium (*e.g.* 1·5g./day) and of phosphorus (2·0g./day) be also available. Poor dietaries lack these, as well as the vitamin D, and average diets are more likely to lack vitamin D than any other vitamin; hence the practice of giving it, as cod-liver oil, to children. Butter, cream and egg yolk are richest among ordinary foods; fish liver oils are especially rich (cod-liver oil averages 100 units per g.), but mammalian liver contains little.

Vitamin E. Recent experiments indicate that, for reproduction to take place, another vitamin may be necessary. Animals deprived of this vitamin may thrive and be to all appearance perfectly well, but do not produce young. Conception takes place, but the embryo fails to attain full development, dies *in utero* and becomes absorbed. The germ cells in males degenerate. There is also muscular degeneration and damage to the epithelium of the convoluted tubules of the kidney. Vitamin E is present in wheat-oil, butter and certain other fats. It is present in the unsaponifiable fraction, is not destroyed by light, heat, acids, alkalis, oxidation or hydrogenation, or distillation *in vacuo*, and has an absorption band at 294 mμ.

The international standard is a particular sample of racemic α-tocopheryl acetate of which 1 mg. = 1 unit. Standardisation is by determination of fertility-rate, *i.e.* the per cent. of positively mated female rats which produced a litter: the only source of vitamin E being that given in the sample, of known weight, under test.

The human requirement is probably 3 mg. per day. It possibly acts through the pituitary. There are several related components which are alcohols of the formula, $C_{29}H_{48}O_2$, called the tocopherols. The formula of α-tocopherol is :—

α-*Tocopherol.*

Vitamin K [*] is another fat-soluble vitamin, lack of which, in animals, produces symptoms rather like scurvy, and involving multiple hæmorrhages in skin and muscles, associated with greatly increased clotting time of the blood. It is present in many vegetable substances, especially cabbage and spinach. It is necessary for the production of prothrombin by the liver ; when it is lacking there is a lowered prothrombin content of the plasma. Bile is essential for its absorption and this accounts for the lowered coagulability of the blood in biliary obstruction. New-born infants are often deficient in vitamin K, and show increased clotting times. Chemically it is a methyl-phytyl-naphthoquinone.[†] The synthetic substitute is 2-methyl-1 : 4 naphthoquinone.

The chemically related substances dichloronaphthoquinone and dicoumarin :— act as competitors and produce symptoms like those of lack of vitamin K, *i.e.* incoagulability of the blood due to lowered prothrombin content of the plasma.

Dicoumarin

WATER-SOLUBLE VITAMINS

The Vitamins B. In man prolonged feeding with polished rice, *i.e.* rice from which the husks have been removed, leads to the production of the disease known as beri-beri. This is distinguished by the occurrence of polyneuritis, pains and weakness in the limbs, loss of sensation in the skin, œdema, and weakness of the heart. A somewhat similar disease may be produced by the same means in fowl or pigeons. The disease may be cured by adding the polishings to the polished rice before eating. It is evident that some substance essential to the normal nutrition of the body is removed during polishing. This was at first called vitamin B, but the effects are now known to be due to several substances.[‡] These are not stored to any extent in the body, so that animals rapidly show the effects of their withdrawal.

The individual vitamins in the complex are ten in number ; the most clearly defined has been called B_1 ; it can be differentiated from the remainder, called collectively the " B_2 complex," by their physiological effects and by the action of heat and alkali, either or both of which destroy B_1. Though both are necessary for growth, vitamin B_1, or "aneurin," or "thiamin," is believed to be related to beri-beri, while the vitamins of the B_2 complex have various functions, some of them still obscure. Yeast is rich in all, wheat germ in B_1, and milk, meat and green vegetables in B_2 complex.

---

[*] Dam *et al.* *Bioch. J.*, 1936, **30,** 1075 ; 1938, **32,** 485.

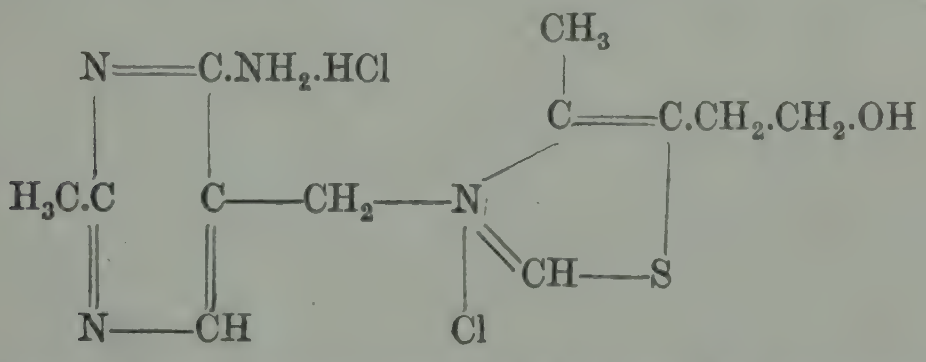
[†] Binkley *et al.* *J. Biol. Chem.*, 1939, **130,** 219.

[‡] Nelson. *J. A. Med. Assoc.*, 1938, **110,** 645.

Included in the vitamin B_2 complex are certain substances such as choline. The various factors in the complex play important parts in the control of metabolism, but these rôles are, as yet, not completely clarified. Other vitamin B_2 components in an average day's diet are said to be pantothenic acid (10 mg.), pyridoxine, biotin (0·25 mg.), inositol (1 g.) and folic acid (1·5 mg.). Whether the first three are needed by man is not known. The various members of the B_2 complex are essential for the growth of certain yeasts and bacteria, and may, in fact, be estimated by utilising this property.

Vitamin B_1 (Thiamin or Aneurin). Absence of B_1 vitamin leads in rats to wasting, failure of growth, atrophy of the testes, and sterility. The wasting is due to lack of appetite and to digestive disturbances. Secretion of gastric juice is reduced.* Among the effects of vitamin B_1 is a quickening of the rate of the heart-beat, which is slow in its absence.† Further, in lack of B_1 there is an accumulation of lactic and pyruvic acids in the blood and especially in the brain.‡ Convulsive symptoms in pigeons in extreme lack of B_1 are probably due to this; when vitamin B_1 is added to the brain of such pigeons *in vitro* the oxygen utilisation of the tissue is raised. It plays a part as a co-enzyme for pyruvate carboxylase (which co-enzyme is the pyrophosphate of thiamin), in the metabolism of carbohydrates (p. 94). It also stimulates conversion of carbohydrate into fat.§

Crystalline, vitamin B_1, was isolated by Windaus and by Otake; its formula was shown by Williams ‖ to be :—



Vitamin-B_1 (Hydrochloride of Thiamin.)

It has been synthesised,¶ and can be estimated by measuring the fluorescence of its oxidation product, thiochrome.

The international standard for vitamin B_1 is the pure substance. The international unit has been defined as 3 μg. of this. The requirement depends on the rate of metabolism. For average human individuals it is at least 300 units (1 mg. thiamin) daily. Up to 25 per cent. of ingested vitamin B_1 is excreted in the urine. Symptoms of lack include fatigue, loss of appetite, dyspnœa on exertion, muscle cramp, neuritis, and disturbances of sensation in the skin.

The richest sources of B_1 are dried yeast (10–20 I.U./g.), the germ of cereals, such as wheat and rice, peas, etc. White flour (72 per cent. extraction) contains very little, but the higher extraction flours (up to 85 per cent.) include the germ and so provide the vitamin (up to 1 I.U./g.).

The daily requirements for man are related to the calorific value of the (non-fat portion of the) diet, and can be calculated from Cowgill's formula :—

$$\text{Vitamin } B_1 \text{ intake (in International Units)} = \text{Calorific intake} \times \text{Wt. (Kg.)} \times 0{\cdot}0284.$$

‖ Williams. *J. Amer. Chem. Soc.*, 1936, **58**, 1063.

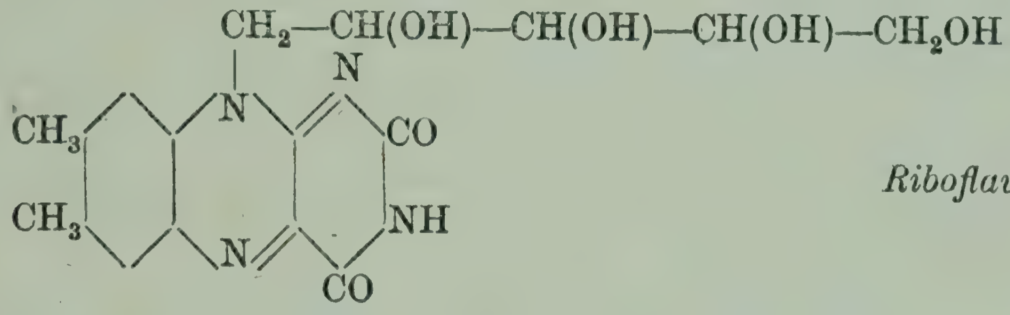
¶ Williams and Cline. *Ibid.*, p. 1504.

The minimum requirement of an adult on a diet of about 3,500 calories would be 550 units (about 1·7 mg.). Many modern diets supply only about 350. There is, however, considerable danger of vitamin B_1 deficiency in patients on restricted diets, or where individuals cut their own food intake down deliberately. The polyneuritis of chronic alcoholism is often traceable to shortage of vitamin B_1 consequent on reduced food intake. The beri-beri "danger-line" appears to be about 200 units (= 0·6 mg.) daily.

The optimal amount is about 500–1,000 units daily, according to the calorie intake. Children probably require about 400 units daily. The nutritional state of a subject regarding B_1 can be ascertained by estimation of the content of the vitamin in the urine before and after administration of a test dose.*

Thiamin provides an example of competition factors. If the sulphur in its molecule is replaced by a vinyl group, the substance pyrithiamine is obtained. When this is given to mice, symptoms of thiamin deficiency ensue; these are cured by increasing the thiamin to at least $\frac{1}{30}$th of the dose of pyrithiamine given.

Riboflavin (also known as lactoflavin). Its chemical name and structural formula are shown below :—



Riboflavin.

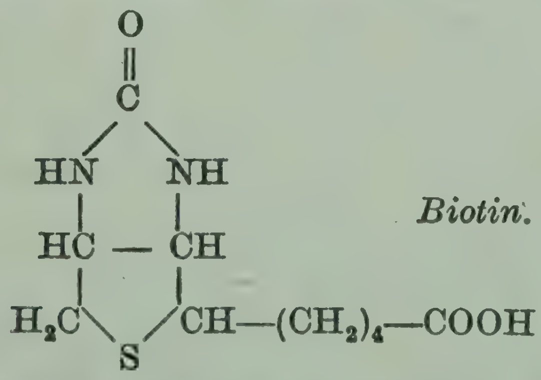
6.7. dimethyl-9-ribityl-isoalloxazin.

It is a yellow substance, present in milk whey, liver, kidney, heart, etc., which promotes growth, prevents cataract, keratitis and alopecia in rats, but does *not* prevent pellagra. Its deficiency in man causes lesions in the mouth (cheilosis) and tongue, vascularisation of the cornea, and neuritic symptoms. It is an important constituent of the "yellow respiration enzyme" of Warburg and occurs in the tissues in that form, viz., as a flavin-adenine-dinucleotide (*v.* p. 94), and hence plays an important part in oxidation processes. The daily requirement for man is 2–3 mg. It can be estimated by fluorescence, or by its absorption spectrum.

Symptoms of riboflavin deficiency can also be caused by administration of a phenazine analogue of riboflavin which acts as a competitor.

Pantothenic acid is a derivative of β-alanine and appears to be present in all living cells. It possibly plays a rôle in the intermediary metabolism of carbohydrates, and its absence from a diet leads to failure of growth and widespread and varied disturbances, including effects on the central nervous system.

Biotin (vitamin H) is a regular constituent of all normal human diets; it neutralises the effects resulting from a diet very rich in white of egg. Its formula is :—



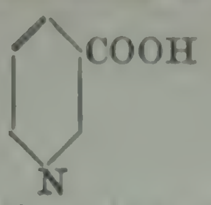
Biotin.

Lack of the vitamin has been experimentally produced in man, and results in a dermatitis of peculiar type. Egg white contains a substance ("avidin") capable of combining with biotin and thus depriving the body of it.

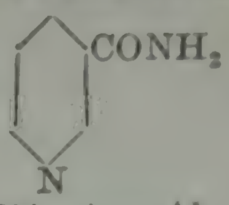
Nicotinamide (niacin or the P–P factor), is the vitamin which prevents pellagra, a disease characterised by dermatitis, diarrhœa and sometimes dementia, which is met with in peoples feeding mainly on maize. The disease called "black-tongue" in dogs is similar. The substance has been shown to be nicotinamide, and that substance is also formed in the body from nicotinic

---

* WANG and HARRIS. *B.M.J.*, Oct. 9th, 1943, p. 451.



Nicotinic Acid.



Nicotinamide.

acid, so that either will cure pellagra in man * or black-tongue in dogs.† It is widely distributed in most foodstuffs, particularly in meat, yeast, liver, fish, wheatmeal flour and beer, though maize contains but little. Average adults excrete 2–8 mg. daily in the urine, chiefly as the nicotinamide methochloride; if a dose, *e.g.* 100 mg., is given by mouth the excretion is raised promptly.‡

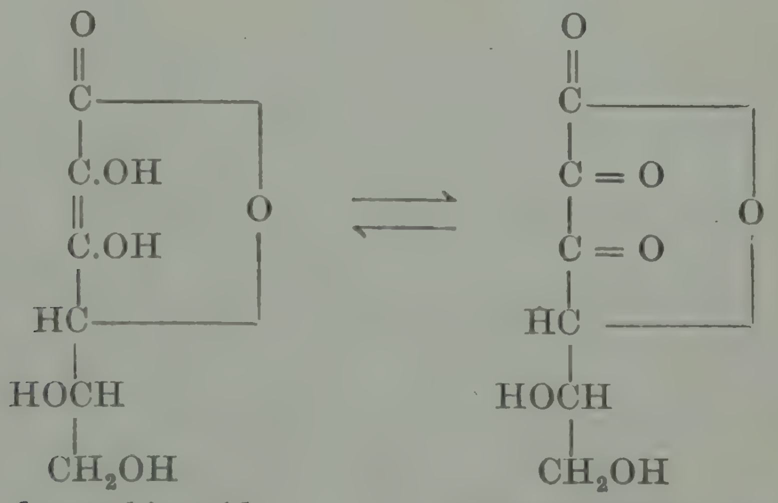
It is worthy of note that, once more we have a vitamin which functions as a co-enzyme. In this instance, nicotinic acid is part of the co-dehydrogenase complex and therefore probably plays a part in oxidative mechanisms (pp. 93, 98). Daily minimal requirement is about 10 mg.: intake in excess of this improves efficiency of strenuous work.

The analogues 3-acetyl pyridine and pyridine-3-sulphonic acid can, by competition, antagonise niacin. Maize appears to contain a similar pyridine compound capable of competing with niacin, and this probably explains why a diet of maize so readily causes pellagra unless the dietary niacin is augmented.

Choline has the effect of producing a lipotropic action (*v.* Ch. XLVI).

Vitamin B_{12} the hæmopoietic factor (*v.* p. 520).

Vitamin C is the antiscorbutic vitamin. Scurvy has been long known: it occurs when men are cut off for a long time from fresh food, especially vegetables. Its main symptoms are weakness, anæmia, skin eruptions, small hæmorrhages under the skin, impaired healing of wounds or fractures, liability to infection, hæmorrhage from the gums and mucous membranes (p. 639), and a liability to peptic ulceration. In children the long bones cease to grow, and there is tenderness of the legs. Captain Cook in 1776 § showed that it could be prevented or cured in sailors by the administration of malt or fresh vegetables. Oranges and lemons are specially rich in vitamin C. We now know ‖ that vitamin C is *l-ascorbic acid*, a hexuronic acid readily oxidisable to dehydro-*l*-ascorbic acid:—



l-ascorbic acid. *Dehydro-l-ascorbic acid.*

In the tissues it exists mainly in the reduced form. It was isolated from oranges, and also from the suprarenal cortex by Szent-Györgyi.¶ It is now made synthetically. It is present in small quantities in fresh meat and eggs, absent from most grains, but is formed when these grains germinate. When fresh

(Courtesy of DR. E. W. FISH.)

vegetable food cannot be obtained, scurvy may be prevented by feeding with beans which have been allowed to germinate, or by giving the pure ascorbic acid. In an acid medium this vitamin will stand exposure to boiling point for some time, but it is destroyed by oxidation almost at once on heating in an alkaline medium.

Vitamin C probably plays some part in the oxidation-reduction processes of the cell, acting as a hydrogen transporter. Blood serum, except in deficiency, contains about 0·8 mg./100 ml. : deficiency is indicated if below 0·4 mg./100 ml.[*] Its main actions in the body are twofold ; it is essential to the functioning of formative cells, such as fibroblasts ; and it is necessary for proper formation of intercellular collagenous substance. Hence a lack of vitamin C leads in guinea-pigs to arrest of formation of enamel and cementum of the teeth, and it has been shown [†] that there is a breakdown in the formation of the collagenous part of the matrix. This is well seen in the persistently growing teeth of the guinea-pig if the animal is deprived of vitamin C for, say, twenty days. The normal dentine produced before the attack appears in strong contrast to the irregular linear deposit of calcium salts (Fig. 540 (A)) held together by distorted traces of organic matter which is thrown down during the attack. If the animal is restored to a normal diet for ten days before being killed, fresh odontoblasts are seen to have developed and to have provided the tooth with a new normal growing end. At the same time a belated mass of calcified collagenous matrix is deposited amongst the old degenerated odontoblasts (Fig. 540 (B)).

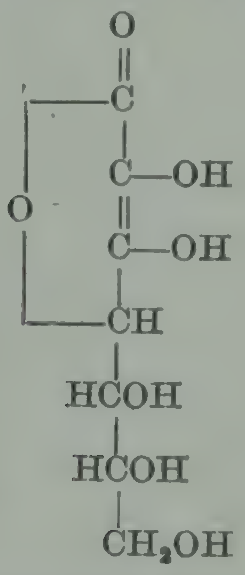
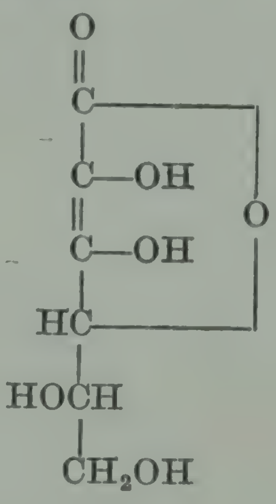
Growing scorbutic animals also show impaired bone formation, both as regards matrix and calcification; and the phosphatase content in costochondral junctions is reduced. It has been suggested that ascorbic acid is essential for the formation of the phosphatase-impregnated matrix in which calcification can occur.*

For experimental work on vitamin C, it is usual to employ guinea-pigs. The international unit is 0·05 mg. pure *l*-ascorbic acid, of which lemon juice contains about 10 units per ml. A young guinea-pig requires about 0·7 mg. per day to prevent scurvy.† The fœtus receives its store of ascorbic acid from the mother. Children and adults require a maximum of about 1,000 units (50 mg.) of ascorbic acid daily (minimum 25 mg.). It is best supplied by fruits, *e.g.* lemons, oranges and black currants, or vegetables. The amount of vitamin C in materials can be determined chemically by titration with "redox" dye (2 : 6 dichlorophenolindophenol).‡ By this means it can be shown that normally most of the ingested ascorbic acid is excreted in the urine, the daily amount being 1 to 2 mg. in children and up to 30 mg. in adults. Scorbutic children excrete very much less than normal amounts (less than 15 mg. daily in adults indicates deficiency). If a large dose (100 mg.) of vitamin C be given to a normally nourished individual it is rapidly excreted, whereas when given to scorbutics the output is scarcely altered, showing that the substance is not excreted until a certain level of saturation has been reached.§ The vitamin may also be estimated by a ferricyanide reduction method,‖ and spectrometrically.

The analogous compound glucoascorbic acid, when given in the diet competes with ascorbic acid, and causes scurvy, even in mice, which do not normally need ascorbic acid: the condition can be cured by suitable doses of ascorbic acid.



Glucoascorbic acid.



Ascorbic acid.

Folic acid is a name given to a group of conjugated derivatives of pteroylglutamic acid; the latter substance, now synthetically made, is also sometimes called folic acid. Pteroylglutamic acid or its derivatives are widely dispersed in animal and plant cells, and can exert curative effects in pernicious anæmia (p. 520) though the nature of these effects is not clear.

Vitamin P is found together with ascorbic acid, is heat stable, and its lack is largely responsible for the capillary hæmorrhages which occur in scurvy. It is also called citrin.

"*Citrin*," found in the rind and juice of citrous fruits, is a mixture of two flavone pigments, viz. a rhamnose-glucose glycoside of hesperidin, and a glycoside of eriodictyol. The human requirement is stated to be 50 mg. daily.

Vitamin Content of Foodstuffs. The vitamin content of some common foodstuffs is shown in the Table on p. 829.

CHAPTER XLIII

THE NORMAL DIET OF MAN

Examination of the actual requirements of the normal human individual involves a consideration not only of the total energy requirements of man according to age, size, sex and occupation, but also of the proper distribution of the foodstuffs in the diet.

We have seen that the energy requirements are a function of the body surface. The average height and weight of English adults is 171 cm. and 70·3 kilos., corresponding to a surface of 1·8 square metres (Fig. 527, p. 794). At 40 Calories per square metre per hour the average man will thus have an hourly basal metabolism of about 72 Calories. When he is taking food this amount must be increased by about 10 per cent., and if he is up and about a further increase in metabolism will be evoked by the muscular movements, exposure to cold, etc. If we divide the twenty-four hours into three portions—eight hours' sleep, sixteen hours awake—(eight hours' work)—we must allow the basal metabolism for the eight hours' sleep, basal metabolism increased by about 30 per cent. for the eight hours during which the man is up and about and taking meals, and the basal metabolism plus an additional amount for work during the eight working hours. It is by no means easy to decide what figure should be accepted as representing the average work of an adult man. It is usual to take this as involving an energy output of 1,000 Calories. Of these Calories 20 per cent., or even more, may under favourable conditions be transmuted into mechanical work, so that 1,000 Calories should be sufficient to provide for the performance of about 100,000 kilogrammetres of external work. With these assumptions we may suggest the following energy requirements for an average adult working man :

8 hours' sleep at 71 (Basal Metabolism)	568	Calories.
8 hours awake at 92 (Basal Metabolism plus 30 per cent.)	736	,,
8 hours' work (Basal Metabolism plus 1,000 Calories)	1,568	,,
Total	2,872	,,

Some additional expenditure of energy will be involved in travelling, so that we are justified in accepting the figure usually given for the daily energy output of an average working man as 3,000 Calories. For purposes of computation, about 400 Calories are usually added to allow for loss in preparation and in digestion, so that for the average man about 3,400 Calories must be purchased.

A man in sedentary employment—*e.g.* typewriting, clerking, etc.—may not expend more than 200 to 400 Calories in the performance of external work ; mental exertion causes no appreciable rise in the metabolic exchanges. On the other hand, a heavy worker, such as a navvy, may easily expend 2,000 or more Calories a day in the performance of external work.

The energy requirements of women will show corresponding variation according to occupation, but will be in general less in consequence of their smaller size and surface. Du Bois has shown that women have a lower basal metabolism per square metre of surface, viz. 37 Calories per hour as against 40 in the case of men. The average height and weight of Englishwomen are 159·3 cm. and 55·7 kilos., corresponding to a surface of 1·511 square metres and to an hourly output of 56 Calories. In estimating the total energy requirements of an average woman, we may reckon her work as two-thirds that of a man, *i.e.* as 600 Calories per day. We then arrive at the following Table for the energy requirements of the average woman :

8 hours' sleep at 56	448	Calories.
8 hours awake at 73 (Basal Metabolism plus 30 per cent.)	584	,,
8 hours' work (Basal Metabolism plus 660 Cals.)	1,108	,,
Total	2,140	,,

We shall not be far wrong, then, in accepting the usual estimate of a woman's net requirements as four-fifths of those of a man, viz. 2,400 Calories, or the gross value as purchased as 2,800 Calories.

In children a computation of the energy requirements is rendered more difficult by two factors. In the first place the metabolism is more energetic than in the adult, even if we take into account the relative surfaces in the two cases. Thus the basal metabolism per square metre in boys of varying ages was found by Du Bois to be as follows :

Mean age.	Basal metabolism, Cals. per square metre per hour.
6·5	57·5
12·6	50·4
13·7	49·4
16·5	43
19·25	40·7

In addition to this increased basal metabolism, if the processes of growth are to occur normally, there must be an excess of matter taken in over that excreted, since the growing child is always putting on weight. Between the ages of eleven and sixteen both sexes put on weight at about 4 kilos. a year, which is equivalent to adding to the body a store of about 800 Calories per month. The second difficulty is due to the fact that children are in a constant state of muscular activity, which is of great value in procuring healthy nervous and muscular development. The degree of this activity seems related to the amount of food taken—the increased energy of a child directly after a meal is a familiar phenomenon. If food is withheld or diminished this activity declines, but in this way energy is saved and the whole of the lessened food may go to maintain the temperature of the body and the normal processes of growth.

We may thus obtain a development of the child not differing appreciably from the normal on widely varying amounts of food, and it becomes difficult to say what is the average or the optimum amount that a child should have.

The table below shows the requirements of the different sexes and ages in terms of the "average man" taken as 1.

MAN-VALUES AT AGES (CATHCART AND MURRAY) (B.M.A. Report, 1933)

Ages.	Man-value.	Calories.
Adult male	1·00	3400
,, female	0·83	2840
Child 1 and under 2 years	0·30	1020
,, 2 ,, 3 ,,	0·40	1360
,, 3 ,, 6 ,,	0·50	1700
,, 6 ,, 8 ,,	0·60	2040
,, 8 ,, 10 ,,	0·70	2380
,, 10 ,, 12 ,,	0·80	2720
,, 12 ,, 14 ,,	0·90	3000
Old person (65 +)	0·75	2550

The figures in the last column represent the Calories as purchased for the average individual, and are therefore equivalent to the food which must be digested and absorbed plus any loss. No food undergoes complete digestion, the average loss being about 10 per cent. with an ordinary mixed diet, as is shown in the following Table :

Percentage of Foodstuffs Absorbed.

	Protein.	Fat.	Carbohydrate.	Ash.	Total Energy.
Average of 5 experiments	92·6	94	97·7	77·4	90·5

A further allowance must be made for unavoidable waste in cooking, etc.

Three thousand net Calories (*i.e. energy* requirements) require therefore the purchase of food with a Calorie value of 3,400.

If the food consists mainly of vegetable products it may be necessary to increase still further the allowance for loss in digestion, not more than 80 per cent. of the protein being absorbed as a rule.

These values are for average well-nourished individuals. It has already been pointed out that in a state of semi-starvation, accompanied by loss of weight, the basal requirements may be reduced considerably. As a result of a number of experiments Chittenden * came to the conclusion that there was a definite advantage to be gained by reducing not only the protein intake of the body but also the total food. But the experience of Germany during the last three years of the 1914 war showed that a forced limitation of food to about two-thirds of what we have put down as normal, resulted finally in a decrease of efficiency of mind and body and in a marked diminution in the resistance to infection, especially to tuberculosis.

Distribution of Foodstuffs in a Normal Diet. Before 1939 there was fairly general agreement that the average diet of an adult man should be somewhat as follows :—

Daily Requirements of an Adult Male of Calories, Protein, Fat, and Carbohydrates (B.M.A. Report, 1933)

Total Calories required : 3400 in food as purchased

Derived from—	Quantity. g.	Percentage of total Calories.	Number of Calories.
First-class protein .	50	6	205
Second-class protein .	50	6	205
Fat	100	27	930
Carbohydrate . .	500	61	2050
Totals . . .	700	100	3390

Since the war nutritional requirements have been more parsimoniously scrutinised, and revised in the light of experience, or the twilight of necessity. A more recent recommendation is that by the Food and Nutrition Board, National Research Council, U.S.A., which was adopted as a goal in 1945.

Quoted from the Recommendations of the Food and Nutrition Board, N.R.C., U.S.A.

	Calories.	Protein. g.	Ca. g.	Fe. mg.	Vit. A. int. Units.	Vit. B$_1$. mg.	Ribo-flavin. mg.	Niacine. mg.	Ascorbic Acid. mg.	Vit. D. int. Units.
Man (70 kg.),										
Sedentary .	2500	70	0·8	12	5000	1·2	1·6	12	75	
Very active .	4500					2·0	2·6	20	—	
Woman (56 kg.),										
Sedentary .	2100	60	0·8	12	5000	1·1	1·5	11	70	
Pregnant (latter half) . .	2500	85	1·5	15	6000	1·8	2·5	18	100	400–800
Nursing . .	3000	100	2·0	15	8000	2·0	3·0	20	150	400–800
Children, 1–3 .	1200	40	1·0	7	2000	0·6	0·9	6	35	400

Wide variations are possible in the relative proportions of the foodstuffs without injury to health. It is important, however, to consider the limits within which these variations are permissible.

Proteins. From 10 to 15 per cent. of the total Calorie requirements should consist of protein, *i.e.* an average mixed diet with a Calorie value of 3,400 will contain about 10 grammes of protein. Where animal protein is entirely absent from the food, a larg amount of vegetable proteins will be necessary, since they are of lower " biological value " and it is safe to lay down as a rule that for an average man the protein ration should not b diminished below 1 g./kg., or 70 g. per day. This should include different kinds of protei and at least half of it should be first-class, or animal protein. For infants of 1–3 years a much as 4 g./kg. may be needed : this requirement is lessened with advancing age, and a

---

* Chittenden. " Physiological Economy in Nutrition." 1904 (Stokes) ; " Th Nutrition of Man," 1907.

17–18 years, is about 2 g./kg. In recent wars and famines large populations have had to submit to lowered protein intake, *e.g.* in the siege of Madrid, total protein 66g. (animal 4·8 g.); in Great Britain in 1944 total protein 70 g. (animal 33 g.) daily, with no evident ill-effects.

Butcher's meat contains from 15 to 20 per cent. protein, and from 15 to 30 per cent. fat. Owing to the high specific dynamic action of protein, a protein meal raises the production of heat in the body, which is a distinct disadvantage when work has to be accomplished at a high external temperature. On the other hand, a diet in which there is a large proportion of meat is of value to men in sedentary occupations in a cold or temperate climate. The idea that the heavy worker requires a large supply of meat is of doubtful foundation, though in occupations involving exposure to cold and wet it will add to the comfort of the individual by keeping him warm.

Meat is not only easily presented in a palatable form, but its flavour renders other kinds of foods acceptable. It is thus habit rather than strict physiological principles which will probably govern the quantity of meat regarded as desirable.

Carbohydrates are as a rule the most abundant and cheapest constituents of any diet, and form the greater part of most diets. A certain amount of carbohydrate is essential for man. In the absence of carbohydrate in the food there is a deficient oxidation of the fats, giving rise to acid intoxication.

Fats can be produced by the animal body from carbohydrate, and part of either the fat or the carbohydrate of a normal diet is mutually interchangeable for an isodynamic amount of the other. Although some men can remain healthy on almost fat-free diets provided vitamins are available, some fat is essential, and quantities greater than the minimum amount are desirable. In practice we have to provide for each race a minimum desirable quantity of fat, which will differ in different races and be larger in northern than in southern races. Thus the Japanese soldier is content with 20 grammes of fat daily, while in our country the average man would not be content with less than 75 grammes of fat per day. Seventy-five grammes of fat has a Calorie value of about 25 per cent. of the daily requirements, and we may conclude as a general rule that one-fourth of the total energy of the diet should be supplied in the form of fat.

In recent times of deprivation due to war, the shortage of fats ("guns before butter") was the most hard to bear. There are probably three reasons for this craving for fat. In the first place, whereas the greater part of the carbohydrate is absorbed within three hours after food has been eaten, the chief absorption of fat occurs between five and six hours after a meal. On this account individuals deprived of fat get hungry some time before the next meal. The lumbermen of Canada satisfy their huge needs in Calories—6,000 to 8,000 a day—by a diet in which the fat represents 35 to 40 per cent. of the Calories.

In the second place, weight for weight, fat has more than double the Calorie value of carbohydrate. But the difference in bulk is still greater, since most other foods contain a considerable proportion of water.

In the third place, carbohydrates are more subject to fermentative changes in the intestines than fats. We may conclude then that although man can for a time dispense with fat, yet, to develop his full efficiency as a working machine, fat is an essential ingredient of his diet.

We thus see that a dietary to maintain a sedentary man in health must fulfil the following requirements:

(1) It must be palatable. Appetite is an essential factor for the digestion and assimilation of the food, so that good cooking and appropriate flavouring becomes an important condition for the maintenance of health.

(2) It must have a sufficient Calorie value (3,400 for the average man).

(3) It must contain protein, fats and carbohydrates. The quantity of each of the first two should be not less than 70 and preferably not less than 100 grammes a day. Of the protein, there should be at least 50 grammes of first-class (*i.e.* animal) protein daily.

(4) It should include a certain proportion of fresh foods, such as green vegetables, meat and eggs, and, in the case of children, milk, in order to supply the necessary vitamins.

(5) It must contain a proper proportion of the salts, especially sodium, calcium, potassium, chlorides and phosphates.

Actual Diets. Statistical inquiries into the food consumption of controlled groups of individuals, *e.g.* soldiers, prisoners, school children,* families, or even of whole nations have given results which lend further support to those obtained from laboratory observations. Thus the population of the United Kingdom in 1911 was about 45¼ million persons: its man-value, as calculated from the age-distribution, had an average of 0·835, so that the total man-value was about

---

* FRIEND. "The Schoolboy" (Heffer, Cambridge), 1935.

37¾ million. The Calorie value of all the food grown or imported during 1911 was about 47 billion Calories, which works out at about 1¾ million Calories per man-value per annum or roughly 3,400 Calories per day.

As an indication of the great improvement in standards in modern times as contrasted with that two centuries ago, the investigations of Friend, Chief Medical Officer of Christ's Hospital School, may be quoted. The requirements of boys of school age are about 2,800 Calories. The diets in the years 1704 and 1929 are given below :

Diet of Schoolboys at Christ's Hospital

(After G. E. Friend)

	In 1704	In 1929
Protein	39 grammes	93 grammes
Carbohydrate	188 ,,	394 ,,
Fat	26 ,,	100 ,,
Calories as beer	730	*Nil*
Total Calories	1,900	2,930

The study of the dietaries of families of different incomes * yielded similar results and showed in particular that there was a great dietary disparity, both qualitative and quantitative, between the different classes of the community. It has been claimed that before World War I, up to 30 per cent. of the population, owing to a combination of poverty and ignorance were undernourished, and a still larger proportion suffered from qualitative defects of diet. The following Table from Rowntree has often been quoted to illustrate the relative Calorie deficiency in the poorest classes as compared with the contemporary standards of diet.

Dietaries of Various Classes in 1900

(After Rowntree †)

		Protein.	Calories, daily
In York	I. Wages below 26*s.* weekly	70	2,574
	II. Wages over 26*s.* weekly	96	3,390
	III. Servant-keeping classes	105	3,807
Agricultural Labourers, Midlands		74	2,868
Able-bodied paupers, York Workhouse		156	3,702
Convicts, hard labour		177	4,159

Since that war more thought has been taken to ensure that the poorest classes do not fall below the border-line of minimum requirements, though it cannot be doubted that prior to the late war there were still many who, for various reasons, failed to get proper nourishment. The position in 1949 is that the disparity between such classes as can still be distinguished has practically vanished ; the uniform diet is apparently now at about the level of Rowntree's poorest class : this is now thought to be adequate.

Rationing of food began in Great Britain in January, 1940 (butter, bacon, sugar) ; then followed meat (March, 1940), the National Milk Scheme in July, 1940, eggs in June, 1941, the points system in December, 1941. During the 1939 war the policy in this country ‡ was, roughly, to have ample supply of carbohydrate (potatoes, bread) which ensures adequate calories, and to distribute the sources of fat, and of protein food, such as meat and cheese, more equally. Protein supplies were also augmented by Lend-Lease : in 1940 it was down to 80 g. (36 g. animal) daily. Control of milk, with additional supplies to pregnant and nursing mothers, and to infants ; supply of vitamins A and D to pregnant women and to infants ; rationing of butter, with fortification of margarine by the addition of 450 I.U. of vitamin A and 30 I.U. of vitamin D per oz., and increased consumption of carrots (for A), have ensured adequate vitamins A and D. Increased use of green vegetables, and, for children, black-currant syrup, supplied adequate vitamin C. The total fat, visible and invisible, was about 131g./day per head before the war: by the middle of 1941 it had fallen to 104 g., but by the end of 1943 recovered to 111 g.* The calorie deficiency was made up on carbohydrates (*e.g.* bread and potatoes) which were then unrationed.

‡ Pyke. *Brit. Med. Bull.*, 1944, **2**, 228.

The bread question is interesting. Before the war, wheat flour was 72 per cent. extraction, *i.e.* only 72 per cent. of the grain was used in flour. The wheat germ, etc., which was rejected, contained more than half the vitamin B_1 of the grain. At the end of 1941 it was decided to extract to 85 per cent., and the resulting National wheatmeal contained 1·3 mg. of B_1 per lb., as compared with 0·5 mg. in white flour. The germ included in the new flour also contained as much iron as the rest of the grain, but it also contained most of the phytic acid, in consequence of which the absorption of calcium was reduced.† As calcium was one of the most general deficiencies of our pre-war diet, this was a serious drawback. It was rectified by adding about 0·15 per cent. of calcium carbonate to the new flour, so adding about 180 mg. to the daily Ca intake.

After the end of the war the situation in Europe generally worsened. Bread rationing was begun in Great Britain on July 21st, 1946, and this greatly reduced the flexibility of the national diet; the subsequent rationing of potatoes in November, 1947, narrowed the safety margin still further, since, under the rationing system about half the total calorie supply was made up by bread, flour and potatoes. The following table shows the position in November, 1946, and includes bread, but not potatoes, in the ration; it should be compared with the U.S. goal, p. 834.

NUTRIENTS PROVIDED DAILY BY RATIONS, PRIORITY ALLOWANCES AND EXPECTED DISTRIBUTIONS OF MILK AND FRESH EGGS (NOV., 1946) IN GREAT BRITAIN ‡

	Calories.	Protein. g.	Ca. g.	Fe. mg.	Vitamin A. I.U.	B_1 mg.	Ascorbic acid. mg.
Normal male adult . .	1842	56	0·6	11	1398	0·77	3
Woman, pregnant . .	2440	85	1·5	13	5892	1·1	49
Woman, nursing . .	2085	69	1·1	11	1684	0·92	8
Children, 2–3 . . .	1745	57	1·1	8	5822	0·74	33

It will be seen that there is, except in the case of young children, a considerable gap in calories, while there is shortage of protein for adult males and nursing mothers; potatoes would normally help to fill this gap, which would otherwise only be filled by restaurant meals.

In these days of widespread semi-education it should be possible to instruct the masses in the matter of economical purchasing and correct cooking of proper food. As an example of pre-war diets which combine cheapness with proper nutritive value we may quote again from the B.M.A. Report. The first is the simplest type of diet for a man, and purchased in the most economical way would cost (in 1933) about 5*s*. per week. It provides no variety however.

To take another example, suppose a family consisting of man, wife, and child aged four. Its man-value, as deduced from the Table on p. 834, would be $1{\cdot}0 + 0{\cdot}83 + 0{\cdot}50 = 2{\cdot}33$, and an example of constituents for a diet costing (in 1933) about 14s. per week for the family is given on p. 838.

The conversion of these raw materials into adequate meals is a matter of cookery, but teachers of domestic science have translated these findings into actual cookery recipes enabling a family, *e.g.* of man-value about four, to obtain wholesome and palatable diet at a cost of about 23s. per week (in 1933).§

During World War II, the Food Ministry in Great Britain gave, to those who heeded it, much useful information regarding diet [*]; though it is probable that this advice was least heeded where it was most needed. There is, however, no indication that the health of the population of Great Britain has suffered under rationing; vitamins A and C are the most likely ones to be lacking, but experimental supplementing with these and other vitamins showed no significant effects on the average, though in individual cases there were indications of some slight deficiency. A diet survey of 849 families in 1941 in eight localities in England and Scotland showed, however, that in groups where food expenditure was less than 9*s.* per head weekly, the calorie intake was inadequate.[†]

Alcohol. When alcohol is taken by man in moderate quantities, up to 10 c.c. per hour, the greater part of it undergoes oxidation, mainly in the liver,[‡] *viâ* acetic acid, to carbon dioxide and water. About 2 per cent. of it, which escapes oxidation, is excreted unaltered by the lungs and kidney. This oxidation of alcohol is a result of true utilisation and alcohol can, in this way, act as a food and supply up to 40 per cent. of the daily calories, provided it is taken in small doses, often repeated, so as not to result in there being a high alcohol content in the blood.[§]

The chief effects of alcohol are on the nervous system. The latent period of responses is increased and the intensity of conditioned reflexes is reduced, while the normal balance between excitatory and inhibitory states is upset.[‖][¶] Hunger contractions are inhibited, and alcohol in moderate doses either does not alter, or else retards, the rate of emptying of the stomach.[**] Gastric secretion is stimulated by moderate doses, probably by release of histamine: concentrations over 10–15 per cent. increase the mucus secretion, and if frequently taken cause acute gastritis. Its value in a diet is chiefly that of an accessory or adjuvant, in exciting appetite by its taste and smell. When taken in large doses, this function is overshadowed by the poisonous action of the substance. The

effect of any given dose depends on its rate of absorption, which is dependent on the rate of emptying of the stomach, for, although alcohol is absorbed slowly there, absorption is much more rapid in the small intestine. Since the natural rate of absorption, and also the natural tolerance to its action, varies so widely from one subject to another (Fig. 541) no definite degree of intoxication can be attributed to any particular concentration in the blood. The more rapid the increase the greater its effect on the nervous system,* and with rapid absorption some degree of intoxication can be observed at a concentration well below 0·1 per cent., though it is generally stated that 0·15 per cent. usually causes mild intoxication and 0·25 per cent. definite drunkenness. There is no clear evidence of increased tolerance by habituation in man, but such an effect has been shown in dogs.† The taking of food, and particularly of fat, delays the absorption of alcohol (Fig. 542), so that alcohol taken on an empty stomach will produce the speediest and greatest effects.

The rate at which alcohol is removed from the body is more closely related to the size of the liver than to body weight or surface and is affected to some extent by the concentration in the blood ‡ (Fig. 543). It varies also with the general metabolic rate, for it disappears more rapidly after the taking of food, particularly of protein. There is no good evidence that its rate of oxidation is increased by habituation.

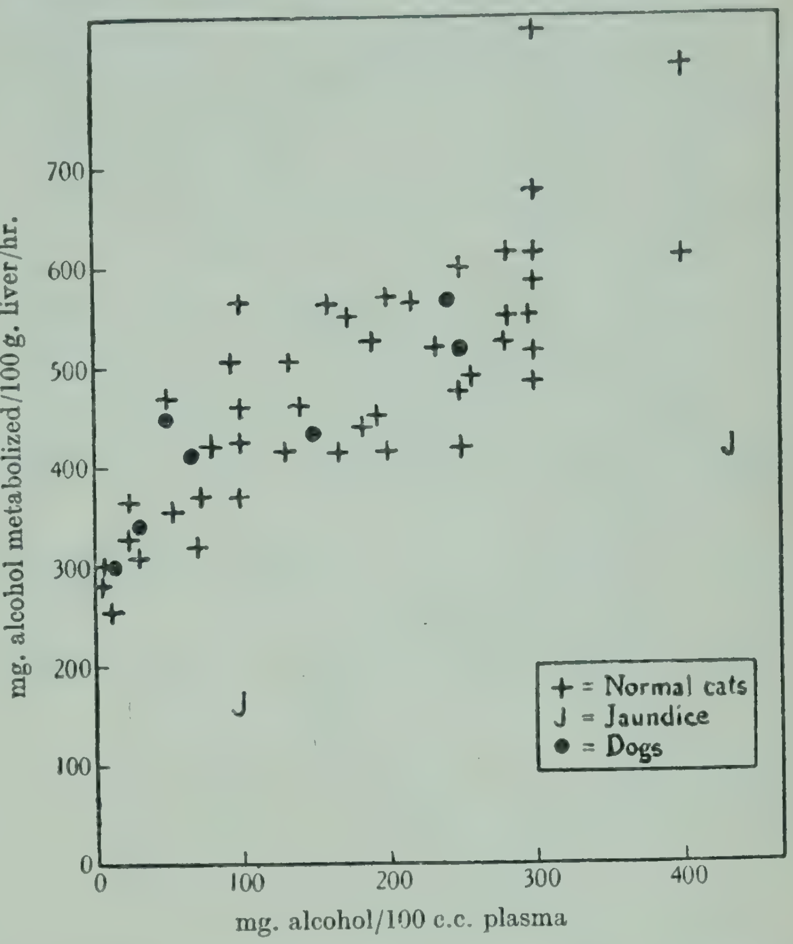

FIG. 543. Relationship between metabolic rate of alcohol per unit liver weight and plasma alcohol concentration. (EGGLETON. *J. Physiol.*, 1940, **98**, 239.)

The removal of alcohol from the blood by excretion and oxidation takes place, according to Mellanby, at a constant rate of about 0·01—0·02 p.c. per hour, so that it takes ten hours to get entirely free from alcohol after it has reached a concentration of 0·12 per cent. in the blood. Alcohol is excreted in the breath and in the urine, the concentration of alcohol in both depending on its concentration in the blood. Alcohol causes a diuresis while the blood alcohol is mounting, and hence a greater one when absorption is slow, because the rise lasts longer : the alcohol in the urine is in equilibrium with that of the plasma water,§ but because the plasma water is lowered by the protein, the concentration in the urine is 1·35 × that in the blood. It is clear from what has been said that the concentration of alcohol in the bladder urine collecting over a long period will bear no close relation to its concentration in the blood at the time of voiding, but a concentration over 0·35 per cent. is likely to correspond to a definite state of drunkenness.

CHAPTER XLIV

THE PHYSIOLOGY OF DIGESTION

CHANGES UNDERGONE BY THE FOODSTUFFS IN THE ALIMENTARY CANAL

In most cases the foodstuffs as we ingest them are colloidal, neutral, and insoluble and have to be rendered soluble and diffusible, in order to allow of their easy transference into the blood. It is necessary that all the carbohydrates shall be altered to the form of monosaccharides. As regards proteins, the change must be even more profound. To form serum albumin, for instance, out of wheat gliadin, an entire reconstruction is necessary. This can only be accomplished by taking the protein molecule to bits, selecting certain of its constituent parts and building these up in the proper proportions to make a new protein molecule. This process of resynthesis must be carried out in the tissue cells themselves.

In all the higher animals the solubilisation of the food is accomplished in the lumen of the alimentary canal by means of *digestive juices,* formed by the activity of glands produced as outgrowths from the wall of the canal. The digestive juices attack the foodstuffs by means of enzymes, and the action of these is hydrolytic. Since each class of foodstuff requires different enzymes, a great variety of these is concerned in the process of digestion.

As the end result of digestion the many kinds of food are reduced to a fairly small number of simple substances. These end-products are :

(1) *Carbohydrates.* The monosaccharides : glucose, fructose, and galactose.
(2) *Fats.* Fatty acids and glycerol ; also finely emulsified fat.
(3) *Proteins.* A great variety of mono- and diamino-acids.

Those constituents of the food, such as the water and salts, which undergo no metabolic alteration in the body, pass along the alimentary canal practically unchanged ; if absorbed they pass without further alteration into the blood.

1. DIGESTION IN THE MOUTH

It is common experience that, when food is taken, there is a flow of " saliva " into the mouth. Saliva is the product of secretion from three pairs of large salivary glands situated in the neighbourhood of the mouth and pouring their secretions into it by means of ducts. It is possible to collect the fluid secreted by each of these glands separately ; and it is found that the saliva varies in properties according to the gland from which it is derived. In addition to these large glands the whole mucous membrane of the mouth is beset with small glands, the buccal glands.

The saliva is in most cases a mixture of the secretions of all these glands. It forms a colourless cloudy liquid, slimy in character. The cloudiness is due to the presence of a number of desquamated epithelial cells, lymphocytes, and clumps of mucin. Its reaction as secreted is neutral, or very nearly so (pH 6·4–7·0), and it is well buffered. On standing or heating it loses CO_2 and becomes alkaline and turbid from deposition of calcium salts, which may be deposited as " tartar " on the teeth.* Its specific gravity varies between 1002 and 1008 and freezing point—0·07 to —0·34° C. Its chief constituents are mucin, and in some cases a diastatic enzyme, ptyalin, and traces of coagulable proteins, potassium thiocyanate, urea, etc. Its approximate composition in man is as follows :

---

* Phillips. *Ztschr. f. physiol. Chem.,* 1935, **233,** 208.

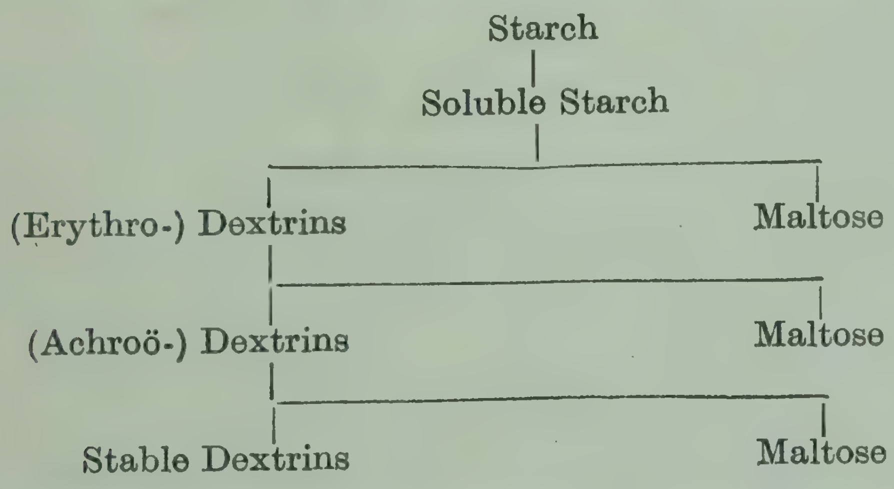
Water	99·27	Na	0·02
Solids	0·73	K	0·06
Organic Solids	0·50	Ca	0·01
Mucin	0·30	CNS	0·03
Inorganic Solids	0·23	HCO_3	0·10
Cl	0·05	Total N.	0·07
P	0·02		

Gases are about 1 c.c. O_2, 2·5 c.c. N_2 and 50 c.c. CO_2 per 100 c.c.

Thiocyanate is formed in the body whenever cyanides or organic nitriles make their appearance, either as the result of administration or as by-products in the normal processes of metabolism. The conversion of the poisonous cyanides into the almost innocuous thiocyanates seems to be a means by which the organism protects itself against the poisonous effects of the former. Saliva of smokers contains more thiocyanate than that of non-smokers, because traces of HCN are absorbed from the smoke. The channels of excretion of the thiocyanate are by the saliva, the urine, and the gastric juice.

The Uses of Saliva. The main function of saliva is to moisten the food and so facilitate its mastication and deglutition. The presence of the mucin is of special value for the latter process, since it renders the mass of food slippery. In animals such as dogs, where the saliva is devoid of any digestive enzyme, this must represent its sole function.

In man and some of the herbivora the saliva contains an enzyme, called *salivary amylase*, or *ptyalin*, which exerts a digestive effect on starch. The stages in the action of saliva on boiled starch can be followed when a very small amount of saliva is added to some starch solution at 37°, and portions of the digest are tested at intervals. The first change is a conversion of the opalescent gelatinising starch solution into a clear solution which no longer sets on cooling, but still gives a blue colour with iodine. This is known as soluble starch. The soluble starch then undergoes hydrolytic dissociation into a dextrin, which gives a red colour with the iodine and is therefore known as erythrodextrin, together with maltose. The erythrodextrin is then hydrolysed into an achroödextrin (giving no colour with iodine) and maltose, and the achroödextrin is still further broken up into stable dextrin and maltose. The conversion of starch into maltose by ptyalin is practically finished when 80 per cent. of the starch has been so converted, the remaining 20 per cent., called stable dextrin, being resistant.* The stages in the conversion are represented in the following Table :



The process by which the huge starch molecule is converted into dextrins and maltose is a very complicated one, and a number of intermediate compounds of dextrins and maltose may exist between those whose presence is revealed by their varying reaction to iodine. On very prolonged action of saliva, some of the maltose formed is further hydrolysed to glucose, but this action is too slow to be of any importance in the body.

Ptyalin is most active at a *p*H of about 6·0, so that the addition of minute traces of acid to an alkaline saliva increases its activity. Further acidification, however, rapidly destroys it. Removal of salts by dialysis renders it almost or quite inactive, the activity returning when the salts are restored. Addition of small amounts of chlorides greatly accelerates the action of saliva. It acts most rapidly at 45°, but even at 0° C. its action is still just perceptible. If heated to 60° C. the amylase is destroyed.

---

* Lovatt Evans. *Journ. Physiol.*, 1912, **44**, 191.

When the starch is in the solid condition, as in biscuits and most farinaceous foods, its stay in the mouth during the normal process of mastication is not long enough to allow any considerable hydrolysis to occur. When a meal is taken, the food is swallowed and forms a mass which is penetrated only slowly by the acid gastric juice secreted by the stomach within five minutes of the taking of food. Even half an hour after a meal the interior of the mass of food in the stomach may be still found to be neutral or slightly alkaline. The food, therefore, thoroughly mixed with saliva, remains in the stomach for thirty to forty minutes, gradually reaching its optimum *p*H—and with chloride accumulating and also accelerating its action—before the amylase is destroyed by the acid gastric juice. During this time the amylase continues to act, so that the chief part of the salivary digestion occurs actually in the stomach, and results in extensive conversion of the starch into dextrins and maltose.*

The Secretion of Saliva. The greater part of the saliva is formed in man by the sublingual and the submaxillary (sub-mandibular) glands.

The arrangement of these glands, especially of those in the floor of the mouth, varies somewhat in different animals. They can be divided into three classes. Among the small buccal glands we may distinguish two types, the *mucous gland* and the *serous gland* (Fig. 544). The mucous gland is distinguished by the fact that its short duct opens into wide alveoli, the lining cells of which are distended with mucin and therefore present a clear unstained space in the section. In the serous gland, the duct lined with columnar cells branches into a series of acini, which present a well-marked lumen and are lined with small granular cells with a very distinct and well-staining nucleus. The same general distinction can be made out in the large salivary glands. The parotid gland in man and in all the higher mammalia is a typical serous gland, though here and there a mucous cell may be seen. The sublingual and submaxillary glands in man represent a third type called *mixed* glands. Most of the alveoli are mucous in character. At the ends of the alveoli are seen crescent-shaped serous cells between the mucin-distended cells and the basement membrane. These are known as the *demilune cells*, or the *Crescent cells* of Gianuzzi. In some cases these mucous alveoli with demilunes may be found alongside of typical serous alveoli.

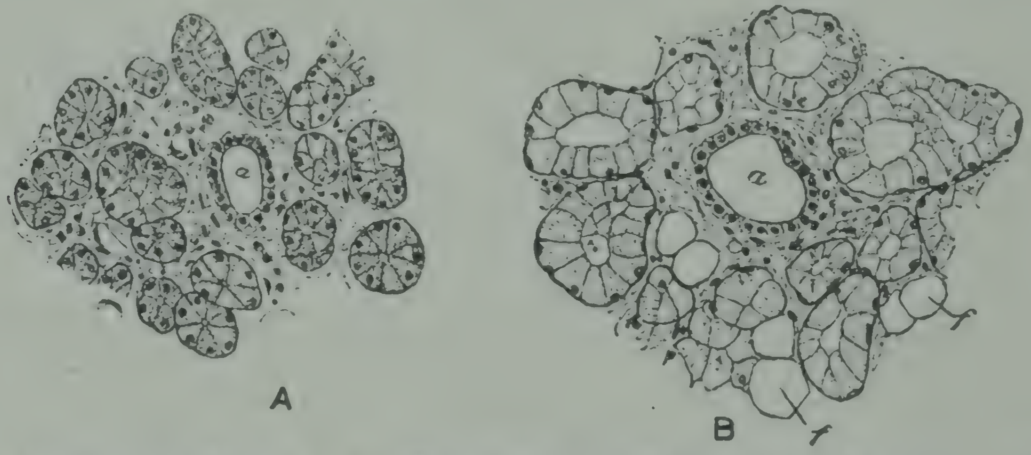


FIG. 544. A. Serous Gland. B. Pure Mucous Gland from Mouth. (KÖLLIKER.)
a. Ducts. *f*. Fat cells.

The secretion of the separate glands in man can be studied by passing a fine catheter into the appropriate duct, and also in certain rare cases where fistulæ occur in the parotid duct. The normal behaviour of the salivary glands is best studied by the aid of fistulæ. It is possible to transplant the papilla, on which the duct opens, to the outside, so that the saliva from any particular gland shall flow externally instead of into the cavity of the mouth. By attaching a small funnel to the fistulous opening, it is easy to collect the pure saliva. These fistulated glands retain their normal structure and functions for many months, though the gland finally becomes fibrotic.

In man the glands are continually secreting slowly † ; in carnivora there is normally no secretion when no stimulus such as food is present ; as soon as food is introduced into the mouth there is a rapid secretion of saliva, the relative extent to which different glands are involved varying according to the nature of the stimulation. Thus with meat and other moist foods there is (in the dog) only a small amount of secretion, which is derived chiefly from the submaxillary and sublingual glands, and is rich in organic constituents. When dry or undesirable material, such as dry powdered meat, or sand, is introduced the flow of juice is more copious and more watery. Secretion may be produced reflexly in the dog by showing food, or even by the suggestion that dry powder is to be introduced into the mouth. This is an example of a conditioned reflex.

---

* BEAZELL. *Amer. J. Physiol.*, 1941, **132**, 42.

† LASHLEY. *J. exp. Psychol.*, 1916, **1**, 461.

The serous and mucous glands differ in the nature of their secretion. A serous gland, such as the parotid, gives a clear watery secretion almost free from mucin, but containing small traces of coagulable protein. The mucous gland delivers a secretion which is viscid from the presence of mucin, and contains also a small trace of coagulable protein. In man amylase is found in the saliva from both kinds of glands, though it is about four times as concentrated in that secreted by the parotid gland. The total amount of saliva which may be obtained varies of course in different animals. Each gland may, however, in the course of the day give an amount of juice far exceeding, *e.g.* ten or twelve times, its own weight. In man it is reckoned that over one litre of saliva may be formed every twenty-four hours, and in the herbivora such as the horse, the total diurnal production must amount to many litres. In thirsting the reflex secretion of saliva is reduced.

NERVOUS ARRANGEMENTS OF SECRETION. Activity of the salivary glands must be elicitable by reflex means. The *afferent nerves* in this reflex include those that supply the mucous membrane of the mouth, *i.e.* the fifth nerve, the pharyngeal branch of the vagus, and the glossopharyngeal.

The salivary " *centre* " consists of a neurone pool in the reticular formation extending from the sensory nucleus of the VIIth cranial nerve down to the anterior end of the nucleus ambiguus ; the more caudal part supplies the parotid, the rest the other two glands. Certain areas of the cerebral cortex also give salivation when excited, but the significance of this is doubtful.

Sympathetic subordinate centres are located in the spinal cord, and are probably under superior control from the hypothalamus.

Each one of the large salivary glands receives efferent nerve fibres from two sources : from the parasympathetic and from the sympathetic system.

The *parasympathetic fibres* to the submaxillary, the sublingual, and the retrolingual glands pass into the facial nerve, and from this nerve along the chorda tympani to the lingual division of the fifth nerve.* The lingual nerve passes below the duct, and just before it crosses the two ducts of the submaxillary and retro- or sub-lingual glands, it gives off a branch of *chorda tympani fibres*, which runs backwards along the submaxillary duct to be distributed to the glands, and in its course gives off fibres also to the retrolingual (Fig. 545). Two neurones are involved in the cranial supply. By means of the nicotine method, Langley showed † that all the preganglionic fibres to the sublingual and the submaxillary glands end somewhere near the glands in connection with ganglion cells, from which non-medullated post-ganglionic fibres pass to the glands. These relay ganglia for the submaxillary gland are scattered cells lying in " Langley's ganglion," in the hilum of the gland itself ; in the cat those for the retrolingual gland are in the so-called " submaxillary ganglion." The fibres to the sublingual gland in man probably take a similar course. The fibres are apparently finally distributed to the secreting alveoli, where they end in the mucous secreting cells.‡

The parasympathetic fibres to the parotid gland leave the medulla by the glossopharyngeal nerve and run in its tympanic branch (nerve of Jacobson) to the tympanic plexus, and then by the small superficial petrosal nerve to the otic ganglion, where relays occur, the post-ganglionic fibres then passing to the gland by the auriculo-temporal branch of the third division of the fifth nerve.* The site of termination in the gland is doubtful.

‡ RAWLINSON. *Anat. Rec.*, 1933, **57**, 289.

The *sympathetic supply* to all these glands is contained in fine filaments on the walls of the arteries with which they are supplied. The fibres are derived from the spinal cord, whence they issue by the upper three or four ventral thoracic nerve roots. They pass into the cervical sympathetic as preganglionic fibres which end around the cells of the superior cervical ganglion, and fresh

* Claude Bernard. *Leçons sur la physiol. et la pathol. dy système nerveux*, Paris, 1858, II., p. 158.

relays of fibres, chiefly non-medullated, arise from these cells and travel on the walls of the branches of the external carotid artery to their destination, which is in the demilune cells of mixed glands, and the main cells of serous glands.

The effects of stimulating the peripheral ends of the parasympathetic nerves going to the glands present a general resemblance, whichever be the gland involved.* Within a period of half to two seconds after the stimulation has been applied, a secretion of saliva is produced, presenting similar characters to that which would be obtained from the gland under normal conditions. The concentration of the saliva, as well as its rate of secretion, depends on the strength of the stimulus. The following table (Heidenhain) shows the effect on the amount and composition of submaxillary saliva obtained by weak and strong stimulation of the chorda tympani nerve :

Strength of stimulus.	Quantity in one minute.	Per cent. of organic solids.	Per cent. of salts.
Weak . .	0·17	0·84	0·20
Strong . .	0·72	2·06	0·46
Weak . .	0·17	1·67	0·26

With the strong stimulus the amount of saliva was increased over fourfold, while the percentage of solids in the saliva was raised. If the excitation be continued for a considerable time, there is a gradual rise in the percentage of inorganic salts and a fall in the percentage of organic matter.

The cranial nerves going to these glands produce another important effect, namely vaso-dilatation. It was shown by Claude Bernard that on exciting the chorda tympani the flow from the vein of the submaxillary gland might increase four to eight times, and indeed to such an extent that, in spite of the fact that the secreting gland has a greatly increased oxygen utilisation,† the blood passing through the gland did not stay long enough to lose much oxygen. As the result of exciting the chorda, therefore, the blood coming from the vein may show distinct pulsation, and may have a brilliant scarlet hue just as if it were derived from an artery. The same dilatation has been observed to attend excitation of the cranial supply to the parotid gland.

It is probable that all the effects of stimulation of the parasympathetic nerve supply upon a salivary gland are due to the liberation at the nerve terminations‡ of small amounts of acetyl choline, the injection of which into the blood stream produces effects similar to those of the nerve stimulation. Both effects are prolonged by eserine and abolished by atropine. Pilocarpine causes profuse salivation, but the saliva produced differs in composition from that resulting from chorda stimulation.

The effects of exciting the sympathetic nerve supply differ according to the gland and the animal. Always there is vaso-constriction. In the dog, excitation of the cervical sympathetic causes the secretion of a viscid saliva from the submaxillary gland but no secretion is obtained at all from the parotid gland, though there are histological changes in the gland cells. In the cat, the submaxillary saliva obtained on sympathetic excitation may be as copious as that obtained on stimulation of the chorda tympani. We shall have later on to discuss how far these results are to be ascribed to a fundamental difference in the effects of impulses carried by the two sets of nerve fibres, and how far to their different effects on the blood vessels.

A motor effect, producing a shrinkage of the gland, is also seen in all the salivary glands on stimulation of the sympathetic supply. It is caused by the contraction of special myo-epithelial cells lying just inside the basement membrane.§

CHANGES IN THE GLAND ACCOMPANYING SECRETION. The fact that a submaxillary gland of the dog under favourable conditions will secrete its own weight of saliva in five minutes, and will on continued stimulation secrete for many hours, shows that there is a continual renewal of the fluid which is turned out in the secretion. If we refer to the diagrammatic representation of the elements which make up a secreting lobule and which may be involved in the act of secretion (Figs. 546, 547), we see that between the lumen of the duct and the blood, which must be regarded as the source of the fluid, the following layers of cells intervene: (1) the endothelium of the blood capillaries; (2) the basement membrane; (3) the epithelial cells of the gland proper. We have in the first place to decide to which of these elements can be ascribed the chief part in the act of secretion.

The secretory activity is usually associated with a considerable dilatation of the vessels of the gland, and a consequent large increase (three and eight times) in the blood flow through the gland. Such an increase in the supply of blood affords a source for the large quantity of fluid which is turned out in the saliva, and raises the pressure in the capillaries of the gland. We cannot, however, regard this rise of pressure as the essential factor in the act of secretion. If a small dose of atropine be administered, excitation of the chorda causes the same vaso-dilatation as before, though no secretion is produced. Moreover, Ludwig showed that if two manometers be connected, one with the carotid artery and the other with the duct, on stimulating the chorda tympani nerve the mercury will be driven up by the pressure of the secretion in the corresponding manometer until it attains a height which may be double that in the carotid artery,* and therefore must be still greater than the pressure in the capillaries of the gland. This showed the impossibility of the act of secretion being a process of mere filtration.

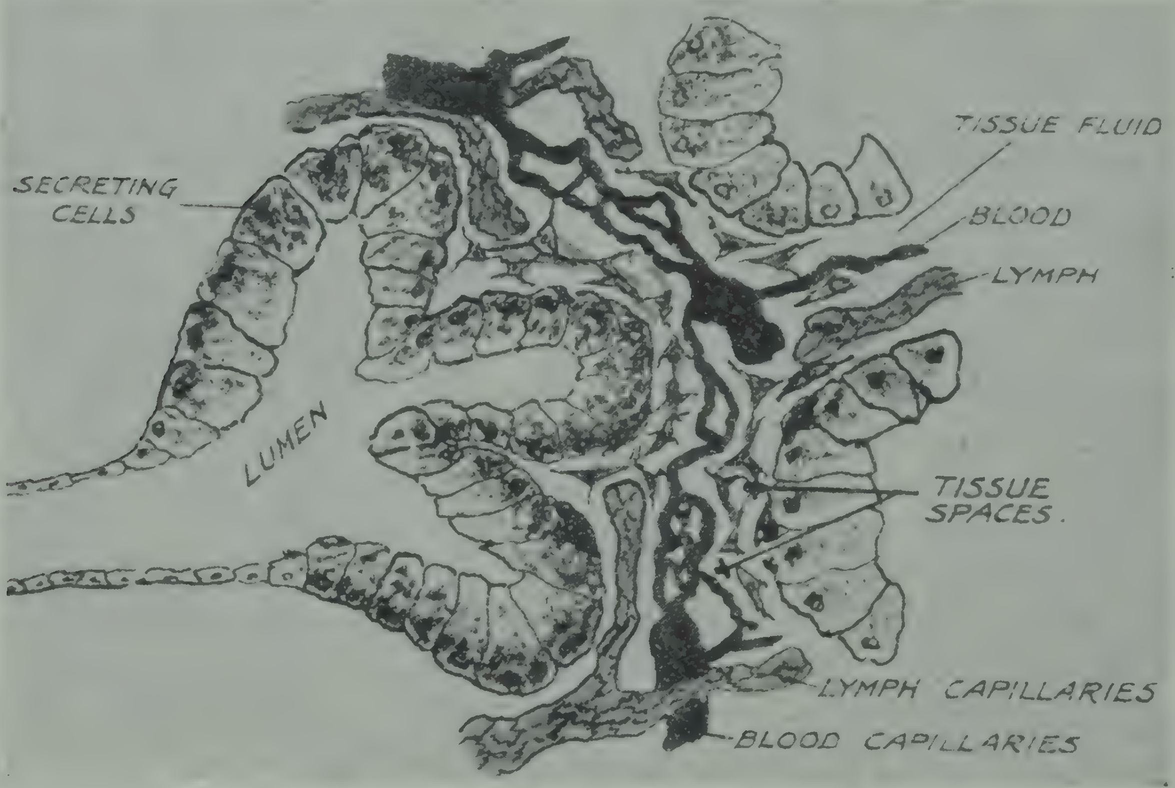

FIG. 546.

There is further evidence that work is done in the production of the salivary secretion. When a fluid containing salts in solution is filtered through a porous membrane, the filtrate has the same content in salts as the original fluid. We can effect a separation of dissolved salts from solvent by filtration under pressure through a semipermeable membrane. Under these circumstances a very large pressure is necessary in order to cause the filtration of any fluid at all, a pressure greater than the osmotic pressure exerted by the substances in solution. Thus if we were filtering a 1 per cent. solution of NaCl through a semipermeable membrane, we should have to exert a pressure of about seven atmospheres in order to obtain a filtrate free from sodium chloride.

---

* LUDWIG. *Mitt. d. Zürch. Naturf.*, 1851, Nr. 50, 271. (Ostwald's *Klassiker d. Exakten, Wiss.* Nr. 18.) This effect is only well seen if the arterial pressure is low.

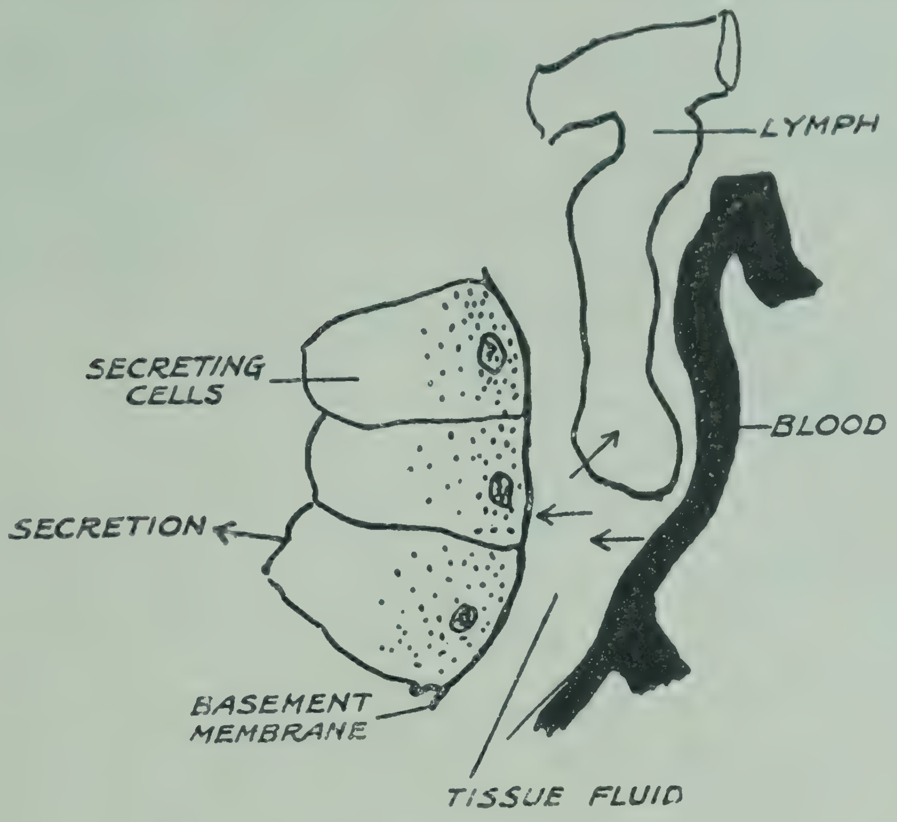

FIG. 547.

FIGS. 546 and 547. Diagrams to show Relation of the Secreting Cells of a Gland to the Blood and Tissue fluid and Lymph Drainage. Figure 547 is schematic.

To obtain a filtrate containing half the amount of sodium chloride, if such were possible, would therefore need a pressure of about three and a half atmospheres. On comparing the osmotic pressures of saliva and blood respectively—using the depression of freezing-point as our index—we find that the osmotic pressure of saliva is between half and three-quarters that of the blood plasma. Supposing the membrane separating the lumen of the duct from the blood vessels could be regarded as a semi-permeable membrane, we should need, in order to effect the separation, a pressure ten to twenty times as large as the arterial blood pressure. We must conclude, then, that work, both osmotic and mechanical, is performed in the separation of the fluid from the blood and its transference in the form of saliva to the duct.

A simple experiment shows that this work must be effected by the gland cells themselves. The fluid passes from the blood vessels first into the tissue spaces, whence it is taken up by the secretory cells. If the first act in secretion consisted in an increased exudation of fluid from the blood into the tissue spaces, the first effect of exciting the chorda tympani nerve should be to cause the swelling of the whole gland. If all secretion be prevented by the previous administration of atropine, stimulation of this nerve produces, as might be anticipated, an increased volume of the gland in consequence of the dilatation of its vessels. If, however, the gland be allowed to secrete, we obtain, in spite of the simultaneous increase in size of the vessels, an actual diminution in the size of the

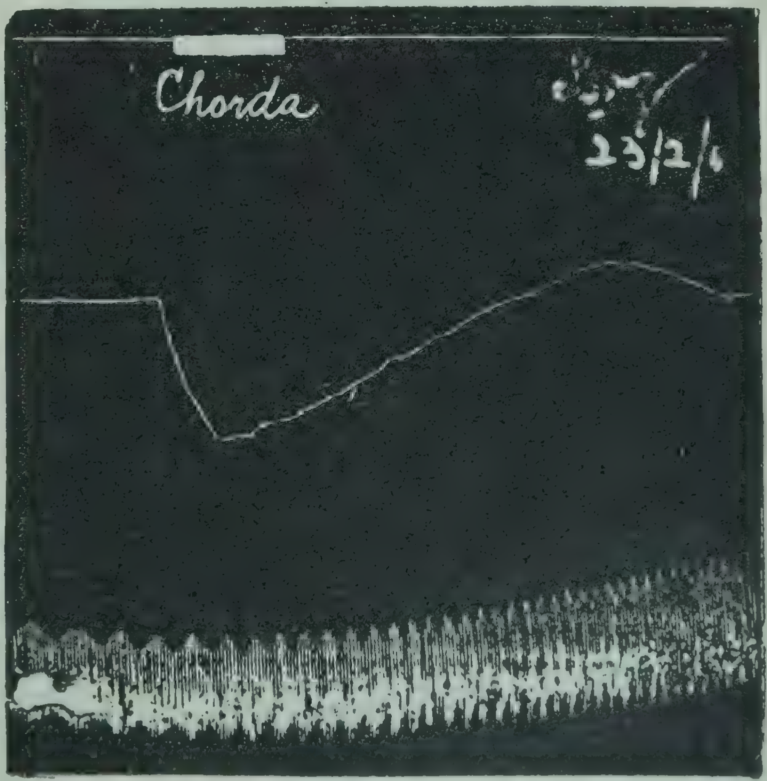

FIG. 548. Tracing of Volume of Submaxillary Gland, showing Decrease on Excitation of Chorda. (BUNCH.)

gland itself,* showing that the first effect of the stimulation is on the cells of the alveoli (Fig. 548). Under the stimulus, these empty themselves of some of their contents, replenishing themselves later at the expense of the tissue fluid. The increased passage of fluid from blood to tissue space is therefore a secondary and not a primary effect of the nerve stimulation.

Histological Changes during Secretion. The process of secretion is associated with changes in the structure of the secretory cells. The changes are of the same general character whatever class of glands we investigate, though the ease with which they are to be demonstrated varies with the effects of the fixing fluids employed. If a small fragment of a mucous gland be teased in blood serum or in 2 per cent. NaCl solution, the cells are found to be packed with a mass of coarse, highly refractive granules (Fig. 549). If a corresponding specimen be made from a serous gland (Fig. 550), the cells are also packed with granules which, however, are much finer in structure. On making similar specimens from glands which have been forced to secrete for six or seven hours, the individual cells are found to be much smaller and the protoplasm of the cell is relatively increased in amount, while the granules are much fewer and are now confined almost entirely to the inner margin of the cell.† Activity is thus associated certainly with a discharge of granules, and probably with some increased building up of protoplasm. We may regard the act of secretion as determined by the alteration of the granules and their discharge, together with water and salts, to form the specific secretion of the gland. During rest the granules are re-formed by precipitation in, or modification of, the protoplasm surrounding the nucleus. We have evidence that, although the granules enter the secretion, they represent, not the secretion itself, but a precursor of some

† Langley. *Journ. Physiol.*, 1879, **2**, 261.

at any rate of its constituents. Thus if acetic acid be added to the saliva obtained from the submaxillary gland, the mucin is precipitated as threads and films. If the granules in the secreting cells also consist of mucin, we should expect acetic acid to have a coagulating effect upon them. We find on the contrary that, on allowing acetic acid to flow over a section of the fresh gland, the granules at once swell up and burst. We must regard these granules therefore, not as mucin, but as a precursor of mucin, mucinogen. The effect of ordinary fixing reagents is to cause these granules to swell up so that the cells become filled with a mass of mucin giving the typical hyaline appearance of ordinary sections of these glands. In the case of the serous glands the granules (Fig. 551) are apparently protein in nature. Where ptyalin is a constituent of the saliva, we are probably justified in assuming that it is contained as a precursor in the granules. It is customary to speak of the granules in a secreting gland as *zymogen* granules, *i.e.* the precursors of enzymes. It is probable that we ought to regard these granules, not merely as precursors of the constituents of the secretion, but as cell organs in which proceed a whole series of chemical and osmotic changes, which determine the production of the fully formed secretion directly from the protoplasm and indirectly from the ordinary constituents of the surrounding tissue fluid.

ELECTRICAL CHANGES. The interpretation of the electric potential changes which accompany secretion is difficult, owing to the simultaneous effect of the movement of fluids through porous membranes. If the hilum of the submaxillary gland and its outer surface be connected with a galvanometer, the outer surface is positive to the hilum. On exciting the chorda tympani nerve a diphasic effect is generally obtained, the resting difference being first increased and later on diminished. On excitation of the sympathetic nerve we generally obtain a purely negative variation of the resting difference. These results were interpreted by Bayliss and Bradford * as due to the co-operation of the two factors, chemical change in the gland cells and movement of fluid through the cells. The positive variation, *i.e.* the current from within out, was ascribed to the movement of fluid, whereas the negative variation of the resting difference was thought to be an action potential, due to the chemical changes in the gland cells.

THE SIGNIFICANCE OF THE DOUBLE NERVE SUPPLY. Heidenhain † claimed that stimulation of the sympathetic supply to a salivary gland causes histological changes in the gland even more marked than those produced by the cranial nerve. He therefore put forward the hypothesis that the salivary glands are supplied by two fundamentally different classes of fibres, namely: (1) trophic fibres, which are responsible for the production of the specific constituents of the secretion, and (2) secretory fibres, excitation of which causes the cells to take up water and salts from the tissue fluid and blood, and pass them in large quantities into the duct. The sympathetic supply would consist almost entirely of trophic fibres, whereas secretory fibres would predominate in the parasympathetic supply.

According to Langley‡ and Carlson, the difference in the action of the chorda tympani and of the sympathetic on the submaxillary gland is due to the opposite action of these nerves on the blood supply to the gland. But this is inadequate to explain the differences observed in the secretion of saliva reflexly aroused by introduction of substances into the mouth. In a dog a copious flow of saliva may be caused by the introduction of 0·25 per cent. hydrochloric acid or of meat powder. The amount of saliva secreted under the two circumstances is approximately the same, but that evoked by the introduction of meat powder contains about five times as much organic solids as that which follows the introduction of acid into the mouth. The clue to the variation is probably to be sought in the different effects of sympathetic and parasympathetic fibres (or of their chemical representatives adrenaline and acetyl choline) upon different cells of the salivary glands. Stimulation of the chorda in the cat, for instance, causes profound histological changes in the alveolar cells of the submaxillary gland, while sympathetic stimulation, leaving those unaffected, causes changes in the demilune cells.§ The composition of the salivas obtained in the two cases is characteristic of the secretions of the mucous and serous cells respectively.||

Even this explanation may not be complete; Babkin has shown that variation in the saliva is found after complete section of the sympathetic, and that there is the same acceleration of the circulation through the gland whether the secretion is aroused by introduction of meat powder or of acid. It is impossible, therefore, to explain the difference in the composition of the saliva obtained under these two circumstances as due solely to differences in the blood supply to the gland, and we must conclude that the chorda tympani contains different kinds of fibres which are excited to varying extents according to the nature of the reflex stimulation. At any rate, it is certain that, according to the nature of the reflex stimulus, either the secretion of water and salts or the secretion of organic solids may preponderate, altogether apart from changes in the circulation simultaneously evoked. It has also been found that simultaneous stimulation of the chorda tympani and sympathetic nerves gives rise to an *augmented secretion* of saliva, greater than that given by the chorda alone, although the blood flow through the gland is less. (GESELL.)

The Energy Involved in the Act of Secretion. Barcroft [*] attempted to determine the total amount of energy set free by the gland in secretion, by measuring its respiratory exchange under conditions of rest and activity. He found that the resting submaxillary gland in a small dog took up 0·25 c.c. of oxygen per minute, while during active secretion it absorbed 0·86 c.c. O_2. Assuming that the total oxygen taken up is employed in the oxidation of a food substance, such as glucose, and that the whole of the energy of the chemical changes is set free in the form of heat, we find that a resting gland weighing about 6 grammes produces about 1·1 calories per minute. We know, however, that a certain amount of external work is performed in the secretion of a saliva of lower osmotic pressure than the blood and also, when there is any resistance to the flow of saliva through the duct, in raising the hydrostatic pressure of the saliva in the duct.

Even during rest, changes are going on in the gland cells, changes leading to the formation of granules. When activity is excited by the stimulation of secretory nerves, the primary change appears to involve simply the granules. These absorb water, apparently against the osmotic pressure of the surrounding cytoplasm. Those nearest the lumen swell up, become converted into spheres containing water and salts in smaller proportion than exists in the fluid bathing the cells (and presumably in the protoplasm surrounding the granules), and in this swollen form are discharged or ruptured on the periphery of the cell into the lumen, so giving rise to secretion.

This discharge of a fluid with a smaller molecular concentration than the blood plasma must lead to an increased osmotic pressure in the remaining parts of the cell. This would induce a flow of water from tissue fluid into cell, and the consequent concentration of the tissue fluid would in the same way cause a flow of water into it from the blood. This pull of water from the blood by the cell is still further increased in another way. The act of secretion can be carried out only at the expense of chemical changes in the cell, which will result in the formation of a number of small molecules from the great colloid molecules of the protoplasm. The products of metabolism, or *metabolites*, will therefore accumulate in the cell, pass into the tissue fluid, and increase the osmotic pressure of the latter. This will call forth an increased transudation of fluid from the blood vessels, and will therefore produce a distension of the tissue spaces of the gland and an increased discharge of lymph along its efferent lymphatics.

As a secondary result of the activity there is a tendency to increased assimilatory changes and a preparation of the cell for further secretory changes, either immediately or thereafter. During prolonged secretion the mucin content of the saliva steadily diminishes. The non-mucin nitrogen of the saliva is, however, not reduced, and hence is being continually passed on from the blood. Replenishment of mucinogen after complete exhaustion may take as long as three days. The submaxillary gland uses glucose from the blood stream at an increased rate when the gland secretes. (Anrep and Cannan.[†])

In the gland, as in muscle, when we attempt to form a conception of the mechanism of the chemical machine in the living cell, we are brought up against insuperable difficulties, and any theories so far put forward merely serve to show how far we are still from the actual comprehension of the events occurring in every living cell and underlying its conditions of rest and activity.

2. MASTICATION AND DEGLUTITION

Mastication. In the act of mastication the food is mixed with saliva and ground by the teeth, aided by the cheeks, lips and tongue. Salivary secretion is augmented by mastication, and the mass of food, moistened and lubricated by the saliva, is finally rolled between the tongue and hard palate to form a bolus, preparatory to swallowing.

It has been shown by Sherrington [‡] that mastication may consist of a series of reflexes, the closure of the jaws producing a stimulus to reflex opening; then, by rebound of the inhibited jaw-closure, another closure results, and so on, so long as anything biteable remains between the jaws.

Deglutition. The food after mastication is carried to the stomach by a complex series of co-ordinated movements involving the muscles of the mouth, pharynx and œsophagus (Fig. 552).

Various methods have been used to study the process of deglutition in man and the higher animals. In various animals, *e.g.* ostrich, horse, giraffe, the movement of the bolus down the œsophagus can be seen or felt from the outside of the neck. Important information can be obtained by allowing a man or animal to swallow either a fluid or solid with which barium sulphate is mixed, and observing the passage of the opaque substance under the X-rays. The substance may be mixed with milk for a fluid, or with bread and milk for a semi-solid substance, or may be enclosed in a cachet and swallowed as a solid bolus. The various sounds produced in deglutition may be timed and suitably recorded in relation to other events. The relative time relations of the events at different parts of the mouth, pharynx and œsophagus may be obtained by passing tubes either open, or provided with rubber balloons, to different levels, that for the pharynx being passed in through the nasal passage, and connecting these sounds with recording tambours or piston recorders. This method has been employed both in men and in animals, but the records from balloons are not easily interpreted because a stationary balloon would probably be treated like a very large bolus, and be subjected to powerful efforts to move it onwards.

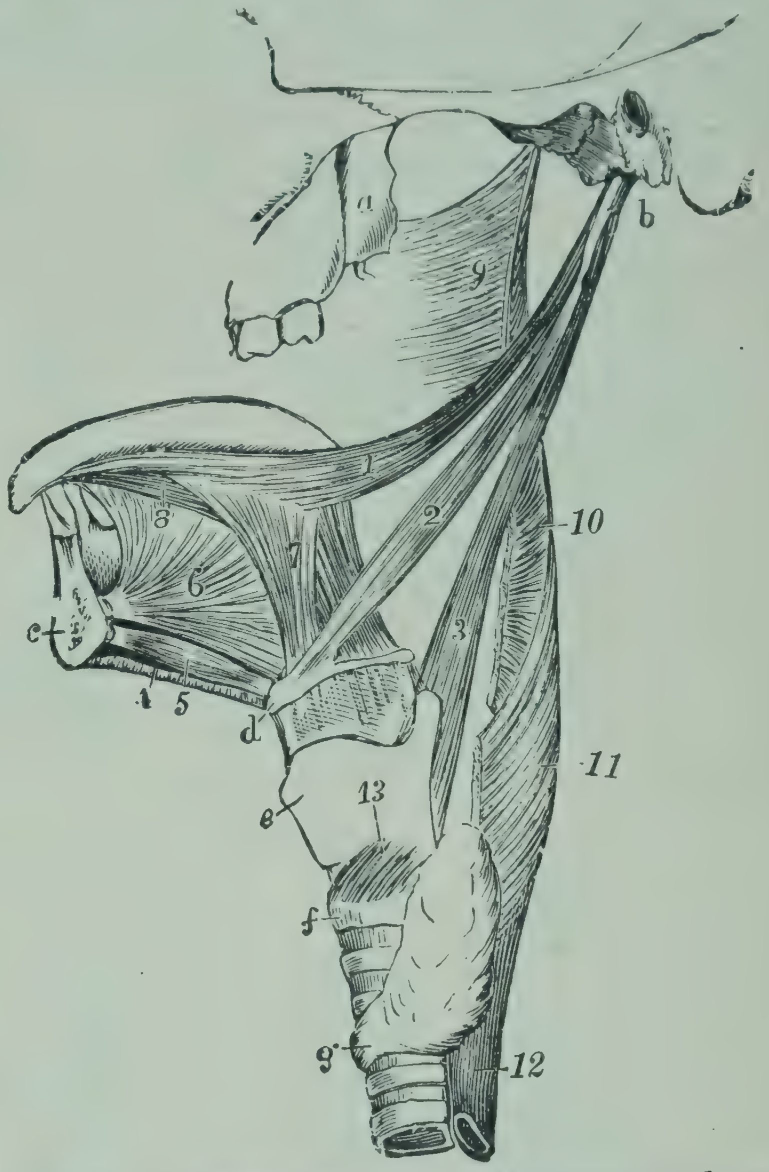

Fig. 552. Dissection to show Muscles employed in Deglutition.

b, styloid process, from which arise 1, the styloglossus; 2, the stylo-hyoid; 3, the stylo-pharyngeal muscles; *c*, section of lower jaw; *d*, hyoid bone; *e*, thyroid cartilage; *g*, isthmus of thyroid gland; 4, cut edge of mylohyoid muscle; 5, 6, 7, 8, muscles of tongue; 9, 10, 11, superior, middle, and inferior constrictors of pharynx; 12, œsophagus. (Allen Thomson.)

When a mouthful of water is taken, two sounds may be heard on auscultating over the œsophagus. The first sound immediately follows the beginning of the act of swallowing and is probably due to the impact of the fluid against the posterior pharyngeal wall, brought about by the sudden contraction of the muscles which throw the fluid from the back of the tongue across the pharynx. The second sound is heard best by listening over the epigastrium. Since a certain amount of air is always swallowed at the same time as the food, the escape of this air through the small cardiac orifice gives rise to a bubbling noise which can be easily heard. It begins from four to ten seconds after the first sound, and lasts for two or three seconds. The interval between the two sounds is not constant. If the observation be carried out on a man lying on his back, the trickling second sound is changed into a series of sounds which have been described as squirts, which vary from two to five in number, each lasting about one second. The second sound may be absent when a solid bolus is swallowed.

On observing the process by X-rays, very much the same time relations are obtained. If a mouthful of milk mixed with barium sulphate be swallowed, it will be seen passing rapidly down the œsophagus to the cardiac orifice of the stomach. Here the passage is arrested for a time, and the fluid enters slowly in a narrow stream into the stomach. The average time which elapses between the beginning of deglutition and the disappearance of the last trace of fluid from the œsophagus is about six seconds (Fig. 553). A similar course of events is induced when the food swallowed is semi-solid. The bolus is shot at a surprising speed through the pharynx and upper œsophagus, but is slowed down at about the level of the clavicle, and travels more and more slowly till it reaches the cardiac orifice. If, however, the bolus be dry, such as a cachet, it may take as much as fifteen minutes to reach the cardiac orifice, although the individual who has swallowed it is quite unaware of its continued presence in the œsophagus. If, as would normally be the case, the cachet be well moistened with saliva or water before swallowing, it passes much more rapidly.

---

* Couvelaire and Crouzon, *J. de Physiol. et de Pathol. générale*, 1900, **2**, 280; Patel and Pellande, *J. de Physiol. et de Pathol. générale*, 1903, **5**, 47.

It has been customary since the time of Magendie to divide the act of swallowing into three stages: during the first, the bolus of food is carried past the anterior pillars of the fauces; during the second, through the pharynx, past the openings of the nasal cavities and of the larynx; and during the third, through the œsophagus into the stomach. There is, however, no pause between these various stages. The act of deglutition is one, and the initiation of the first stage inevitably involves the completion of the whole. The food when masticated is collected as a bolus on the dorsum of the tongue. A pause then takes place in the movements of mastication, and a slight movement of the diaphragm usually occurs known as "respiration of swallowing." An early event in swallowing is the closure of the mouth and nasal passages and slight raising of the larynx. If the thyroid cartilage is held down, or if the mouth is open to the pharynx, normal swallowing cannot occur. Next, a sudden elevation of the tongue throws the bolus back through the anterior pillars of the fauces. In this movement the chief factor is the contraction of the mylohyoid muscle, which presses the tongue against the palate and pushes it backwards. The backward movement of the tongue may also be aided by the contraction of the styloglossus and palatoglossus muscles, which pull the base of the tongue suddenly backwards. These muscles, especially the palatoglossi, serve to close the isthmus faucium, thus preventing any return of the food towards the mouth.

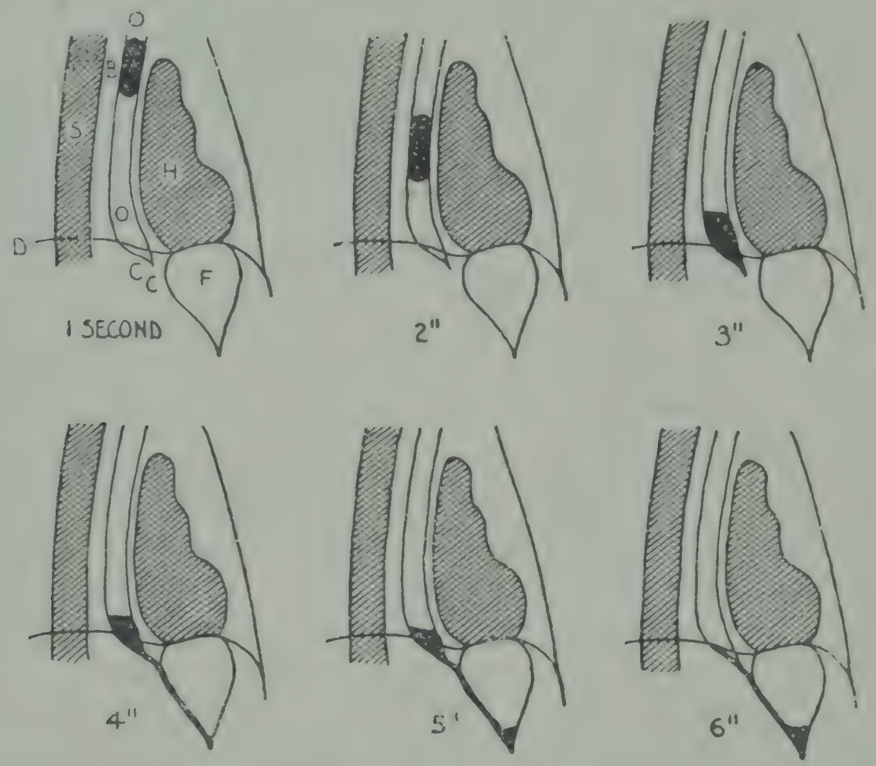

Fig. 553. Appearance of lower end of Œsophagus and Cardiac Sphincter, at one to six seconds after swallowing; observed under X-rays. (Hurst.)

As the food is passing through the upper part of the pharynx, it traverses a region common to the respiratory as well as the digestive passages. Its passage through this region is therefore rapid, and is associated with a closure of the two openings of the air passages into the pharynx. The nasal cavity is shut off by a simultaneous contraction of the levator palati and palato-pharyngeal muscles and azygos uvulæ, by which means the soft palate is raised (Fig. 554) and the posterior pillars are approximated to the uvula. The upper and back wall of the palate is thus formed into a tense sloping roof.

More important is the shutting off of the lower air passages. The contraction of the mylohyoid muscles, which initiates deglutition, is followed almost immediately (at an interval of 0·1 sec.) by an abrupt further elevation of the larynx, and this elevation is accompanied by closure of the glottis as well as of the superior opening of the larynx. The laryngeal opening is bounded in front by the epiglottis, behind by the tips of the arytenoid cartilages, and at the sides by the aryteno-epiglottidean folds. When deglutition takes place, the arytenoid cartilages, which normally lie against the posterior wall of the pharynx, are rotated and move inwards and forwards, so that the laryngeal opening assumes the form of a tri-radiate fissure, the vertical limb being short, while the transverse limb is rounded owing to the pulling inwards of the margins of the epiglottis. The epiglottis does not descend as a lid.* At the same time both the true and false vocal cords come together, while the movement of the dorsum of the tongue backwards enables the closed laryngeal orifice to lie directly under the back part of the tongue. The muscles which are actively involved in this closure of the lower air passages are the external thyro-arytenoid arytenoid, ary-epiglottidean, and the lateral crico-arytenoid muscles. Since the approximation of the posterior to the anterior boundary of the laryngeal opening is rendered possible only by the elevation of the whole larynx under the hyoid bone, the act of deglutition cannot be carried out unless the larynx is free to move.

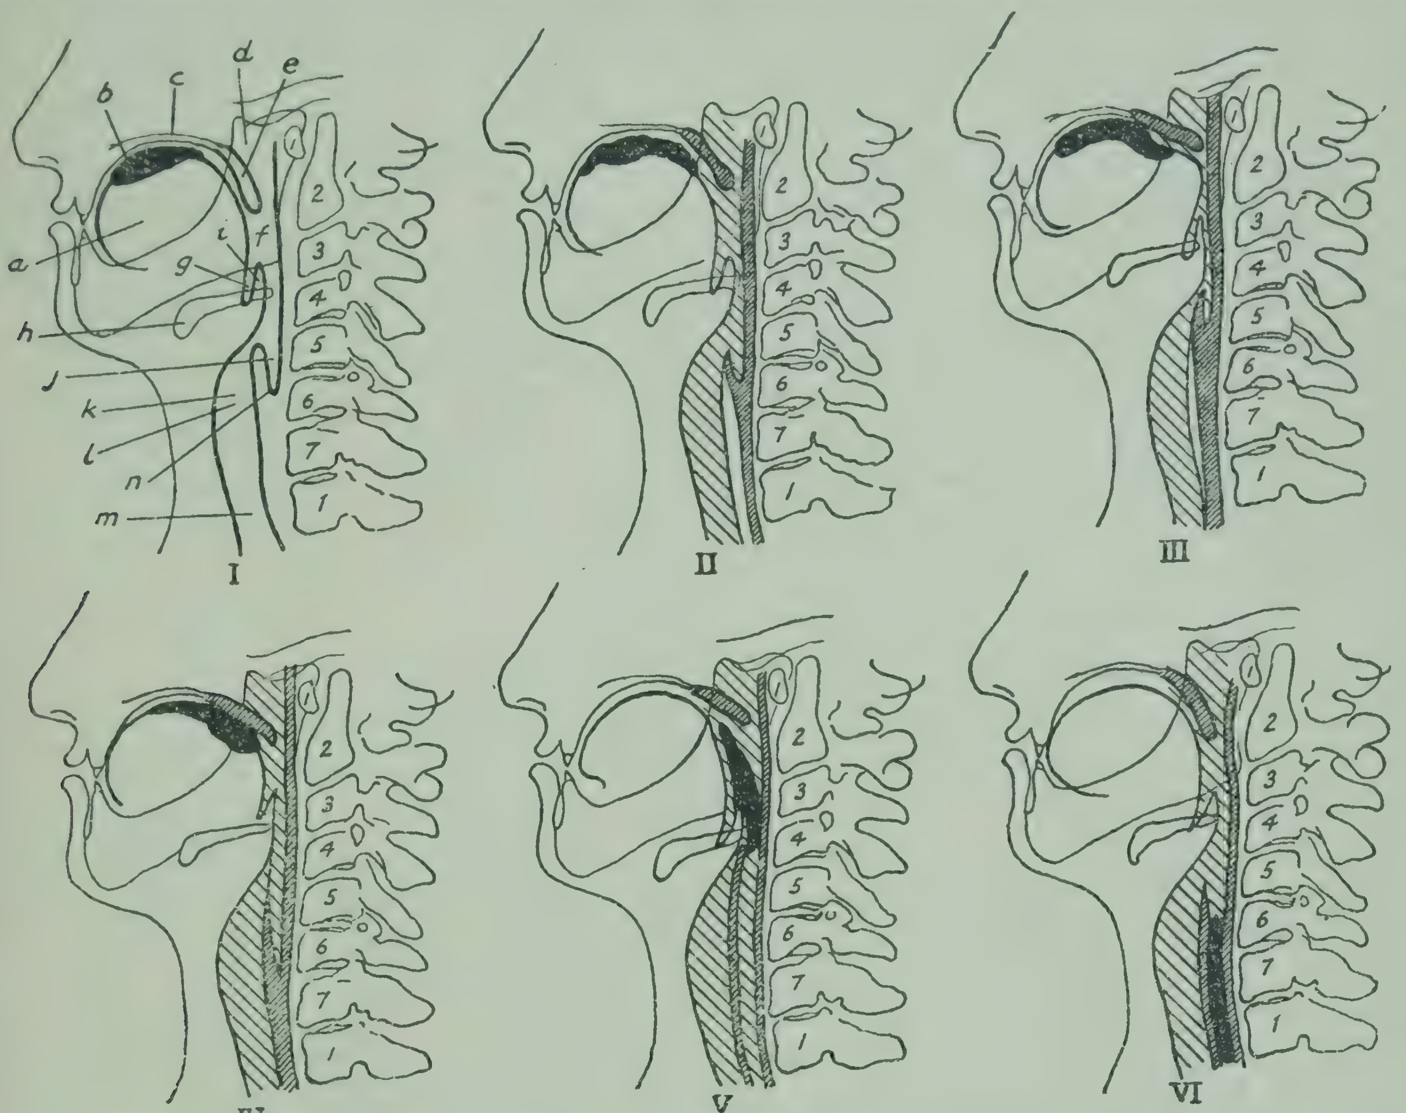

Fig. 554. Diagrams showing events in deglutition, as deduced from radioscopic observations. I. Before commencement: *a*, tongue, *b*, bolus, *c*, hard palate, *d*, nasopharynx, *e*, soft palate, *f*, pharynx, *g*, vallecula, *h*, hyoid, *i*, epiglottis, *j*, laryngeal pharynx, *m*, trachea, and *n*, œsophagus.
II. 1st stage, soft palate closing, larynx rising and pharynx narrowed.
III. 2nd stage: nose closed off, larynx raised, pharynx and upper larynx obliterated.
IV. Pharynx opening up, laryngeal pharynx drawn up to epiglottic position, œsophagus and upper larynx open.
V. Pharynx open, drawing bolus in.
VI. Laryngeal pharynx and œsophagus drop back with contents to normal position. (Barclay.)

The two openings from the back of the pharynx into the air passages being thus closed, the bolus is shot rapidly past them into the region of the middle and inferior constrictors of the pharynx. If the bolus be liquid, the movement of the back part of the tongue may be sufficient to propel the substance past the constrictors through the lax œsophagus to its lower end. It is on this account that, when corrosive fluids are swallowed, we very often find the damage to the œsophagus limited to the three points where it is narrowed and there is a slight hindrance to the onward flow of fluid. If the bolus be large and semi-solid, it nevertheless passes through the pharynx with great speed. One view of what happens here is that it is seized in the grasp of the middle constrictors on passing through the upper part of the pharynx, and is thrust by successive contractions of this muscle, and of the inferior constrictor, into the œsophagus. The walls of the cervical part of the œsophagus are composed of striated muscle. In the thorax, striated and unstriated muscles are associated together, while the lower third, in the neighbourhood of the stomach, consists almost entirely of unstriated muscle. Corresponding to these differences in structure, Kronecker and Meltzer * found differences in the duration and rapidity of propulsion of the contraction waves in each part. The contraction of the constrictors must be very rapid if this explanation is correct. Registration of pressures at different levels has not always given the same results in different investigations. According to Kronecker and Meltzer, a series of positive pressure changes travels along pharynx and œsophagus. Others have

obtained negative pressures in the pharynx and upper œsophagus (*vide* Fig. 555) preceding the positive wave.* This would agree with the radioscopic observations of Barclay,† who describes the following events :

" (1) The mouth and nose are closed.

(2) The larynx is raised and closed and its upper part is obliterated by the back of the tongue.

(3) The pharyngeal space is obliterated by (*a*) raising the larynx, and (*b*) retraction of the tongue. (The posterior wall of the pharynx does not come forward ; the pharynx is not constricted but is compressed from before backward against the posterior wall, that is, against the vertebræ.)

(4) The pharynx is opened up, and with the three outlets closed a negative pressure is obtained by (*a*) dropping the larynx, and (*b*) allowing the tongue to go forward.

(5) During this movement the laryngeal pharynx still remains high, in close relation to the epiglottis. It is in an open-mouthed condition.

(6) Food is tipped over the back of the tongue.

(7) Food is sucked into the open mouth of the laryngeal pharynx, which, as it receives the bolus, drops from the epiglottis down to its normal position, thus opening up the larynx again, after the food has passed.

(8) The food is probably sucked some distance down the œsophagus."

" The mechanism by which the larynx is cut off during the act is by a dragging up of the laryngeal pharynx behind the larynx to form contact with the epiglottis, possibly about a quarter of an inch below the tip of the epiglottis."

The free passage of liquids down the œsophagus under the influence of the propulsive force exercised by the mylohyoid muscles shows that the walls of this tube must be lax, and in fact one must assume that the first act of deglutition, so far as concerns the œsophagus, is an inhibition initiated reflexly with the beginning of the act of deglutition. When a second act of deglutition succeeds the first with a sufficiently short interval, the reflex inhibition due to the second act may prevent the development of any wave of contraction in the œsophagus. This tube thus remains in a lax condition and allows the free rapid passage of the food downwards until the movements of deglutition have come to an end, when a peristaltic contraction occurs and sweeps all remaining adherent particles of food into the stomach.

The circular fibres of the lower end of the œsophagus, which form the cardiac sphincter of the stomach, are normally in a state of tonic contraction. When one mouthful of food is swallowed, it may either pass directly into the stomach by gravity, or remain at the lower end of the œsophagus until the following peristaltic wave forces it through the orifice. Entry into the stomach often occurs as an expiration begins. Distension of the œsophagus causes peristaltic œsophageal contractions (Fig. 556) of simpler form than those resulting from conscious swallowing ; these contractions move the bolus forwards if it tends to stick. Considerable distension causes pain beneath the sternum.‡ When several acts of deglutition succeed one another, the cardiac sphincter shares in the in-

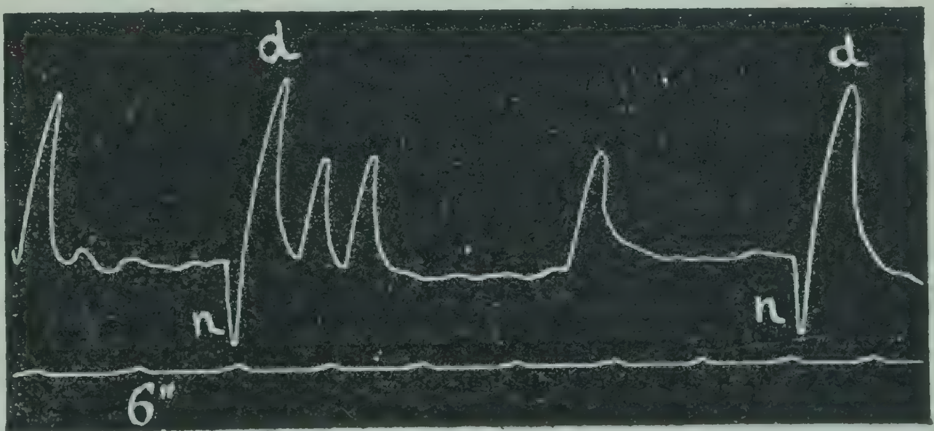

Fig. 556. Contractions of œsophagus recorded in man by a balloon method. At *n*, swallowing movements occurred. The subject was unaware of the other contractions. Note the negative wave as first event in conscious swallowing. (Danielopolu *et al.*)

hibition of the œsophageal walls, and offers no resistance to the direct propulsion of food from the mouth to the stomach. Cannon has shown that the relaxation of the cardiac orifice which accompanies swallowing, extends also to the cardiac end of the stomach. This relaxation lowers the pressure within the stomach, and makes room for the incoming food.

When the contents of the stomach are only feebly acid, the cardiac sphincter opens at intervals, especially if the pressure in the stomach is high, and allows of the regurgitation of the stomach contents into the lower part of the œsophagus. This is at once followed by a peristaltic contraction of this part of the œsophagus (apparently entirely unconscious), which drives the fluid back into the stomach. It has been supposed that movements of regurgitation become more and more infrequent as the gastric contents become acid ; but the modern view associates the increasing tone of the sphincter with distension of the stomach and the stage of digestion.

The Nervous Mechanism of Deglutition. Deglutition is a reflex act. Swallowing reflexes are readily elicited in the decerebrate animal, when water or dilute alcohol is placed in the mouth. When we swallow voluntarily we supply the necessary initial stimulus, either by touching the fauces with the tongue, or by forcing saliva or food into the fauces. Normal swallowing is abolished by cocainisation of the mucosa of the pharynx. The afferent channels of the reflex are contained in the second division of the fifth nerve, the glosso-pharyngeal nerve, and the pharyngeal branches of the superior laryngeal nerve. We can excite a single act or a whole series of acts of deglutition by electrical stimulation of the central end of the last-named nerve. The efferent fibres travel by the hypoglossal nerve to the muscles of the tongue, by the fifth to the mylohyoid, by the glossopharyngeal, the vagus and the spinal accessory nerves to the muscles of the fauces and pharynx. The closure of the larynx is effected by impulses which travel through the superior and inferior laryngeal branches of the vagus. Normal swallowing is impossible after section of both nerves near their origins. The centre for the act is situated in the medulla oblongata, and can be considered as consisting of a chain of centres, stimulation of one of which involves the firing off of all the others in orderly sequence ; the propagation of the contraction down the œsophagus is determined by the intracentral nervous connections, and does not require the integrity of the muscular tube itself. If the œsophageal nerves be divided, the act of deglutition is abolished, the upper part of the œsophagus becoming permanently relaxed, while the lower part,

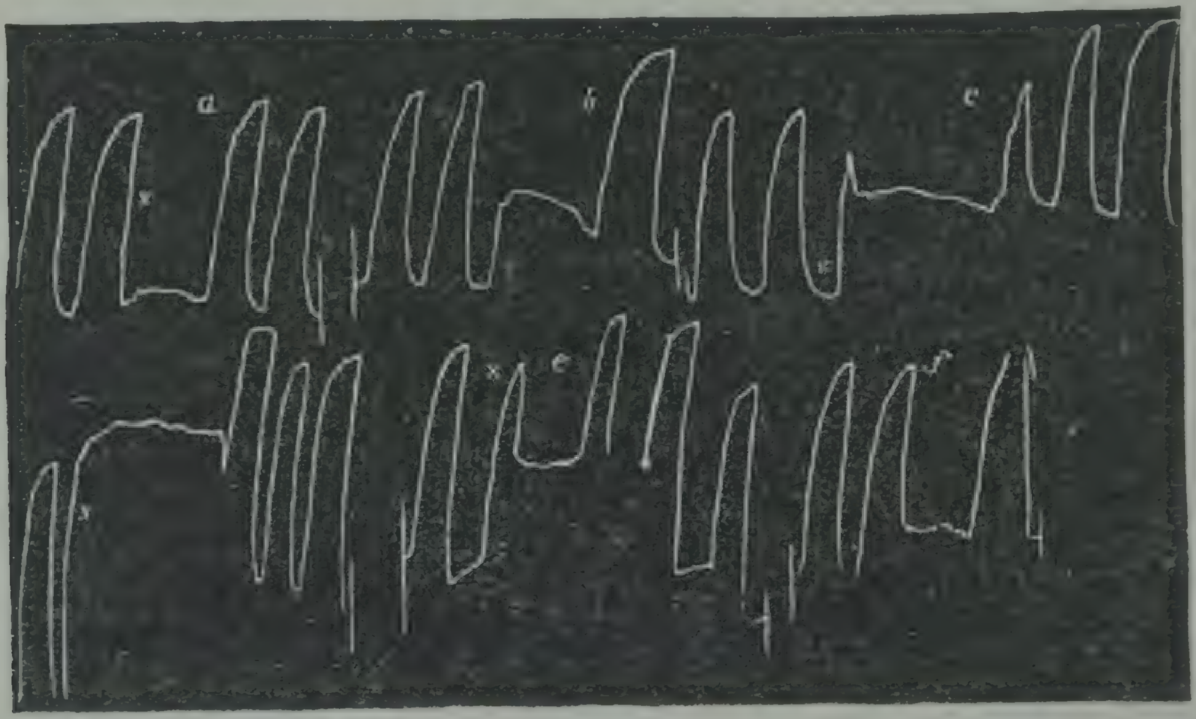

Fig. 557. Tracings of Respiratory Movements to show the Effect of Stimulating the Central End of the Glossopharyngeal Nerve. (Marckwald.)

The point of stimulation is marked with a cross. Note that the stoppage may occur at any phase of the respiratory movement.

including the cardiac sphincter, enters into a state of tonic contraction. On the other hand, the œsophagus may be ligatured or cut across without interfering with the progression of the wave of contraction, started in the pharynx, from one end of the tube to the other. Stimulation applied to the mucous surface of the œsophagus is without effect.

There is an important interdependence between the functions of respiration and deglutition. If an inspiratory or expiratory movement were going on during the act of deglutition, food might be drawn into the lungs or driven into the nasal cavities. Such an accident is prevented by the fact that every act of swallowing inhibits a respiratory movement. This can be shown on oneself. If the breath be held until the feeling of dyspnœa becomes insistent, relief is at once experienced by swallowing, and the feeling of relief will last for three or four seconds. In some animals this inhibition appears to be effected reflexly through the glossopharyngeal nerve. Stimulation of the central end of this nerve in the rabbit * at once causes cessation of respiration in whatever phase it may happen to be (Fig. 557). This cessation lasts for five or six seconds, *i.e.* a sufficient length of time for a whole series of acts of deglutition. Respiration then recommences, and the inhibition cannot be prolonged by continuing the stimulation of the glossopharyngeal nerve. In other animals, *e.g.* cat, there may be acceleration of breathing, while the dog gives variable results.† The afferent path is thus doubtful.

3. DIGESTION IN THE STOMACH

The Gastric Contents. The normal stomach several hours after food is rarely empty, but usually contains from 30 to 50 c.c. of fluid consisting of gastric juice, mucus, saliva and regurgitated duodenal contents. Within five minutes of the taking of food into the mouth, a secretion of gastric juice begins from the multitude of tubular glands which make up the greater part of the mucous membrane of the stomach. As the food is swallowed in successive portions, it accumulates in a mass in the body of the stomach, and the mass thus formed is penetrated with difficulty by the gastric juice,‡ so that salivary digestion can be continued for a considerable time. The flow of juice may continue for several hours and amounts in man, after a good meal, to 500 c.c. or more.

Gastric contents for examination can be obtained in various ways. The present method (fractional test meal) consists, after administering a standard meal (*e.g.* gruel), in withdrawing small samples of the contents at 15-minute intervals through a narrow tube which can be swallowed until its lower opening is about 20 inches from the incisor teeth, and left in place throughout the examination (Rehfuss).

Gastric Juice. The earliest case in which human gastric secretion was adequately studied was in a man with a permanent gastric fistula.§ Similar cases are studied from time to time.‖

Human gastric juice can best be obtained by the subcutaneous injection of 0·5 mg. histamine hydrochloride (or 0·1 mg. per 10 kg.), the stomach having been previously washed out. In normal subjects this leads to a secretion of gastric juice at the rate of about 200 c.c. per hour : the juice as secreted probably contains 0·5 to 0·6 per cent. HCl, but this is reduced by neutralisation by mucus, which is also secreted throughout. The free acid of the juice varies considerably in consequence, the average in healthy men being about 0·39 per cent. HCl (= 107 c.c. n/10 per 100 c.c. ; standard deviation 31·5 ; standard error 2·42) ¶ ;

more individuals are above the mean than below it. The juice contains less pepsin in the later than in the earlier stages of secretion.*

It is sometimes necessary in a patient to perform gastrostomy, *i.e.* to make into the stomach an artificial opening through which he can be fed. In such patients it is observed that merely taking food into the mouth is followed by the secretion of gastric juice. Pavlov produced this condition artificially in dogs. The œsophagus was divided and the two ends brought to the surface of the neck. At the same time an opening was made into the stomach (Fig. 558).

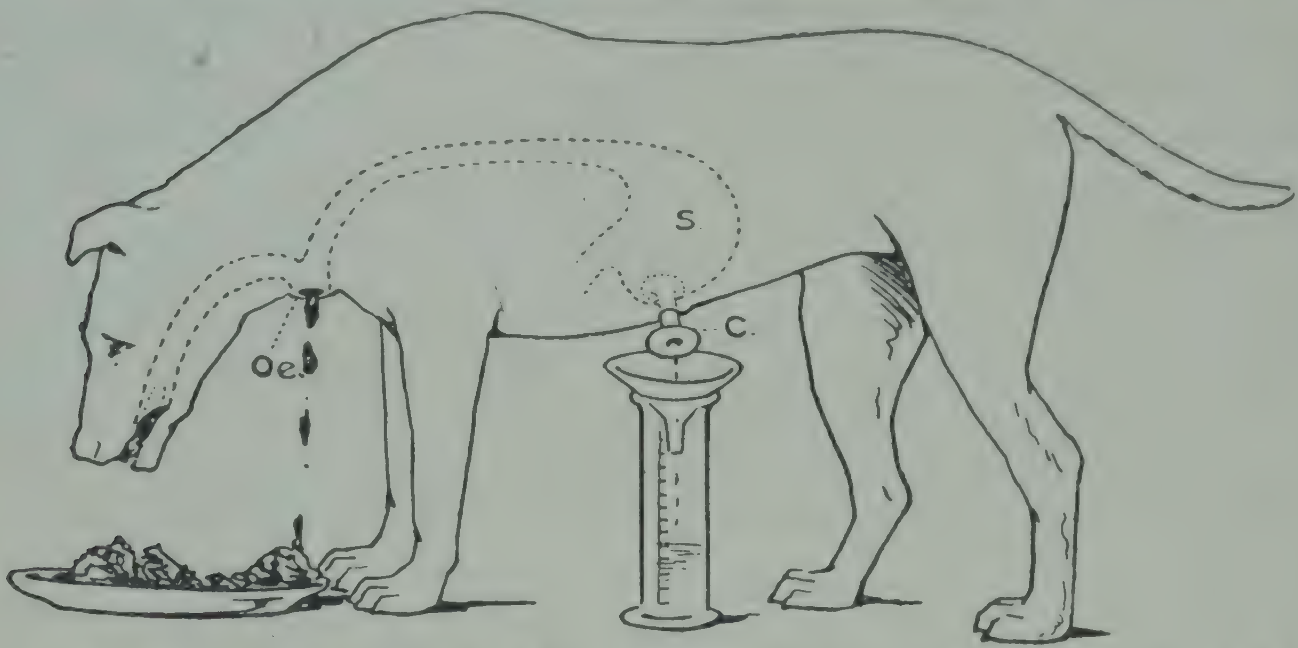

FIG. 558. Illustrating Pavlov's Method of obtaining Pure Gastric Juice. Oe, the œsophagostomy opening ; S, the stomach, with fistula in which is fixed the silver cannula C.

The animals could eat and swallow food, but the food thus swallowed fell out of the fistula in the neck instead of passing into the stomach. Under these circumstances it is found that the "sham feeding" is quickly followed by a secretion of gastric juice. If taken from a fasting animal, such a juice can be regarded as pure gastric juice. It is clear, colourless, strongly acid (pH about 1·0), and without smell. It contains only traces of protein. The following table represents its average composition.†

Hydrochloric acid	0·5 p.c. (= 136 m. eq./l.)
Other Chloride	0·107 p.c. (= 30 m. eq./l.)
Na	0·05 p.c. (= 22 m. eq./l.)
K	0·028 p.c. (= 7·2 m. eq./l.)
Ca	0·02 p.c. (= 0·5 m. eq./l.)
Total solids	0·43 to 0·65 per cent.
Enzymes and other organic solids	— ,, 0·45 ,,
Total nitrogen	0·05 ,, 0·08 ,,

Freezing point = − 0·59° C.

The actions of gastric juice are due partly to the acid, mainly to the combined action of the acid and the enzymes.

The free acid of the gastric juice is entirely hydrochloric acid. Dog's juice contains on the average about 0·5 per cent. HCl. When, however, we examine the gastric contents, composed of a mixture of gastric juice and semi-digested food, we also often find lactic acid which is produced by fermentation occurring in the carbohydrates. As the gastric juice gradually renders the contents acid, it stops this lactic acid fermentation. The free H ions present, as measured by indicators, or by the hydrogen electrode, are diminished considerably by the presence of proteins, proteoses or peptones, which act as weak buffers. But it does not seem that the adjuvant action of the acid on the proteolytic powers of the gastric juice is in any way affected by the diminution of its acidity ("combined HCl") caused by the presence of peptone.

In some pathological conditions, *e.g.* pernicious anaemia and gastric carcinoma, free hydrochloric acid may be entirely wanting from the gastric juice and the detection of this acid in gastric contents becomes therefore a matter of considerable clinical importance. For this purpose we can employ various indicators, which change colour in the presence of a strong acid such as HCl, but are unaffected by weak acids such as lactic acid or the fatty acids. The reagent which is most employed is Günzberg's reagent, a mixture of phloroglucinol and vanillin in absolute alcohol. A drop of this is evaporated to dryness. A drop of the fluid to be tested is then added, and also evaporated to dryness. If free HCl be present, the residue becomes a brilliant red colour, an effect which is not produced by the presence of free organic acids.

* HELMER. *Amer. J. Physiol.*, 1934, **110**, 28.

† Based in part on figures by GRAY and BUCHER, *Amer. J. Physiol.*, 1941, **133**, 542.

In order to determine quantitatively the amount of total acidity and free HCl, the gastric content is titrated with $N/10$ NaOH using thymol blue as indicator The reading is taken when the red colour changes to yellow-orange, and gives the free HCl. The titration is then continued until the indicator turns blue ; the further amount of alkali needed for this represents the combined HCl and organic and other weak acids. Probably the most accurate method is to titrate with standard NaOH after adding to the juice nine times its volume of acetone, using naphthylamine orange as indicator : end points are at pH 3·4 (pink) and pH 4·0 (orange). The weak acids are so much further weakened by the acetone that they scarcely require any alkali as compared with free HCl.* Estimation of total chlorides and mineral chlorides is also valuable.†

The Actions of Gastric Juice

Acid. By the action of the hydrochloric acid, certain changes are induced in the foodstuffs. Cane sugar is inverted to glucose and fructose ; a small amount of hydrolysis also takes place in the dextrins and maltose produced by the action of ptyalin on starch. Some proteins, such as blood fibrin, and the collagen of the connective tissues, are swollen up to form a jelly-like mass.

Pepsin. The chief digestive function of the gastric juice is dependent on the action of the enzyme pepsin. (Cathepsin is present also.‡ It is a proteolytic enzyme functioning at pH 4–5 : its maximal activity is obtained in presence of certain activators, *e.g.* H_2S, cysteine, etc.)

Pepsin, which is inactive in neutral medium, is actively proteolytic in strongly acid solution (optimum of pH 1·5–2·0), hydrochloric acid being the natural acid. Its effect is on the proteins, and may be best studied on blood fibrin. If fibrin be immersed in 0·4 per cent. hydrochloric acid, it swells up to a gelatinous mass. On adding chopped gastric mucosa, or pepsin, and warming to 37° C., the gelatinous mass rapidly undergoes solution. After some hours, a whole series of products of hydrolysis is found in the mixture. On boiling and neutralising the fluid, a precipitate may be thrown down consisting chiefly of *acid-meta-protein.* After boiling and filtering the filtrate contains *proteoses* and *peptones.* The proteoses are precipitated by saturation with ammonium sulphate, by which peptones are not precipitated.

In the course of peptic digestion it can be shown that COOH groups and NH_2 groups become liberated, and in equal numbers,§ which show that pepsin acts by breaking certain of the peptide linkages of proteins, thus :—

$$\cdots R.CO.NH.R'\cdots + H_2O = \cdots R.COOH + NH_2.R'\cdots$$

After completion of its action, about one-tenth of the total peptide linkages of the protein molecule have been severed in this way.

Proceeding from primary through secondary proteoses to peptones, there is a continuous diminution in the size of the molecule. During the time over which gastric juice can act, a maximum, say, of eight hours, the breakdown never passes beyond the proteose and peptone stage, and it is in this form, and as acid meta-protein, that the proteins of the food pass on into the small intestine. Analysis of gastric contents in man shows that, whereas carbohydrates may have been largely converted into reducing sugar in an hour, less than 3 per cent. of the protein nitrogen had been resolved into non-protein derivatives.||

|| Beazell. *Amer. J. Physiol.*, 1941, **132**, 42.

Action on particular Proteins. *Collagen.* The connective tissues are made up chiefly of collagen, which on prolonged boiling is converted into gelatin. The gastric juice dissolves collagen, converting it into gelatoses and gelatin peptones. On account of this action, adipose tissue is broken up. The cellular envelopes are dissolved, and the fat floats freely in the gastric juice.

Elastin, the chief constituent of elastic fibres, is indigestible.

Mucin, which forms a considerable proportion of the ground substance of connective tissues, is converted by gastric juice into peptone-like substances, and into reducing bodies allied to glucosamine.

The *Nucleo-proteins* are broken up into two moieties. The protein half is converted into proteoses and peptones, the nuclein half into *nucleic acid.*

CHYMOSIN. Caseinogen of milk is present in the form of calcium *caseinogenate.** The first effect of gastric juice, even in neutral medium, is to convert the caseinogen into an insoluble form called *casein.* This action is often in part due to the presence of a distinct enzyme named *chymosin* or *rennin.*† Although crystalline pepsin also clots milk, an active chymosin preparation can be obtained which has no peptic activity, is a thioproteose and in various other respects differs chemically from pepsin.‡ It has been stated that adult human gastric juice contains no chymosin.§ For the clotting of milk by chymosin the presence of calcium ions is necessary. The addition of chymosin to oxalated milk apparently produces no effect, but clotting ensues if calcium chloride is then added to the mixture. It is therefore thought that, in the clotting of milk, the caseinogen first undergoes conversion into casein, the sodium salt of which is soluble, but the calcium salt insoluble. Hence if calcium ions are present, calcium caseinate, or insoluble casein, is precipitated. Under the further action of the gastric juice, the clot of casein first formed is dissolved.

Action on Carbohydrates. The chief digestion of carbohydrate which takes place in the stomach is that of starch, since the amylase of the swallowed saliva continues to act until the contents become definitely acid. The hydrolysis of cane sugar and some other carbohydrates, *e.g.* inulin, which takes place in the stomach can be accounted for by the action of hydrochloric acid.

Action on Fats. The chief action of this juice on fats is the solution of their connective tissue framework and protoplasmic envelopes, so as to set the fat free in the gastric contents. After a fatty meal it is found, moreover, that a proportion of the fat in the stomach has undergone hydrolysis with liberation of free fatty acid. In this hydrolysis three factors are involved : (1) the action of the warm dilute hydrochloric acid ; (2) the action of a *lipase,* which is secreted by the walls of the stomach, and acts especially at the beginning of gastric digestion before the contents have attained a high degree of acidity. The action of this enzyme is conspicuous only if the fat be present in a finely divided form, as in yolk of egg ; (3) the action of lipase regurgitated from the duodenum. In any case, the chief digestion of fat takes place in the duodenum.

ANTI-ANÆMIC FACTOR. Gastric juice also contains an important principle called the *intrinsic factor* which reacts with substances present in certain foods to form a substance essential to the proper maturation of red blood corpuscles (p. 520). The intrinsic factor is thermolabile.

The Secretion of Gastric Juice

Source of Components. The stomach consists of the *cardiac portion,* the *corpus* or main body, and the *pyloric part.* There are definite differences between these as regards their functions.

---

* In the U.S.A. and on the Continent caseinogen and casein are respectively called *casein* and *paracasein.*

† In French, *présure* ; in German, *Lab* ; Italian, *presame.* The English name, *rennin,* is derived from "rennet-bag," the fourth stomach of the calf. An International name such as *chymase* or *chymosin,* is clearly preferable.

‡ TAUBER and KLEINER. *J. Biol. Chem.,* 1932, **96,** 745 ; 1934, **104,** 259.

§ DOTTI and KLEINER. *Amer. J. Physiol.,* 1943, **138,** 557.

Four types of cells are recognisable in the gastric mucosa, viz. surface, mucoid, peptic and oxyntic cells.* The surface cells cover the inner surface of the mucosa, and line the ducts of the tubular gastric glands; they secrete mucus. Mucoid cells form the secreting cells of those pyloric and cardiac glands which are near the two sphincters; they are also mingled with the peptic cells lining the cardiac glands. They are probably connected in function with the peptic cells, since in new-born animals they precede these in the cardiac glands.

Oxyntic, or parietal, cells are absent from the pyloric part of the mucosa, and the juice secreted in the pyloric portion contains no free HCl. A survey of the distribution of enzymes in sections of gastric mucosa, when correlated with the distribution of the various cells, shows that pepsin is related to peptic cells and a peptidase to the peptic and neck cells.†

The pepsin is not present as such in the resting peptic cells, but is represented by a zymogen, *pepsinogen*, present in the form of granules. ‡ As secretion proceeds the granules diminish in number, and are confined to the inner margin of the cell. Pepsinogen has been isolated in pure crystalline form from the mucosa of the body of the stomach.§ It is converted autocatalytically into pepsin in solutions more acid than pH 6, and in the process about 15 per cent. of the nitrogen content is split off as a polypeptide.

The secretion of a strong acid in concentrations of about one-tenth normal must be admitted to be an arresting phenomenon. It has long been known that the secretion of acid is effected by the oxyntic cells; it is also known that these contain large amounts of the enzyme carbonic anhydrase. Several theories have been put forward to explain the secretion. Ultimately the H-ion is derived from water:—

$$H_2O \longrightarrow H^{\cdot} + OH'$$

and the energy for separating the ions of water and transporting the $H^{\cdot}$-ion towards the lumen of the gland must be provided by the aerobic metabolism of the oxyntic cells.

The OH'-ion has to be neutralised and this is done by uptake of CO_2, from the blood, and this, under the action of carbonic anhydrase, goes to H_2CO_3, which then reacts to give the HCO_3' ion ‖ :—

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$
$$H_2CO_3 + OH' \rightleftharpoons H_2O + HCO_3'.$$

This HCO_3' passes into the blood plasma. Electric neutrality is maintained by the entrance of Cl' ions which pass through the cell and are secreted with the $H^{\cdot}$ ions as HCl.

It has been shown that there is normally an electrical potential difference between the inner and outer surfaces of the frog's resting gastric mucosa, the inner side being about 20–30 mV. negative. When secretion occurs there is an increase in the rate of metabolism, and electrical energy is used to set up an electrochemical cycle *within* the cells, and this results in a diminution of the resting potential difference between the two sides of the mucosa. It is this electron-cycle which produces the separation of H^+ and OH' ions, and draws them to opposite sides of the cell. In support of this is the fact that if a current is passed through the mucosa from outer to secretory surface, *i.e.* enhancing the resting potential, HCl is secreted at an increased rate and if in the opposite direction the secretion is reduced or stopped.¶

Analogous explanations can be given for the secretion of alkali in the pancreatic juice and of acid in the urine.

There is an even higher concentration of carbonic anhydrase in the oxyntic cells than there is in red blood corpuscles; in the peptic cells there is very little.**

There certainly appears to be a close relationship between the total CO_2 content of the blood and the acidity of the gastric juice secreted.†† When dyes are injected into the blood, only those with an electropositive coloured ion are secreted into the gastric juice, those with electronegative chromogen ions being retained in the blood. This is due to the electric charge on the secreting membrane.‡‡

The normal resting stomach secretes some gastric juice, which appears to consist of a mucilaginous secretion, often rich in pepsin, but containing little or no acid. During and after a meal, brisk secretion of acid gastric juice occurs and persists for some time. Secretion as a result of mechanical stimulation of the gastric mucosa was described by Beaumont. Distension of the stomach readily causes secretion of acid juice.

Secretory Nerve. The efferent gastric nerves are the vagus and the sympathetic. That the former is secretory is shown by direct stimulation of the vagus, which was carried out by Pavlov as follows: An animal with fistulæ of œsophagus and stomach had one vagus nerve divided in the neck. Four days later, the vagus was drawn out of the wound and its peripheral end stimulated. No effect was produced on the heart, owing to the degeneration of the cardio-inhibitory fibres. After five minutes stimulation the first drop of gastric juice appeared and a steady secretion was obtained with continuation of the stimulation. The length of the latent period before gastric secretion begins has not been satisfactorily explained. The vagus also controls secretion of all the mucous and mucoid cells of the stomach.* That it is the essential secretory nerve is proved by the fact that reflex secretion of gastric juice is abolished by section of both vagi. It also contains secretory inhibitory fibres, which have the effect of stopping or diminishing the secretion under certain conditions.

The sympathetic supply is vaso-constrictor, but stimulation of the splanchnic nerves five days after section (to allow degeneration of vaso-constrictors) gives a secretion of gastric juice, as also does the injection of adrenaline. This secretion is probably of subsidiary importance, and its significance is doubtful. In emotional states the secretion of gastric juice is greatly reduced.

Reflex Secretion. In "sham feeding", secretion of gastric juice begins in about five minutes after the onset of feeding, and continues as long as this goes on, which can be for hours. This method does not, however, enable us to determine whether the character of the juice will be altered in any way by the presence of food in the stomach itself. In order to form an idea of the normal course of secretion of gastric juice the "Pavlov pouch" † was devised. A small diverticulum, representing about one-eighth of the whole stomach, is made in the body of the stomach, in direct vascular and nervous continuity with the rest of the stomach, but shut off from the main part of the viscus by a double diaphragm of mucous membrane (Figs. 559, 560). In a dog treated in this way it is found that the amount of juice secreted by the small stomach is always a constant fraction of the amount secreted by the large stomach, while the digestive powers of the two juices are equal.

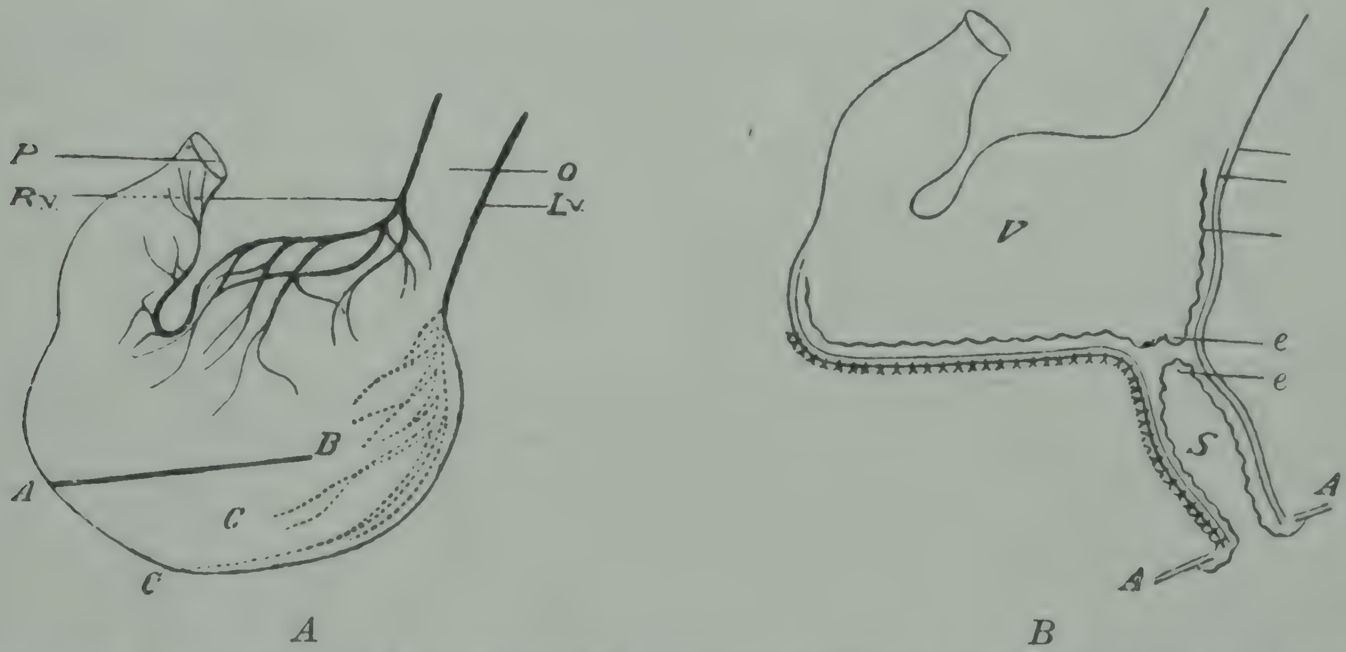

Fig. 559. Diagram to show Pavlov's Method of making a Cul-de-sac of the Body of the Stomach, with Vascular and Nerve Supply intact.

In A the line of the incision into the gastric wall is shown. B. represents the operation as completed.

In A: *O*, œsophagus: *R.v*, *L.v.*, right and left vagus nerves; *P*, pylorus *C*, corpus, or body of stomach; *A.B.* line of incision.

In B: *V*, main portion of stomach; *S*, the cul-de-sac; *A*, abdominal wall; *e*, *e*, mucous membrane reflected to form diaphragm between the two cavities.

We may therefore regard the secretion obtained from the stomach pouch as a sample of that produced by the rest of the organ, and from the juice collected from the pouch infer the behaviour of the whole stomach, *e.g.* the effects of a normal meal in which the food is swallowed, or of a sham meal in an animal with an œsophagostomy, or of a meal directly introduced into an opening into the large stomach.

---

* Jennings and Florey. *Q. J. Exp. Physiol.*, 1941, **30**, 329.

† The "Heidenhain" pouch is not innervated. Cope, *Arch. Surg.*, 1940, **40**, 717, has described a modified Pavlov pouch.

The fact that sham feeding causes the production of gastric juice shows that we have to do, in the first place, with a reflex nervous mechanism. This is an unconditioned reflex. But a secretion, which is at least as vigorous as that produced by a sham meal, can be evoked through a conditioned reflex, by merely providing some stimulus associated with the animal's food habits. If the animal be hungry, it is sufficient to show it the food to produce this effect. In the experiment from which the following Table is taken, the dog was continually excited by showing it meat during a period of an hour and a half. At the end of this time the animal, which had an œsophageal fistula, was given a sham meal. It will be observed that the "psychical secretion" obtained during the first period of the experiment was rather greater than the secretion produced by the introduction of food into the mouth.

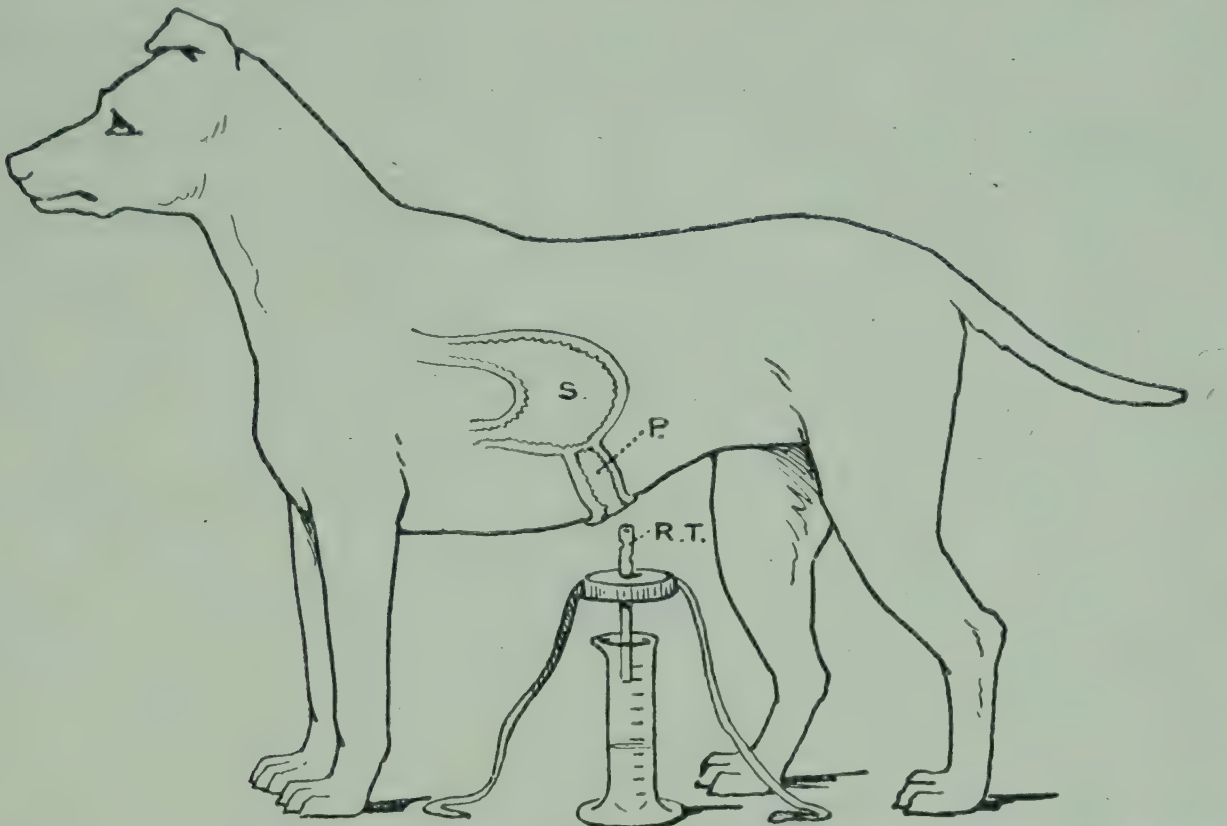

FIG. 560. Illustrating the Principle of the "Pavlov Pouch." S, body of stomach; P, the pouch; R.T., cannula made of indiarubber tubing, which is inserted into P, and held in position by tapes when juice is to be collected.

The efferent nerves in the reflex arc are the vagi; if they are divided the reflex disappears (this has also been shown in man); the afferent channels may be either the afferent nerves from the mouth or, in the conditioned reflex, any of the nerves of special sense, such as sight, which have, by being brought into use in association with the unconditioned reflex, acquired the properties of conditioned afferents. Or the action may be central in origin, as when the blood sugar has been lowered by insulin (7 units).

Chemical (Humoral) Secretion. The reflex secretion elicited by sham feeding soon declines after the feeding ceases. After a normal meal, the secretion of gastric juice continues for three to four hours, and much more juice is formed than by sham feeding alone.

It is thus evident that there are two phases of secretion of the gastric juice, the first a reflex phase occasioned by seeing or eating the food, the second due in some way to the presence of the swallowed food in the stomach. There has been some difference of opinion as to the manner in which this second phase is brought about. One experiment, however, settles an important point : a totally denervated pouch can be made, and transplanted into the mammary region ; if a dog so prepared is fed, the isolated pouch begins to secrete some considerable time after the animal has been fed, and the secretion continues for an hour or two.* This proves beyond all doubt that the second phase is not reflex, but is due to a blood-borne or humoral stimulus.

Several substances are known which will cause secretion of gastric juice, for instance, alcohol, soap, meat or liver extracts and peptone, when given by mouth, or histamine or pilocarpine, when given by intravenous injection. It might be supposed, therefore, that the secretion of the chemical phase was due to the absorption, into the blood, of some constituent of the food which had a secretagogue action. But it is not so simple as that : if a dog is furnished with a gastric fistula and also with a Pavlov pouch, and if meat is introduced through the fistula into the main stomach without the animal being aware of it, there will, of course, be no reflex secretion : but it will be found that there is no delayed secretion either. If the experiment be repeated, but with the difference that, together with the meat, some fresh gastric juice be also introduced into the main stomach, then, although the reflex secretion still remains in abeyance, the second phase secretion begins after the usual interval of time, and continues for a normal period. It is clear, therefore, that the humoral phase depends in some way on the presence, together in the stomach, of food and gastric juice. It must be the products of the action of the gastric juice on the food which act as secretagogues ; that this is so is proved by digesting the meat *in vitro* with gastric juice, and then giving the solution by stomach tube, when secretion begins almost at once.

The humoral secretion can be elicited by the contact of the exciting substances (*e.g.* liver extract or predigested meat) for a sufficient time with an adequate area of the mucosa of any part of the stomach, or of the small intestine This has been shown as follows : a dog was provided with a transplanted (*i.e.* a denervated) pouch, and the remainder of the stomach, with or without the pyloric part, was then isolated, denervated, and made into a large pouch : the lower œsophagus was connected directly to the duodenum. When the dog wa fed, or given liver extract orally, both stomach pouches secreted, *i.e.* the humora agent can function via the small intestine. When liver extract was introduce into the main pouch, the small transplant, as well as the main pouch, secreted But if the mucosa of the main pouch was anæsthetised with procaine, n secretion was obtained from either pouch when the main stomach was treate with liver extract, although on giving the extract by mouth, secretion followe in both, as usual.†

Nature of Humoral Excitant. The most obvious suggestion would be that th potent humoral agents are digestion products of proteins ; this would fit all but a few the facts. But the experiment just mentioned suggests that the active substance migh be a hormone, liberated into the blood from the gastric or intestinal mucosa when th chemical excitants formed by partial digestion of the food are brought in contact with it, the liberation of the hormone being inhibited if that mucosa had been previously treated with procaine. A claim to have identified a gastric hormone was, in fact, made by Edkins in 1906 [*]; he gave the name "gastrin" to the supposed hormone, and stated that it was only engendered from pyloric mucosa; but attempts to repeat his experimental results have been unsuccessful; so also were attempts to elicit gastric secretion when various excitants were placed in isolated pyloric pouches.[†] It seems established, nevertheless, that a histamine-free substance can be extracted from pyloric mucosa which, when injected intravenously, provokes secretion of gastric juice [‡]; the substance is a protein, rather resembling secretin, and it excites secretion of HCl, but not of pepsin.[§] It remains to be proved, however, whether this is a true hormone, *i.e.* whether that substance is actually taken up from the mucosa by the blood stream.

* Ivy and Farrell. *Amer. J. Physiol.*, 1925, **74**, 639.

† Gregory and Ivy. *Q. J. Exp. Physiol.*, 1941, **31**, 111.

It is unlikely that histamine is identical with the gastric hormone because the action of the chemical excitants, but not that of histamine, is inhibited by atropine. It is possible that histamine is liberated in the cells by the action, either of acetyl choline from vagus stimulation (abolished by atropine), or by the presence of the gastric excitant (or hormone).[‖]

Effect of Distension. The mechanical stimulus of distension causes secretion of acid gastric juice.[¶] The response must be caused by a hormone, since it still occurs when all nervous channels are eliminated. This has been shown by transplanting the pyloric part subcutaneously; when this is distended the body of the stomach secretes juice actively.[**]

Enterogastrone. The second phase of the gastric secretion is largely influenced by the character of the contents of the stomach. Thus after the ingestion of large quantities of fat, the secretion of gastric juice during the second phase is greatly delayed and also reduced in amount, in acidity, and in pepsin content. Emptying of the stomach is delayed, and there is considerable regurgitation of duodenal contents into the stomach, so that the volume of the gastric contents is subsequently increased. The inhibitory effect of the fat seems to be exerted from the duodenum and not from the stomach itself, as may be shown by the results of introducing fat into stomach or duodenum when these have been separated from one another. The effect is a humoral one, and the hormone concerned has been named *Enterogastrone*; it reduces volume and acidity of the juice resulting from a given stimulus: the pepsin content is also reduced when fat is administered, but this is a vagal effect.[††] Enterogastrone also reduces the motility of the stomach. After the preliminary delay, gastric secretion commences, often three or four hours late, and may then be quite brisk. This secretion is due to the action of the soaps which have been formed in the meantime by digestion of the fat by the regurgitated duodenal contents. A similar substance, *Urogastrone*, probably an excretory product of enterogastrone, has been extracted from urine. The main conclusions on the action of fat have been confirmed on man, *e.g.* when oil is introduced directly into the duodenum, or given before the meal, the inhibition of gastric secretion is greater than when it is swallowed with or after a meal.[‡‡]

The Normal Course of Secretion. We may say that the gastric secretion in response to a normal meal shows three phases: (1) a *reflex phase*, which begins within five minutes of the taking of the food and is determined by the reflex nervous mechanism described above; and (2) a *second phase*, of humoral nature, of later onset and longer duration, due to the presence of products of the digestion of the food in the stomach; (3) a *third phase*, small and variable, and due to the presence of digestion products in the duodenum. The normal gastric secretion is mainly due to the co-operation of the first two factors. The first and most important is the reflex secretion, determined through the vagus nerves by stimulation of the mucous membrane of the mouth, or by conditioned reflexes. The second factor, which provides for the continued secretion of gastric juice long after the reflex effects of feeding have disappeared, depends on the formation of an agent which acts as a chemical messenger to all parts of the stomach, being absorbed into the blood and thence exciting the activity of the gastric glands.

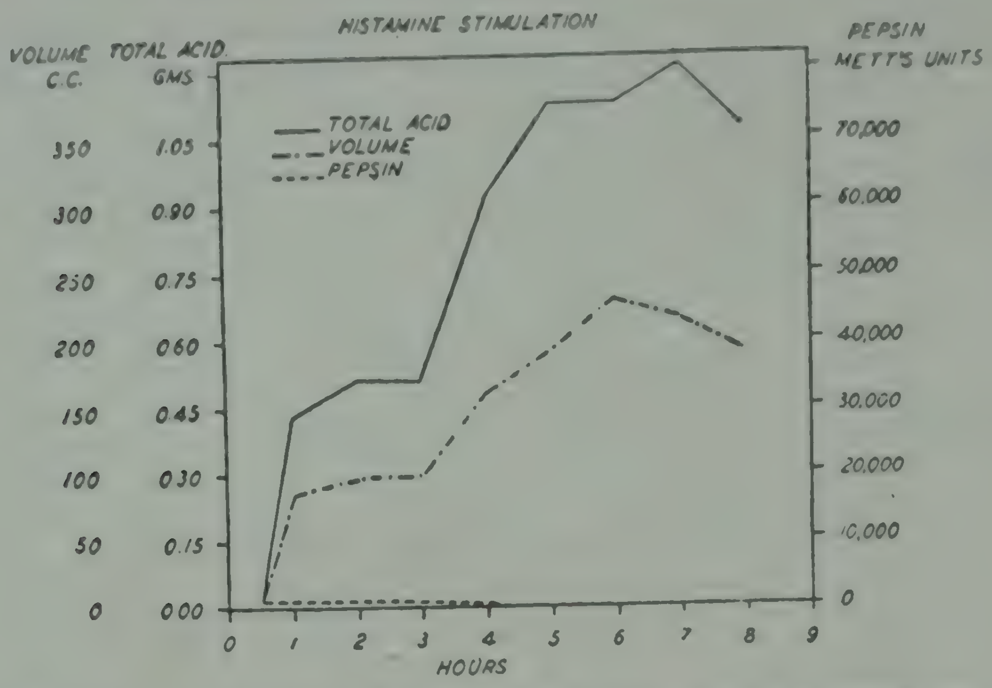

FIG. 561. Gastric juice resulting from hourly injections of histamine. The pepsin falls to zero, while acid and volume increase. (BOWIE and VINEBERG. *Q. J. Exp. Physiol.*, 1935, **25,** 247.)

It has long been known that the gastric juice is more acid the more rapidly it has been secreted. Pavlov believed that this was because there was a practically constant secretion of alkaline mucus, with which the gastric juice, of constant acid content, became mixed. This has been shown to be substantially correct by Gray and his co-workers.* They have also shown, by statistical examination of juices secreted at different rates that, in all probability, the parietal cells form a secretion containing 166 m.eq./l. of Cl, 7·4 of K, 158·6 of H-ion, while the non-parietal secretions contain 133·3 m.eq./l. of Cl, 33·0 of HCO_3, 154·5 of Na, 7·4 of K, and 3·7 of Ca. The composition of the juice can only vary between the limits set by these two components, and will be nearer to that of the parietal cells the faster the rate of formation.

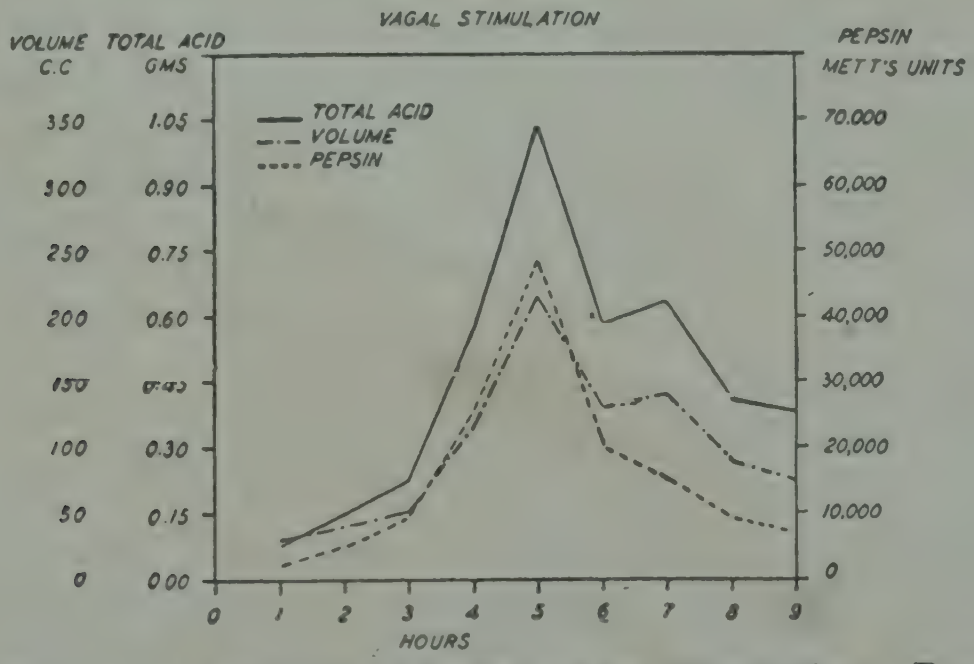

FIG. 562. Gastric juice from nine hours' vagus stimulation. Pepsin and acid are maintained. (BOWIE and VINEBERG.)

The acidity of gastric juice is constant, or nearly so, at about 0·135 N or 0·5 p.c. HCl, during the height of secretion. At the beginning and end, the juice is mixed with mucus, which dilutes and neutralises the acid.† Irritation of the mucosa by chemical or mechanical means increases the amount of mucus secreted.

A further important question is whether there is any alteration in the composition and amount of gastric juice with variations in the character of the food. So far as concerns the "appetite" juice, Pavlov showed that, whatever the previous diet, the juice always has the same characters. Since this "psychic" juice depends on appetite, it will be greater in amount the larger and the more welcome the meal. But in the case of the chemical phase, there is considerable variation in the nature of the juice. Whereas the volume of juice is greatest in amount after a meal of meat, the digestive power is greatest after one of bread. The juice secreted in this phase must vary according to the quantity of humoral agents produced, and therefore with the nature and amount of the substances produced in the preliminary digestion of the gastric contents, as well as with the initial composition of the food, and the composition and activity of the juice may vary with the intensity of stimulus. Fats reduce the gastric secretion and prolong the stay in the stomach. Water, tea or coffee taken with food augment gastric secretion, and various articles of food, such as vegetable juices, contain powerful chemical excitants (*e.g.* histamine in spinach).

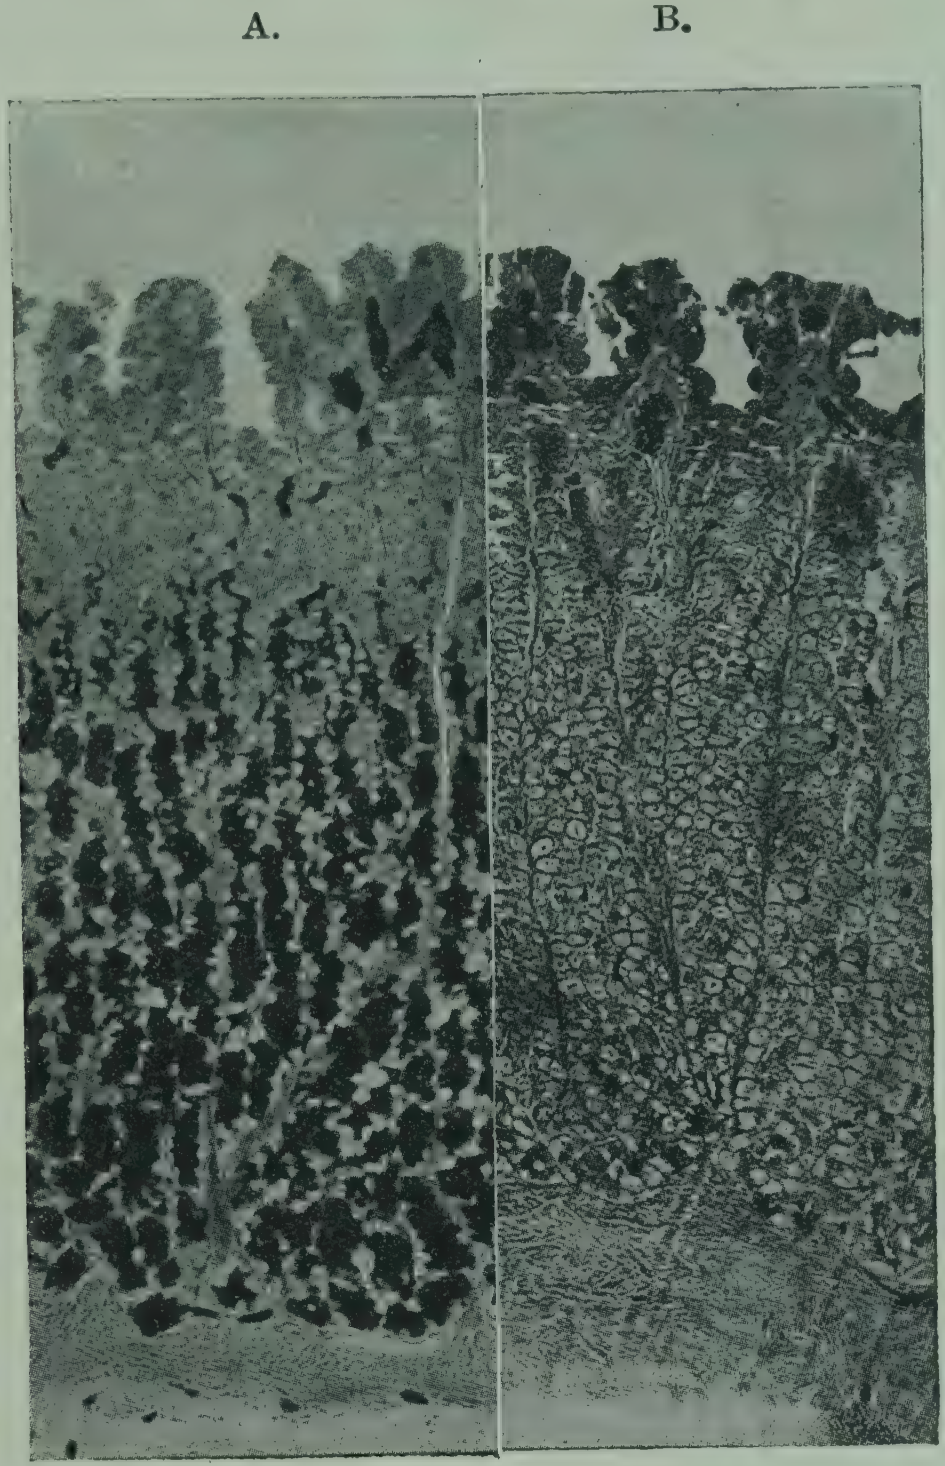

FIG. 563. A. Histological appearance of gastric mucosa after eight hours of histamine injection. The pepsinogen content is normal. B. Histological appearance of gastric mucosa after nine hours' vagal stimulation. The pepsinogen granules have nearly all vanished. (BOWIE and VINEBERG.)

According to Babkin * the vagus or reflex secretion is responsible for the control of the mucus, acid and pepsin, while the water and acid are mainly affected by the humoral control. These views have received strong confirmation from the work of Bowie and Vineberg.† They showed that when gastric secretion was excited for several hours by repeated injections of histamine, the pepsin content of the juice soon fell to zero, while the acid secretion continued (Fig. 561). Prolonged vagal stimulation, however, gave a juice rich in both acid and pepsin (Fig. 562), and vagus stimulation also caused the appearance of pepsin in the juice from which it had vanished after induction of secretion by histamine. Pepsinogen was found to be still abundant, as in the resting stomach, after prolonged secretion by histamine, whereas after prolonged vagal secretion the pepsinogen granules had almost entirely disappeared (Figs. 563 A and B). The juice secreted in response to pilocarpine is especially rich in pepsin, when compared with that provoked by histamine[*]: it also contains much mucin, which may be due to powerful contractions.[†]

† BOWIE and VINEBERG. *Q. J. Exp. Physiol.*, 1935, **25**, 247.

A possible collaboration of nervous and humoral factors has been suggested by Uvnas,[‡] who claims that vagal secretion is diminished if the pylorus is removed or cocainised: cross-circulation experiments show that during vagus stimulation a secretagogue, derived from the pylorus, enters the blood stream; the agent is presumably identical with that responsible for the gastric phase of secretion, and excites HCl secretion.

4. THE MOVEMENTS OF THE STOMACH

These can be best studied by observation by means of the X-rays.[§] In order to make the shape of the stomach visible, the food—bread and milk—is mixed with a quantity of barium sulphate. The presence of this does not interfere with the processes of digestion, but renders the gastric contents opaque to the X-rays.

In the human stomach the term *fundus* is limited to that part of the stomach situated above the cardiac orifice (in the erect position). The *body* of the stomach is marked off from the pyloric part by the *incisura angularis* on the lesser curvature, represented in many animals by a strong " transverse band " (Fig. 564). The pyloric portion consists of the *pyloric vestibule* (or *antrum*) and the *pyloric canal*, the latter being a tubular portion with thick muscular walls about 3·0 cm. in length. A somewhat thicker ring of plain muscle surrounds the canal at its junction with the duodenum, and is called the *pyloric sphincter.*

When food has been swallowed (in the erect position) its weight is sufficient to overcome the resistance of the contracted gastric wall and some of it rapidly passes to the pyloric part. The remainder stays in the body of the stomach, which keeps constant pressure on its contents, tending to force them towards the pylorus. Contraction waves begin almost at once, each constriction starting near the middle of the stomach, and deepening as it slowly progresses towards the pylorus (Figs. 564, 565). These waves succeed one another, so that the pyloric part may present a series of constrictions. Their effect is to force towards the pylorus the food which has been mixed with gastric juice and detached from the surface of the mass in the corpus. If the pylorus is closed the food cannot escape, but it is doubtful whether the pyloric sphincter remains as persistently contracted as was formerly believed[||]; in fact it has been claimed that it is normally relaxed, closing only after a wave has passed over it from pyloric antrum to duodenum, this closure preventing reflux from the duodenum.[¶] The pyloric contractions last throughout the whole period of gastric digestion, and become more marked as it proceeds. By their action a thorough mixture of food and gastric juice results. Each wave as it travels along exhibits at intervals of a few seconds the rhythmic fluctuations in intensity common to most plain muscle contractions, and when a wave at a phase of increase reaches a point about one inch from the pyloric canal it results in part of the pyloric vestibule being nearly shut off from the rest of the stomach. The part thus confined then diminishes in size in every direction.[**]

part of its contents being forced through the pyloric canal, while the remainder escapes back into the stomach. The waves recur at regular intervals of fifteen to twenty seconds, and three or four are present simultaneously. They continue without cessation until the stomach is empty—from one to four hours after the meal, according to its bulk and composition.

Although the co-ordination between the tonic contractions of the fundus and the rhythmic contractions of the pyloric part may be carried out by the local nervous system—Auerbach's plexus—situated between the layers of the muscular coat, it is probable that the advancing waves of contraction observed in the antrum are myogenic, *i.e.* directly originated in and determined by the muscle fibres themselves. Cannon has shown that these movements persist after complete division of Auerbach's plexus by from two to six circular incisions carried through the muscular coat of the stomach.

c. Situation of œsophageal opening.

yz. "Transverse band."

wx. Junction of body and pyloric portions.

The influence of the nervous system on stomach movements is undoubted, and emotional states or unpalatable food lead to suspension or reduction in the tone and movements of the stomach, a fact which should be borne in mind in interpreting X-ray findings after barium meals. Stimulation of the peripheral end of the vagus nerves may exercise varying effects on the gastric wall as well as on its sphincters. In the normal animal, stimulation of the peripheral end of the vagus as a rule causes strong contractions of the œsophagus as well as of the cardiac sphincter. After the administration of atropine, stimulation of the same nerve will occasion dilation of the cardiac sphincter. On both cardiac and pyloric portions of the stomach the vagus can exercise inhibitory as well as augmentor effects. So far as concerns the musculature of the fundus or body of the stomach, the most usual result is an inhibition during stimulation of the vagus, succeeded by an augmented tonus immediately the stimulus is removed. If the vagus be excited a number of times, the tonus of the muscular wall augments with each stimulus. On the pyloric portion, stimulation of the vagus also causes inhibition, followed by contraction and augmented peristaltic waves. McSwiney and Wadge * found that the effect of vagus stimulation on the stomach as a whole depends on its state of tonus. When the tonus is low, stimulation of the vagus causes contraction; when it is high, relaxation results. In the pylorus itself we may obtain from vagal stimulation either increased or diminished contraction.

Whether the splanchnic nerve has a direct influence on the movements of the stomach has been disputed. Most observers regard the splanchnic as having an influence on the stomach similar to its action on the intestine, and regard it as the chief inhibitory nerve to this organ.

Emptying of the Stomach. In the fasting stomach the pyloric sphincter is normally relaxed, and the pressures in the stomach and duodenal bulb are equal. When food is in the stomach, the pressure within it is generally slightly above that in the duodenal bulb.† As peristaltic waves pass along, the intragastric pressure first rises and then falls.

The mechanical factors concerned in the emptying of the stomach have been followed by studying the pressures in the pyloric antrum, within the sphincter, and in the duodenal bulb (first part of duodenum).

The principal factor in the emptying of the stomach is the passage of waves of contraction along the antrum.* During emptying, these waves pass uniformly along the antrum, sphincter and duodenal bulb,† and hence, when the pressure gradient is favourable, evacuation of some contents follows.‡ The pyloric sphincter plays a more subsidiary rôle, and is more important in preventing regurgitation of duodenal contents than in regulating the onward passage of contents from the pylorus.§ As emptying proceeds, the rate of evacuation is readily slowed down by influences, probably reflex, but also in part hormonal, which operate from the duodenum and upper intestine. The chief influences are those of large amounts of fluid, or the presence of fats, HCl, peptones,‖ sugars, or hypertonic solutions; all of these cause an inhibition of the tonus and movements in the antrum, sphincter and bulb. In emptying, the more fluid portions of the chyme are passed on first, and larger lumps retained for further digestion.

The normal emptying of the stomach is also largely dependent on the integrity of the connection of this viscus with the central nervous system. Hence if, in a dog, both vagus nerves be divided below the point at which they give off their branches to the lungs and heart, a large amount of food may remain in the stomach in an undigested condition. The secretion of gastric juice is deficient, and the opening of the pylorus is not easily carried out.

Quantitative study of the emptying of the human stomach has been made by the use of "serial test meals."¶ To obtain basal data an indifferent substance such as pectin solution was used: 750 c.c. of the solution, dyed with phenol red and of fixed pH and osmotic pressure were given daily. Each day the whole contents were withdrawn, the time of withdrawal being varied each day, and the results were synthesised into one "serial meal" which gives the normal sequence of emptying. The volume of gastric contents passing the pylorus between any two stages is got from the amount of dye lost by the contents between the stages. In this way Fig. 566 was obtained. Fig. 567 derived from this, shows that the rate of emptying stands in linear relationship to the volume of the gastric contents. A further calculation can be made to give the volume of secretion added to the contents.

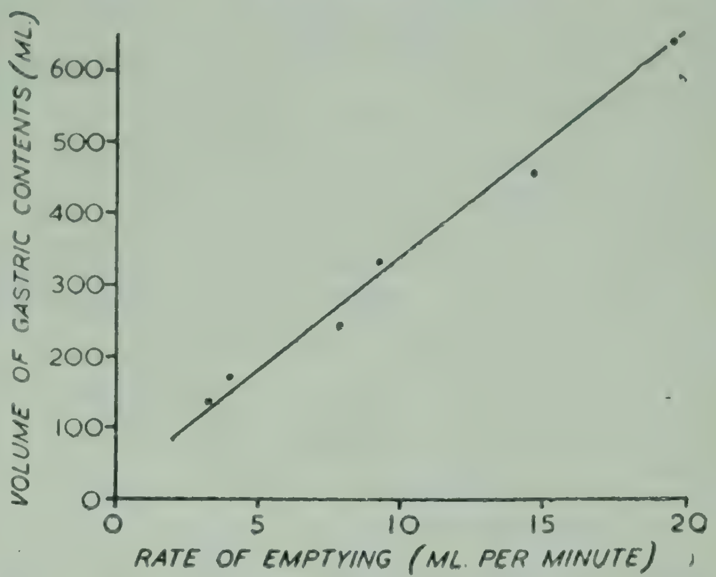

FIG. 567. Rate of emptying of gastric contents plotted against volume of gastric contents. (Courtesy of J. N. HUNT and W. R. SPURRELL.)

Liquids leave the stomach earlier than solid material. If fluid alone be swallowed, as when water is taken to quench thirst, it may arrive in the duodenum within a minute or two after being swallowed. An increase of duodenal pressure causes increased tone in the pyloric sphincter, and so retards emptying of the stomach, while a lowering of duodenal pressure has the reverse effect.* After larger meals the emptying time is greater in most subjects than after small meals, *e.g.* doubling a small test meal may increase the time by 17 per cent., and trebling it may increase it by 38 per cent.†

Meals of different foodstuffs remain in the stomach for different periods. Carbohydrates leave early, whereas with fats there is longer retention, the delay being proportional to the quantity of fat,‡ and produced when fat enters the upper intestine; it is humoral in origin, and due to liberation of enterogastrone (p. 867). It would follow from this, and indeed, it has been proved— that when fat is taken with a meal, the stomach empties so slowly that the duodenal contents never become more than slightly acid, whereas in absence of fat the pH falls considerably during emptying of the stomach.

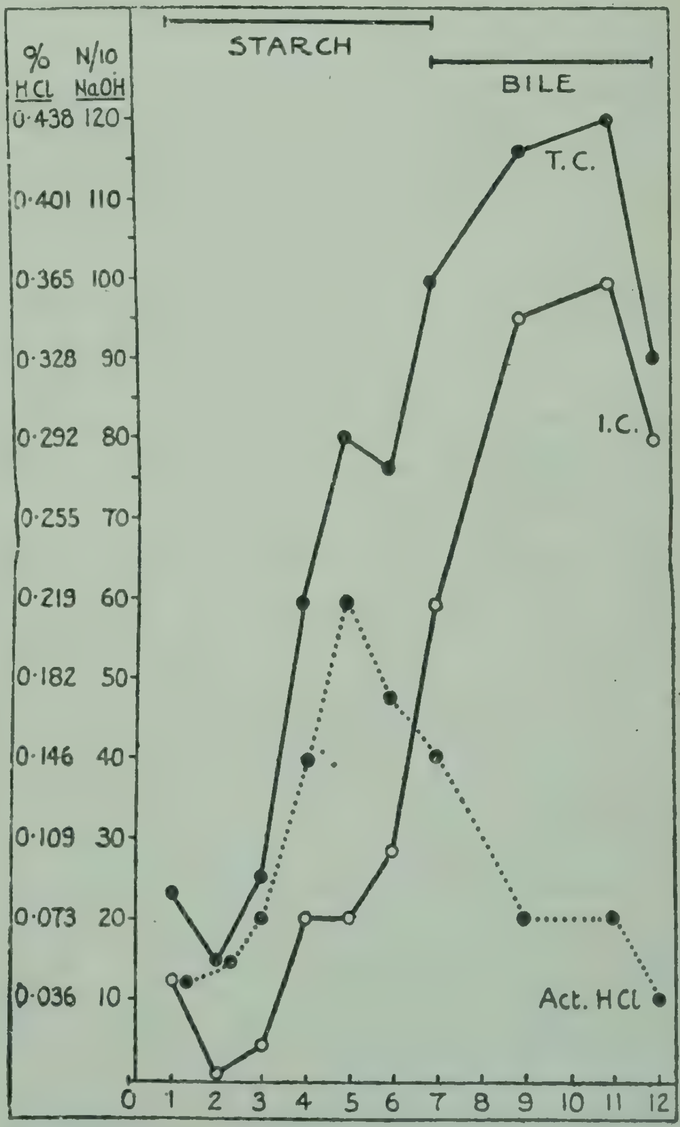

FIG. 568. Analysis of Gastric Contents at 15 min. intervals after a Test Meal of Gruel. T.C., total chlorides; I.C., inorganic chlorides. Act.HCl., "active" hydrochloric acid. (BOLTON.)

Towards the end of digestion a regurgitation of duodenal contents into the stomach will occur if the pressure is higher in the duodenum than in the antrum. The normal pressure in the duodenum is about 15 cm. water, and the pyloric intragastric pressure only 10 cm. during relaxation, but 20 to 30 cm. during an intense wave.

* SPURRELL. *J. Physiol.*, 1935, **84**, 4.P.

† CRIDER and THOMAS. *Amer. J. Physiol.*, 1938, **123**, **44**.

‡ MCSWINEY and SPURRELL. *J. Physiol.*, 1935, **84**, 41.

The contractions of the duodenum itself play an important part in regulating the emptying of, and regurgitation into, the stomach. Forward contractions empty the duodenal cap and facilitate exit from the stomach. Anti-peristalsis also occurs and, by filling the duodenal cap, gives an opportunity for regurgitation (Bolton).

The exact parts played in this mechanism by the local nerve net and by the central nervous system respectively have not yet been thoroughly made out, though there is no doubt that some movements may proceed independently of any connection with the central nervous system.

When the stomach is empty the pylorus is kept relaxed, admitting of the free entry of duodenal contents (pancreatic juice and bile) into the stomach. But this regurgitation, especially of pancreatic juice, seems to be a frequent phenomenon even during digestion, and particularly when the meal contains fat, and to be a means by which the acidity of the gastric contents is prevented from rising above an optimum of 0·15 to 0·2 per cent. HCl.

Fractional examination of the gastric contents shows that, normally, the acidity reaches a maximum and then declines ; after the decline has begun, bile is present in the fractions, showing that regurgitation has occurred (Fig. 568). If regurgitation is prevented in any way, the contents do not show the declining acidity, and no bile is found (Bolton).

The " *pangs of hunger* " are associated with, and are probably due to, prolonged rhythmic contractions of the stomach wall, which come on as soon as the stomach is empty, and increase in force and frequency ; each contraction lasts about 20 seconds, and is accompanied by salivation and augmentation of the knee-jerks.* The hunger contractions are inhibited by the introduction of food into the stomach, by the act of swallowing and also by intravenous injection of glucose. Administration of insulin, which lowers the blood sugar, augments the contractions and causes hunger pangs.†

Vomiting. Rejection of the stomach contents may occur as a result of over-distension, especially of the pylorus, of the presence of irritating contents, or reflexly from various organs. It is generally preceded by a feeling of nausea, associated with excessive salivation, and other signs of central autonomic stimulation, *e.g.* pupil dilatation, sweating, pallor, etc. In the act of vomiting itself, the first event is a deep inspiration. The glottis is then closed and the nasal chamber often shut off by raising of the soft palate, and this is followed by a strong contraction of the diaphragm and of the abdominal muscles. At the same time the œsophagus, the body of the stomach and the cardiac orifice are relaxed, and the tone and movements of the upper intestine first inhibited, and then augmented.‡ By means of X-rays it is seen that at this time a strong contraction occurs at the incisura angularis, dividing the stomach into two separate portions. The dilated body of the stomach is pressed between the abdominal muscles and the diaphragm, so that its contents are expelled. Contraction of the body of the stomach may be slight or absent and the main factor in the expulsion is the contraction of the abdominal muscles and diaphragm. In fact, vomiting may be excited in an animal in which the stomach has been replaced by a bladder. Finally, the œsophagus is emptied, partly by the positive pressure in the chest as a result of the action of the abdominal muscles, partly by contraction.

Nervous Mechanism of Vomiting. Normally the action of vomiting is reflex. It can be excited by tickling the back of the throat, when the afferent nerves are the trigeminal and the glossopharyngeal, or by irritation of the stomach, through the afferent fibres of the vagus. But it may be excited reflexly from almost any of the abdominal viscera, *e.g.* uterus, kidney, intestines, etc., or through the labyrinth or eyes, as is supposed to be the case in the vomiting of sea-sickness, and it is a marked symptom in many cases of disease of the cerebrum or cerebellum. The efferent impulses are carried by the vagi to the stomach, by the phrenics to the diaphragm, and by the various spinal nerves to the abdominal muscles. There are also inhibitory impulses descending the vagi to the œsophagus and cardiac sphincter, and inhibitory, followed by excitatory, impulses to the intestines.* The reflex act depends on the integrity of the medulla (" vomiting centre "). Drugs may produce vomiting either reflexly, by irritating the stomach, *e.g.* mustard and water, or by direct action on the medullary centres, *e.g.* apomorphine, etc.

5. INTESTINAL DIGESTION

The contents of the stomach are passed at intervals into the first part of the duodenum. Here they meet the secretions of the pancreas, the liver, the tubular glands of the intestine, and the secretion of Brunner's glands. The acidity is partly neutralised in the duodenum, the contents of which have a fasting pH of about 6·5, which may fall to 3·5 during gastric emptying ; further reduction of acidity occurs lower down in the intestine, the pH in the ileum being about 6·0 to 6·5, though alkalinity occurs rarely if at all.

The secretion of these various juices is simultaneously aroused by the entry of the acid chyme into the duodenum. Although they co-operate in their action on the foodstuffs, it will be convenient to deal separately with each.

Duodenal Contents. Samples of the duodenal contents may be obtained in man by passing an Einhorn's duodenal tube, a 30-in. long narrow rubber tube with a small lead plummet embedded at the end. This is swallowed, and when the plummet reaches the stomach the patient lies on the left side until it reaches the duodenum, where its position can be verified by X-ray examination. By suction with a syringe the contents, frothy, and yellow, are withdrawn. If 20 c.c. of 50 per cent. $MgSO_4$ is injected down the tube a copious flow of bile follows.

The Pancreatic Juice

The Secretion of Pancreatic Juice. The normal secretion of pancreatic juice can be studied on an animal with a pancreatic fistula.

In order to establish a pancreatic fistula in a dog, a small piece of the duodenal wall is exsected, having the papilla of the lower (and larger) duct opening in the middle of its mucous surface. The integrity of the gut is restored, and the exsected piece is brought to the surface and stitched in the middle of the abdominal wound. The greater part of the pancreatic secretion will escape by the fistula, and can be collected. An alternative and more modern method is to tie a glass cannula into the pancreatic duct, and to it attach a rubber tube which is led out through the abdominal wall. The continual loss of pancreatic juice may seriously affect the animal's health. This may be obviated to a certain extent by keeping the animal on a milk diet with the addition of sodium bicarbonate to replace the loss of base by the juice.

Clinical observations of human pancreatic fistulæ have confirmed the experiments made on dogs.

In the fasting condition there is for long periods (one to two hours) no expulsion of juice from the duct. Probably, however, there is occasional slow secretion of juice, coincident with a phase of spontaneous periodic activity of the alimentary canal (Babkin), so that the escape of a few drops may be observed at long intervals. If a meal be administered, a flow of juice begins in one to two minutes. This first secretion is reflex. From this time there is a steady, slow rise in the rate of secretion, which lasts for two to three hours, and then gradually diminishes. The greatest increase in flow is observed at the time when the first portions of digested food escape from the stomach into the duodenum. The secretion must therefore be determined in some way by this entry into the duodenum. By experiments on dogs possessing a gastric as well as a pancreatic fistula, it has been shown that the introduction of acid, *e.g.* 0·4 per cent. HCl, into the stomach evokes, as soon as it passes into the duodenum, a rapid flow of pancreatic juice. A smaller effect is produced by the passage of oil from the stomach into the duodenum. The introduction of alkalies is without influence. Dilute acids are also effective exciters of secretion when introduced directly into the duodenum or small intestine. The secretion produced diminishes as the loop employed is nearer to the cæcum, and as a rule the injection of dilute acid into the lower foot or eighteen inches of ileum is without effect. This response to acid is not due to a reflex, but to a humoral (chemical) mechanism.

* Gregory. *J. Physiol.*, 1947, **106**, 95.

Nervous Secretion. The pancreas receives fibres from the vagi and from the splanchnic nerves. Pavlov noticed that if the vagus on one side were cut in the neck and left for four days in order to allow the cardio-inhibitory fibres to degenerate, prolonged stimulation of the peripheral end of the nerve evoked a slow flow of pancreatic juice. He obtained the same results by stimulating this nerve below the heart, in animals with the cervical spinal cord divided. Pancreatic secretion resulted from vagus stimulation when every care was taken to prevent acid stomach contents being expelled into the duodenum by contraction of the stomach wall ; *e.g.* when the pylorus was ligatured and the stomach filled with an alkaline solution. There can be no doubt that the vagus is a secretory nerve to the pancreas, and that the secretion of pancreatic juice which occurs within a minute or two of the taking of food is a reflex. The juice obtained by vagus stimulation is glairy, very concentrated in solids, and rich in enzymes. When secretion has been established by prolonged and repeated stimulation of one vagus, a stimulation of the other vagus at first checks it. This is due to constriction of the ducts.* A slight secretion, inhibited by atropine and potentiated by eserine, also occurs on stimulation of the splanchnic nerves, but not on injection of adrenaline. The splanchnic therefore contains some cholinergic fibres.†

Humoral Secretion. The injection of acid into a loop of small intestine is followed by secretion of pancreatic juice. Bayliss and Starling ‡ found that a secretion of juice was produced even when the acid was introduced into a loop of the small intestine entirely freed from any possible nervous connections with the rest of the body. It was evident, therefore, that the stimulus from the intestine to the pancreas, which causes the secretion of the latter, must be carried, not by the nervous system, but by the blood stream. The injection of acid into the portal vein was without effect, but on boiling some scrapings of the intestinal mucous membrane with dilute hydrochloric acid, neutralising and filtering, and injecting the filtrate a copious flow of pancreatic juice was produced. This classical experiment provided the first known instance of a chemical excitant, and the name " hormone " was given to this class of substances.

Secretin. This chemical messenger, or hormone, is called " secretin." That it is present in the mucous membrane is shown by the fact that secretin can be extracted also by water, solutions of soap, or dilute alkali, or by the prolonged action of alcohol upon mucous membrane which has been killed by heat. Neutral solutions, however, extract less secretin than do acid solutions.

This may be because some of the secretin is held in an adsorbed or otherwise "bound" form, from which it is freed by acids.*

Highly active preparations of secretin may be prepared in various ways. One † is by extraction of the duodenal mucosa with absolute alcohol, precipitation by dilute acid, and resolution of the precipitate in acid alcohol and precipitation by acetone. Various other methods have been used and crystalline preparations ‡ § may be obtained. Greengard and Ivy's crystalline secretin is obtained as a picrolonate of empirical composition C_3H_5ON; 0·014 mg. of the free secretin from this = 1 Ivy-dog-unit, *i.e.* it gives 1 c.c. of juice. It is a readily soluble substance resembling a protein or high polypeptide, is rapidly destroyed by pepsin and trypsin, and diffuses slowly through animal membranes. Though stable in acid solutions, it is very rapidly destroyed in alkaline or neutral solutions, especially under the influence of bacteria.

In this secreting mechanism we have an example of a correlation effected by chemical means, between the activities of two different portions of the body. The acid chyme enters the first part of the duodenum. Immediately a certain amount of secretin is extracted by the acid, is carried by the blood stream to the cells of the pancreas and excites there the secretion of strongly alkaline pancreatic juice. As soon as sufficient juice has been secreted to nearly neutralise the acid chyme, the formation of secretin, and therefore the further secretion of alkali, comes to an end. If the stomach still contains food, however, the process is renewed, the pylorus relaxes and allows the entrance of a further portion of acid chyme. Thus the whole chain of processes goes on until the stomach is empty and all its contents have passed into the intestine. One of the actions of the powerful secretin preparations made by Mellanby is that it causes contractions of the intestinal muscle; it also causes some bile secretion.

STILL (1931). Secretin. *Physiol. Rev.*, **11**, 328.

"***Pancreozymin.***" Pure secretin produces a secretion of water and salts, but does not excite secretion of enzymes, though crude secretin preparations do so. Further, when a meal is given to a dog with a transplanted pancreas, the enzyme content, as well as the amount of the juice secreted, increase.||

The explanation appears to have been provided by the discovery that, as usually prepared, secretin extracts contain a substance which does excite the secretion of enzymes, but not of water and salts. The substance is called pancreozymin, and it and secretin can be prepared free each of the other. The two substances are extracted together by alcohol: the alcohol is distilled off, the secretin removed by bile-salts, and the pancreozymin precipitated by sodium chloride.¶ Pancreozymin appears to have similar chemical and physical properties to secretin. It accompanies secretin in the epithelium of the intestine. Like vagus stimulation, pancreozymin causes a discharge of zymogen granules from the cells of the pancreatic acini, which secretin alone does not. But pancreozymin acts on the atropinised pancreas, while vagus stimulation does not. Its action is thus probably a direct one on the cells.**

The secretin mechanism provides alkali for the neutralisation of the acid stomach contents. But the pancreozymin and the nervous mechanism provide the enzyme content of the juice, so that, even when for any reason the gastric contents are not acid, pancreatic digestion is still possible.††

In the absence of HCl from the gastric contents, it is doubtful what is the responsible agent in starting the secretin mechanism. The presence of bile or

bile salts in the intestine does not augment the secretion of pancreatic juice, and may even reduce the response to acid, peptone or soap.*

The amount and activity of pancreatic juice obtained after a meal varies with the nature of the latter. The differences seem largely determined by the amount of acid passed on to the duodenum, and by the presence of specific excitants, such as fat and soap, which raise the enzyme content of the juice.

Electrical Changes. Stimulation of the pancreas by secretin injection causes electrical changes in which the duct of the pancreas becomes positive to the surface of the gland.†

THE STRUCTURAL CHANGES IN THE PANCREAS ACCOMPANYING SECRETION. A normal resting gland on section is seen to consist of numerous secreting alveoli, the cells of which present two well-marked zones: a narrow peripheral zone in which the nucleus is embedded, and which is strongly basophile; and a central zone which is turned towards the lumen, occupying two-thirds or three-quarters of the cell, and is closely packed with highly refractive granules, strongly oxyphile, and containing the zymogens of the pancreatic juice (Fig. 569 A). After the induction of secretion by stimulation of the vagus, the lumen of each alveolus is enlarged, the cells are shrunken, and the granules are found to lie only along the border of the cell turned towards the lumen, the rest of the cell, which is much reduced in size, being made up of the basophile cytoplasm (Fig. 569 B). After secretion has been caused by secretin injection, the changes are only slight.

Properties of Pancreatic Juice. Pancreatic juice can be obtained by the injection of secretin or pilocarpine intravenously, or by stimulation of the vagus. The average composition varies according to the means used to cause secretion, as is shown in the table on p. 879.

"Secretin" juice is a clear or slightly opalescent fluid, alkaline ($p\text{H} = 7\text{–}8$) from the presence of sodium bicarbonate, its titratable alkalinity varying between $\frac{N}{10}$ and $\frac{N}{7}$ alkali, and therefore about equivalent to gastric juice in normality. The proteins include the enzymes and serum proteins. The juice tends to become poor in enzymes, but not in alkali, as secretion proceeds. The concentrated juice obtained by injection of pilocarpine, or by vagus stimulation, which

may contain as much as 6 per cent. total solids, is always considerably less alkaline and richer in proteins and enzymes than the more dilute juice got by injection of secretin.

The most interesting and important constituents of the juice are its enzymes. The juice on arrival in the intestine has an effect on proteins, fats and carbohydrates, due to the presence of distinct groups of enzymes, viz. trypsin, lipase and amylase.

The pancreas tissue contains the same enzymes as the juice, and in the same relative amounts.

The Activation of Pancreatic Juice. Freshly secreted pancreatic juice, collected without contact with the intestinal mucosa, has no digestive action on egg-white, though able to digest peptone, histone or protamines. Succus entericus very rapidly activates it, owing to the presence in it of *enterokinase.** Enterokinase acts like an enzyme † on the inactive enzyme (trypsinogen), splitting off a polypeptide and releasing the activated enzyme trypsin. Trypsinogen has been prepared in pure crystalline form,‡ and is rapidly activated by enterokinase at about *p*H 5·5.

Most of the controversy as to whether enterokinase is an enzyme appears to be due to the use of crude preparations.§ Pure crystalline trypsinogen is autocatalytically activated by the minutest trace of trypsin. Crude preparations, however, contain an inhibitor of trypsin which checks this reaction, so that normally only the kinase can start it, and this is the state of affairs in the alimentary tract, where activation occurs in a few seconds.

If pancreatic juice be allowed to stand, it gradually acquires activity. If, however, sodium fluoride be added, the juice remains permanently inactive. The spontaneous activation of the juice may be hastened by neutralisation. The most potent means next to enterokinase is the addition of calcium salts. According to J. Mellanby and Woolley ‖ the calcium acts simply by neutralising the juice and thus allowing minute traces of kinase already present in the juice to exert their effect; or it might act by diverting the trypsin inhibitor.

The Action of Pancreatic Juice on Proteins. Activation is effected directly the juice enters the gut, and it thus acquires a proteolytic activity superior to that of any other digestive juice.

The enzymes of the juice may be separated from one another, and so studied separately, by appropriate adsorption treatment as outlined in Chapter IX.

Inactive pancreatic juice contains two zymogens, viz. chymotrypsinogen and trypsinogen.* Chymotrypsin clots milk, and hydrolyses casein and gelatine, but differently from trypsin; it does not hydrolyse polypeptides in general. Enterokinase converts trypsinogen to trypsin, but does not act on pure chymotrypsinogen. This is, however, acted upon by trypsin and converted into chymotrypsin. Hence, enterokinase added to a mixture of the two zymogens results in activation of both.

Trypsin acts on proteins generally, converting them to polypeptides.

It is now known that "trypsin" is a mixture of several proteolytic enzymes, *e.g.* trypsin, aminopolypeptidase, carboxypolypeptidase, protaminease, and no doubt others. It also contains a substance which inhibits trypsin. These enzymes act in different ways, or on different substrates. Thus carboxypolypeptidase does not act on proteins, but only on some of their hydrolysis products, from which it splits off a terminal amino acid which in the intact substrate had a free carboxyl group. The free amino group is not necessary and hence carboxypolypeptidase will act on peptic digests which have been treated with formaldehyde to remove free NH_2 groups.† Aminopolypeptidase only acts on polypeptides with free α-amino groups, splitting off the amino-acids.

The different constituents of the protein molecule show a varying resistance to the action of trypsin. Denaturation of the protein may be the earliest stage. The greater part of the molecule is rapidly broken down and yields proteoses, peptones, polypeptides, and amino-acids; and the same change is undergone by the proteoses and peptones resulting from the gastric digestion of proteins. Within a few minutes, therefore, after the chyme has reached the small intestine, a certain amount of amino-acids will have been formed. Trypsin thus differs fundamentally in its action from pepsin, which never yields amino-acids. Some of the products present a resistance to disintegration. This part gives the biuret reaction. Even when the trypsin has acted *in vitro* for weeks, and the biuret reaction has entirely disappeared, the mixture will be found to contain, in addition to the separate amino-acids, some lower polypeptides not attacked by trypsin.

In all, activated trypsin alone can split about half the peptide linkages in native protein. Why it leaves some simple polypeptides unattacked is not at present explained. The investigation of its action on the higher polypeptides has shown that very minute differences in the grouping of the molecule may determine whether or not the molecule is attacked by trypsin.

CONDITIONS OF TRYPTIC ACTIVITY. The contents of the duodenum are faintly acid (pH 4·5—5·1). *In vitro*, trypsin is more active in alkaline solutions. The optimum pH varies with the substrate, *e.g.* 9·7 for gelatin and 8·0 for caseinogen and peptone. However, trypsin in alkaline medium is extremely unstable, though the destructibility of trypsin, as well as its action, is largely affected by the presence of proteins or their digestion products in solution. The trypsin enters into some form of combination with the protein molecule and this protects the trypsin from the destructive action of alkali. Destruction of the enzyme nevertheless occurs in the intestine, and intestinal contents collected at the lower end of the ileum show little proteolytic activity.

THE ACTION OF PANCREATIC JUICE ON MILK. On the addition of activated pancreatic juice to milk, a clot is produced which speedily redissolves. The inactive juice has no milk-clotting action. The enzyme to which the effect is due is called *chymotrypsin*, and it closely resembles trypsin, with which it is associated. The two enzymes have, however, been separated in crystalline form.

The Action of Pancreatic Juice on Carbohydrate. The pancreatic juice, as well as a fresh extract of the pancreas itself, contains a strong amylolytic enzyme, amylase or amylopsin (optimum $p\text{H} = 7{\cdot}0$). The stages in the hydrolysis of starch brought about with pancreatic juice are exactly similar to those effected by ptyalin.

If the juice be neutralised, or faintly acidified, the process of hydrolysis goes on to the formation of glucose.‡ This is due to the presence in the juice of a second enzyme—maltase—which converts maltose into glucose. The juice in the gut is therefore able to effect the further digestion of the products of salivary digestion. On the other disaccharides pancreatic juice is without effect.

The Action of Pancreatic Juice on Fats. Fresh pancreatic juice contains a powerful esterase, called *lipase*, by means of which, in the presence of water, neutral fats are broken up (*v.* p. 26) into glycerol and the corresponding fatty acids. This enzyme is active either in an alkaline, neutral or very slightly acid medium (optimum at pH = 8·0). It also hydrolyses various other esters besides fats. If the reaction be alkaline, the fatty acids produced by the lipolysis combine with the alkali present, with the formation of soaps. The enzyme may be obtained from extracts of the fresh gland, but is rapidly destroyed if active trypsin be present. It is also contained in some of the dried commercial preparations of trypsin. It is insoluble in distilled water, but easily soluble in glycerol. The velocity with which lipolysis occurs is much increased (four to five times) by the addition of bile. This adjuvant action of bile is due entirely to the bile salts. These act, firstly, as activators of lipase ; secondly, by assisting emulsification, so exposing a larger area of fat to the enzyme ; and thirdly, by helping to dissolve substances otherwise insoluble in water, as explained later.

Adaptation of Pancreatic Juice to Diet. The enzymes of the pancreatic tissue alter in quantity according to the nature of the diet, so that, *e.g.* on a high carbohydrate diet there is after a time an increased amount of amylase and a reduced amount of trypsin. After a period on a high fat diet, however, all the enzymes are reduced, though the lipase suffers least. The following table shows the type of change caused by habituation to given diets.

6. THE LIVER AND BILE

In the adult, the relation of the liver cells to the ducts is entirely subordinated to their relation to the blood vessels of the organ, and it requires special histological methods to make out the relations between the liver cells and the bile ducts. The circulation through the liver is described in Chapter XXXV.

Liver tissue is very rapidly removed if it becomes necrotic as, *e.g.* after occlusion of a branch of the hepatic artery or after chloroform poisoning ; it rapidly grows again after destruction or removal and regains its normal size. Even after extirpation of three-fourths of the liver the remainder soon recovers its normal size, though it is of softer texture. The liver varies greatly in size according to the state of digestion, and in fasting may be only half the normal size. The size of the liver is very delicately adjusted, and if after removal of part of the liver the animal be fasted, recovery growth ceases when the size of the fasting liver has been reached. (Rous.)

As might be expected from its structure, the secretory functions of the liver represent but a small proportion of its activities in the body. The liver is in fact the greatest chemical factory of the body, receiving by the portal vein the products of digestion as they are absorbed from the alimentary canal. It converts these into other substances, breaking them down or building them up according to the needs of the body as a whole. Hence the liver plays an important part in the metabolism of proteins, carbohydrates and fats, so that its functions will have to be dealt with in the various chapters concerned with the fate of the different foodstuffs in the body.

---

* GROSSMAN, GREENGARD and IVY. *Amer. J. Physiol.*, 1943, **138**, 676.

So-called tests of "liver function," carried out for purposes of clinical diagnosis, each examine only one aspect of the liver's many functions. Among other changes seen in hepatic derangement are a rise of plasma bilirubin, phosphatase and globulin, a fall of plasma albumin, and reduction of lævulose tolerance and of hippuric acid synthesis.

The Bile. In addition to its function in digestion, the bile must also be regarded as an excretion representing the channel by which the products of disintegration of hæmoglobin are got rid of. Hence the production of bile must be continuous, but, as a digestive fluid, it is needed in the gut only during digestion. We therefore require a continuous excretion, but a discontinuous entry of bile into the small intestine. This is secured, in the majority of animals, by the existence of the gall bladder, in which bile, secreted during the intervals between the periods of digestive activity, can be stored up. In the horse and the rat, where the gall bladder is absent, its place is taken to some extent by the great size of the bile ducts. Since the bile accumulates in the gall bladder during the whole time that digestion is not going on, and is only poured into the gut during digestion, in a fasting animal the gall bladder is distended, whereas some hours after a meal it is less full.

The common bile duct and one of the pancreatic ducts open together into the duodenum in man, the ape, horse, cat and dog ; in other animals either the pancreatic duct opens into the bile duct (sheep, rat), or else the two open separately, the pancreatic duct being the further down the duodenum (ox, pig, rabbit, guinea-pig).

The gall bladder and bile ducts have an incomplete layer of peritoneum on the outside ; the middle coat consists of plain muscle and fibrous tissue and the inner lining of tall clear columnar cells. The common bile duct runs obliquely, sometimes for a centimetre or two, through the duodenal wall before opening on its inner surface. This part forms an expanded portion, or ampulla, having a strong muscular wall, which is further reinforced near the opening by a circularly arranged layer of plain muscle fibres, the sphincter of Oddi.

The epithelium of the gall bladder and bile ducts secretes a fluid containing mucin, and also absorbs water from the bile. When the cystic duct becomes obstructed the gall bladder ultimately becomes filled with a colourless mucilaginous secretion—the so-called "white-bile" of surgeons. During its stay in the bladder the bile is rapidly concentrated by the loss of water and by the addition to it of mucin or nucleo-protein, derived from the cells lining the bladder. This is shown by comparison of the composition of bile obtained from the gall bladder with that obtained from a fistula of the bile duct. The speed with which the gall bladder concentrates the bile is remarkable, the total solids of bladder bile reaching as much as ten times that of fistula bile, and the volume showing a corresponding reduction.

The inorganic salts are mostly sodium chloride and bicarbonate, the fixed CO_2 of the bile varying from 10 to 60 volumes per cent. The reaction of liver bile in the hepatic ducts is usually slightly alkaline (pH 7·7), while in the gall bladder it is slightly acid (pH 6·8) as a rule.

ANALYSES OF BILE (HUMAN) [per cent.]

From a biliary fistula (Yeo and Herroun)		From the gall bladder (Czyhlarz *et al.*)	
Mucin and pigments	0·15	Mucin	1·64
Sodium taurocholate	0·06	Bile Pigments	0·16
Sodium glycocholate	0·16	Bile Salts	4·67
Cholesterol	0·04	Cholesterol	0·66
Lecithin		Lecithin	0·56
Inorganic salts	0·84	Inorganic Salts	0·85
Water	98·72	Water	90·57

From the point of view of digestion, the important constituents of bile are the "*bile salts*," with the lecithin and cholesterol held in solution by these salts.

The Bile Salts. Characteristic of bile are the so-called "bile salts," which give the well-known Pettenkofer reaction—a purple colour with cane sugar and strong sulphuric acid. The bile salts are sodium salts of mixtures of complex acids, called *glycocholic and taurocholic acids.* Glycocholic and taurocholic acid are both present in human bile, but in the bile of the dog and the sheep there is no glycocholic acid. These acids are compounds of the cholic acids, and can readily be resolved, by hydrolytic splitting of a peptide link by means of acids, into their proximate constituents thus :—

Glycocholic acid = glycine + cholic acid
Taurocholic acid = taurine + cholic acid.

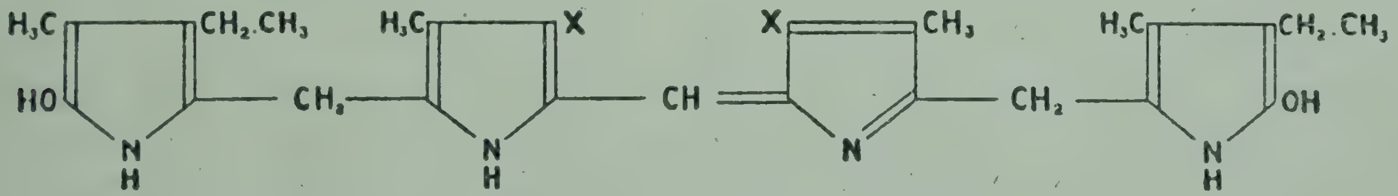
Taurine is amino-ethylsulphonic acid, $NH_2.CH_2.CH_2.SO_2.OH$, and is probably derived in the body from the metabolism of cystine.

The Cholic Acids (cholic acid, desoxycholic acid, chenodesoxycholic acid and lithocholic acid) are also often present free in the bile ; on dehydration and subsequent reduction all yield *cholanic acid*, $C_{24}H_{40}O_2$. Cholanic acid or its isomer, allo-cholanic acid, can be obtained from cholesterol by reduction, and subsequent oxidation with chromic acid. It is thus clear that the bile acids are chemically closely related to cholesterol (see formulæ, p. 28).

If cholic acid is administered it is rapidly re-excreted, and largely in the conjugated form if the liver is normal, and if glycine or taurine is also given or made available, as when a liberal protein diet is given. Although it is probable that the conjugation of the bile salts is effected in the liver, there is no conclusive evidence for this, and very little for the supposition that, in the body itself, cholic acid is actually derived from cholesterol.

Many substances, *e.g.* fatty acids, higher alcohols, etc., form loose compounds, called *choleic acids*, with desoxycholic acid, and as these compounds are soluble in water, the bile salts are capable of bringing into aqueous solution many normally insoluble substances. This is called "hydrotropic action."

The Bile Pigments, *bilirubin* and *biliverdin*, are by-products, formed by the cells of the reticulo-endothelial system in various parts of the body from hæmoglobin of the blood (p. 522). Injection of hæmoglobin into the blood stream, or extensive destruction of blood in the body, lead to an increased formation of bile pigment. The pigment thus formed circulates in small amount in the blood plasma from which it is excreted by the liver into the bile. The bile pigments pass into the intestine, and are there converted by bacterial reduction into stercobilin which is excreted for the most part with the fæces, a small proportion being absorbed into the blood and turned out as stercobilin in the bile or as urobilin in the urine. When the bile of a dog is all drained off by a biliary fistula, stercobilin disappears from the fæces and bile ; if bile is given by mouth it reappears. When absorption of stercobilin is excessive, urobilin appears in the urine.



Urobilin. ($X = -CH_2 \cdot CH_2 \cdot COOH.$)

The Secretion of Bile. It is important to distinguish between the formation of the bile in the liver, which is a continuous process, and the expulsion of the bile, either direct or from the gall-bladder, into the intestine, which is discontinuous and principally dependent on the taking of food. The time-relations and other phenomena of the secretion of bile can be learnt from animals or men in which, by operation, the bile is conducted to the outside by means of a permanent fistula. Very little reliable information can, however, be obtained direct from men, and most of our information has been obtained from dogs. Of the various types of operation suited for the study of the bile flow, the best is probably that called "altercursive intubation," is illustrated in Fig. 570.

The secretion of the bile is independent of the action of the nervous system on the liver, since complete denervation of the liver leaves it unaltered and does not affect the influence of food on bile secretion.[*] Bile formation also occurs in an excised perfused liver. Though the bile is always being secreted, the amount and concentration are both lowered during fasting. It is also reduced if the bile as it is formed is collected instead of being allowed to enter the duodenum.

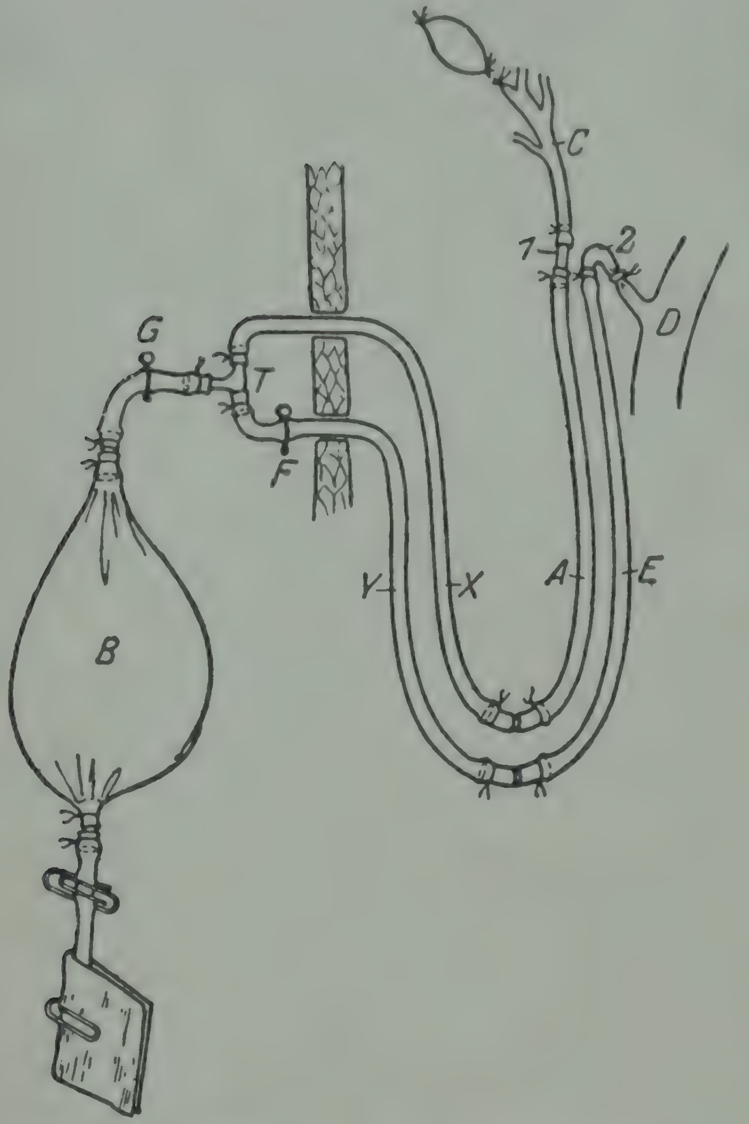


FIG. 570. Schema of the operation for "altercursive intubation." The bile can flow normally from *C* along the tubes *A*, *X*, *T*, *Y*, *E*, into the natural opening in the duodenum. When desired, *F* is closed and *G* opened, so that bile collects in the rubber bag *B*. A manometer can be connected to *X* to register secretion pressure, or a bile-filled manometer connected to *Y* to measure the resistance to flow of bile into the duodenum. The gall-bladder is excluded by ligatures. (McMaster and Elman, *J. Exp. Med.*, 1925, **41**, 513.)

If the hepatic duct be obstructed, as by attaching to it a manometer (Fig. 570) filled with bile, it is found that the flow continues at a constant rate, so that the pressure rises uniformly, until a pressure of about 300 mm. of bile is reached, at which point it abruptly ceases. At this level reabsorption of the bile into the lymph and/or blood takes place.

The rate of bile secretion in man is about 15 c.c. per kg. body weight per day, or, say, about 800–1,000 c.c. for average adults ; in dogs it varies in different individuals between about 5 c.c. and 20 c.c. per kg. per day. When food, especially meat or fat, is taken, the rate of secretion begins to increase in about an hour and reaches a maximum in two to five hours after the taking of food, then declining to the fasting rate. Carbohydrate food causes no increase. The secretion of the bile, after meat or fat, thus runs roughly parallel to that of the pancreatic juice.

Various other substances cause an increased bile secretion when introduced into the stomach or duodenum, even after the division of all the nervous connections of the liver. The most potent of these is bile, or the bile acids,[†] which also increase the total solids of the bile formed. The active substance is cholic acid, which acts similarly when given by intravenous injection. The introduction of dilute acids into the duodenum, or the intravenous injection of secretin [‡] also greatly augments the bile flow. Probably an alteration in the blood flow to the liver is an important factor in modifying the rate of bile secretion.

Bile Storage and Expulsion. The alterations occurring in the size of the gall-bladder can be most readily observed clinically by the administration of tetra-iodo-phenol-phthalein, which is excreted in the bile and is opaque to the X-rays, so that the outline of the gall-bladder can be seen on X-ray examination (Graham-Cole test).

[†] J. Mellanby. *J. Physiol.*, 1928, **64**, 331.

[‡] Still, McBean and Ries. *Amer. J. Phys.*, 1932, **99**, 94.

The storage of bile in the gall-bladder and its expulsion therefrom are best investigated by simultaneously studying the pressure of bile in the common duct and the resistance to its entry into the duodenum. This may be done by the triple intubation operation of McMaster and Elman,* shown in Fig. 571. The sphincter of Oddi is competent to close the entrance of the bile duct into the duodenum when the pressure of bile is low (below 150 mm. H_2O), and its action is further aided by contraction of the muscular wall of the duodenum itself.† After a fast of twenty-four hours, or on a carbohydrate diet, the resistance to the entry of bile into the duodenum is high, sometimes as great as 300 mm. H_2O. Hence the bile as it is secreted by the liver is diverted into the gall-bladder, and, since it is there very rapidly concentrated by loss of water, the storage of bile can continue for days without there being a great rise of pressure in the bile ducts, in which it is usually about 100 mm. H_2O during fasting. There is thus no entry of bile into the duodenum, since a pressure over 300 mm. would be necessary to force the sphincter.

When food is seen or eaten, there is at once a lowering of the sphincter resistance and a contraction of the gall-bladder great enough momentarily to raise the pressure in the duct system to about 200 mm. H_2O. This is probably assisted by a contraction of the ampullary part of the common duct. A gush of bile into the duodenum follows. Afterwards the resistance suddenly rises again, but in about half an hour another rise of pressure with relaxation of the sphincter occurs, and thereafter at fairly frequent intervals for the next few hours bile is expelled into the duodenum.

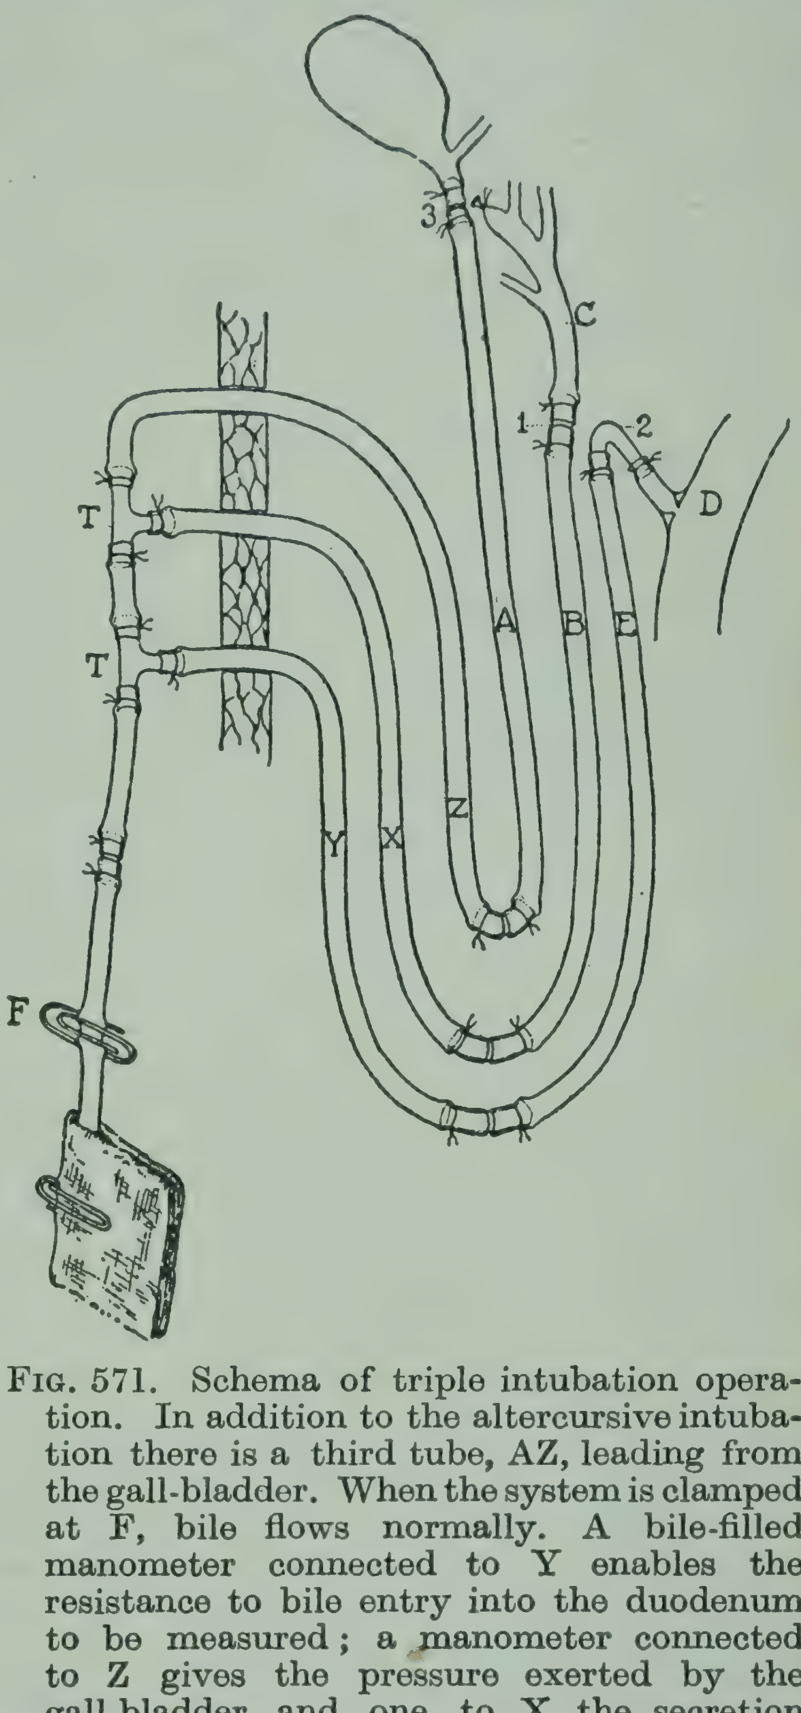

Fig. 571. Schema of triple intubation operation. In addition to the altercursive intubation there is a third tube, AZ, leading from the gall-bladder. When the system is clamped at F, bile flows normally. A bile-filled manometer connected to Y enables the resistance to bile entry into the duodenum to be measured; a manometer connected to Z gives the pressure exerted by the gall-bladder, and one to X the secretion pressure of the bile. (McMaster and Elman.)

The control of the gall-bladder seems to be a twofold one—by a reflex and by a hormone. The muscular wall of the gall-bladder shows rhythmic contractions, and is under the control of the vagus and the sympathetic,‡ the former conveying motor and the latter inhibitory impulses, while the sphincter of Oddi receives branches from the same sources, but having the opposite functions. It seems certain that the sight of food, or the act of eating it, causes a reflex contraction of the gall-bladder, with reciprocal relaxation of the sphincter of Oddi. It has also been supposed that the entry of acid into the duodenum provokes a similar reflex,* and there is clear evidence that under these circumstances the resistance of the sphincter is reduced.

† Lueth. *Amer. J. Physiol.*, 1931, **99**, 237.

‡ Bainbridge and Dale. *J. Phys.*, 1905, **33**, 138; Westphal, *Z. f. klin. Med.*, 1923, **96**, 52.

That much of the activity of the gall-bladder is due to the action of a hormone liberated into the blood by the presence of certain substances in the duodenum seems equally certain. Acids, fat and egg-yolk are the most active substances, and cause contraction even of the denervated gall-bladder, when they are introduced into either the intact intestine, or a transplanted loop. Ivy and Oldberg † have extracted from the duodenal mucosa a secretin-like substance, "*cholecystokinin*," which stimulates contraction of the gall-bladder when injected.

Introduction of magnesium sulphate into the duodenum causes relaxation of the sphincter and expulsion of bile. Morphine causes strong spasm of the sphincter.

It is of interest to note that the expulsion of bile into the duodenum serves a twofold function. First, it promotes pancreatic secretion by aiding in the transference of secretin into the blood, and secondly, it augments the formation of the bile itself.

Entero-hepatic Circulation. Although bile is regularly passed into the intestine, very little bile salts are to be found in the fæces. This is because they are reabsorbed from the intestine into the portal blood, whence they are picked up and excreted again by the liver : this is called the entero-hepatic circulation of the bile salts. Hence, if a biliary fistula is made, so that the bile is lost from the body, the cholic acid derivatives of the bile rapidly decline, but they finally reach a steady level at about 100 mg./kg/day in dogs, or about 1·5 g./day for man. This means that new formation of cholic acid occurs at that rate—the so-called " endogenous production." If now, in the fistula dog, we return bile of known cholic acid content to the duodenum, the output of cholic acid by the bile rises by an amount equal to that administered, minus about 12 per cent., whatever the amount of cholic acid, within limits, given.‡ If we thereafter regularly return all the bile produced, the daily output of bile acids steadily subsides (or rises), until it sooner or later reaches a new steady level, at which synthesis exactly balances loss. This level depends on the diet, but can be about 1 g./kg./day for the dog. One of the factors which brings about this homoiostatic control is probably the effect of bile salts in increasing the rate of secretion of bile, so quickening up the entero-hepatic circulation, and increasing the loss (= 12 per cent. of turnover), and *vice versa*. Owing to the fact of their ready excretion by the liver cells, bile salts are the most reliable cholagogues with which we are acquainted. By this circulation of salts between liver and intestine, the synthetic work of the liver in the production of the bile salts is reduced to a minimum, and it has only to replace such of the bile salts as undergo destruction in the alimentary canal under the influence of micro-organisms, or as are lost to the organism by passing out in the fæces as a gummy amorphous substance known as *dyslysin*.

There appears also to be a similar circulation of the bile pigments. Thus, if in a dog with altercursive intubation the bile is collected in the bag for a time, the pigment content of the later samples secreted becomes reduced. If the bile be now returned to the duodenum, the pigment content of the subsequently secreted samples of bile is increased again. If the dog be fed with the bile of an herbivorous animal, the characteristic herbivorous pigment appears in the dog's bile. The presence of bile in the intestine seems to be essential to health. If the bile is all led away, bone defects are liable to occur, and a serious state of anæmia sets in ; the animal is restored to health again by being fed with bile, or with blood or blood pigment.

The Digestive Functions of the Bile. The digestive functions of bile are due, not to the presence of enzymes, but to the bile salts. Most important is the part played in the digestion and absorption of fats. The fat-splitting action of pancreatic juice is at least trebled by the addition of bile, whether boiled or unboiled.

‡ BERMAN *et al.* *Amer. J. Physiol.*, 1941, **131,** 776.

In the first place, the bile salts act as powerful emulsifying agents, as explained below.

Further, the bile salts are activators of pancreatic lipase, even when this acts on substances in solution. It is possible that this activating effect is due to the bile salts in some way bringing the enzyme and substrate into sufficiently close contact with one another. Lipase is insoluble in water, but soluble in fatty media. An important digestive function of bile, therefore, lies in the power of bile salts of serving as a vehicle for the suspension and solution of the interacting fats, fatty acids, and fat-splitting enzyme. This vehicular function is probably due to hydrotropic action, and plays an important part in the absorption of fats and cholesterol. These pass, with bile salts, through the striated basilar membrane bounding the intestinal side of the epithelium, and the bile salts are then released and carried by the portal vein to the liver.

The action of pepsin is checked by bile owing to its inclusion in a precipitate which is thrown down.

Emulsification of Fat. In the course of its digestion, triglyceride fat is very finely emulsified in the intestine, the particles being negatively charged, and the emulsion being stable over a considerable *p*H range, say 6·0–8·5. So many possible emulsifying agents (*v.* p. 27) are present in the intestine that attempts to explain emulsification suffer from a confusion of choice. Thus soap, fatty acid, monoglyceride, cholesterol, lecithin, bile salts, mucin and other proteins, can all, under certain conditions, act as emulsifying agents.

Trial, *in vitro*, of possible substances alone or in varied double or triple combinations indicate that the requisite criteria are satisfied by a triple combination of monoglyceride, fatty acid and bile salts. In digestion the monoglyceride and fatty acid are formed by lipolysis of some triglyceride, and then aid in emulsifying the remainder of it. The system of three agents ensures stability over wide *p*H ranges ; fatty acid supplies the charge on the monoglyceride-stabilised particle at the more alkaline *p*H ranges, while the fatty acid/bile salt complex provides the charge when the ionisation of the fatty acid is depressed in more acid media.*

Jaundice. If the bile ducts are ligatured, or obstructed in any way, so as to prevent the entry of bile into the intestine, the bile is reabsorbed and passes by the lymphatics into the blood stream. The bile pigment circulating in the blood permeates the various tissues of the body, giving them a yellow colour ; bile pigments and bile salts are also excreted with the urine. This condition is known as jaundice. Certain types of jaundice have long been known in which no apparent obstruction of the bile ducts was present. It was therefore assumed that in these cases the bile pigment was set free in the blood, apart from the activity of the liver. Pathologists thus distinguished two kinds of jaundice, hepatogenous and hæmatogenous. The existence of the latter form was long disputed, although it was known that bilirubin could be formed as a product of the disintegration of hæmoglobin in old blood clots. F. C. Mann succeeded in totally extirpating the liver, and, by means of injections of glucose, in keeping the animals (dogs) alive for thirty-six hours. He found that, six hours after the extirpation, bile pigment begins to accumulate in the blood and in the tissues, showing that this substance can be formed as the result of the disintegration of hæmoglobin without the co-operation of the liver, thus justifying the long-disputed division of jaundice into the two varieties of hepatogenous and hæmatogenous.

This conversion of hæmoglobin into bilirubin occurs in the scattered intravascular macrophages in the liver, spleen and bone marrow, all of which belong to the reticulo-endothelial system.

7. THE JUICES OF THE SMALL INTESTINE

The juice of the small intestine consists of the secretion of Brunner's glands, together with the *succus entericus*, or intestinal juice proper.

The glands of Brunner extend only over about an inch at the very beginning of the duodenum in the carnivora, but in the herbivora they may be found occupying the upper six inches of the intestine.

The duodenal secretion is rich in mucus, and is alkaline. There is no secretion during fasting, but juice begins to be formed within a few minutes of the taking of food. The natural flow occurs at normal rates after section of all nerves, and also in the transplanted duodenum.* The glands appear to contain a peptidase and an esterase,† but the only significant enzymes in their secretion are amylase and enterokinase. One function of the juice may be, by its mucin, to protect the mucosa from the gastric juice.

The intestinal juice proper is probably secreted by the Lieberkühn's follicles but the villi may also contribute to it. There are differences between the upper, middle and lower portions of the gut ; secretion is better marked in the upper portions, absorption predominates in the lower sections.

Secretion in the small intestine may be studied by isolating loops, in an anæsthetised animal, or better, by establishing permanent fistulæ, the best type being the Thiry-Vella. This consists in separating a loop of intestine, and restoring the continuity of the gut from which the loop had been excised. Both ends of the loop are left open and brought into the abdominal wound. In such a fistula it is easy to introduce substances into the upper end and determine the flow of juice from the lower end, the constant emptying of the loop being provided for by the peristaltic contractions of its muscular coat. Intestinal fistulæ resulting from war injuries have been studied in man by Savitsch, and have given results confirming those made on dogs. Observations can also be made by intestinal intubation in normal man.‡

In animals with intestinal fistulæ, no qualitative difference has been recorded between the upper and lower ends of the gut. Fasting animals show no secretion, or merely a scanty periodic flow about every two hours, from an empty loop. Administration of food is also without effect on the isolated loop, so long as this remains empty. Vomiting excites a reflex flow, through efferent vagal impulses.§ An important factor in exciting a flow of juice is local mechanical stimulation : thus the introduction of a drainage tube into the isolated loop is followed by a steady flow of succus entericus, whether the animal be fasting or fed. The flow of juice thus initiated is greatly modified by feeding the animal ; thus, a meal of fat will often double the rate of secretion.

It seems probable that the normal flow of intestinal juice is provoked locally by the presence, in the intestine, of its normal contents. One factor is the mechanical stimulus of the contents ; the other is probably a local chemical stimulation by various products of digestion.

The response to local mechanical or chemical excitation is apparently brought about through the local nerve net (Meissner's plexus), since section of the vagus does not abolish the reaction. But if nervous influence normally plays any part in causing secretion, it is probably effected through the vagi, since the rate of the secretion can be augmented by stimulation of the vagus, though only after a very long latent period (one hour), and the juice obtained, unlike that resulting from local mechanical stimuli, is very rich in enzymes. (Savitsch.)

As might be expected, cholinergic substances introduced into the blood stream, *e.g.* acetyl choline, eserine, or pilocarpine, produce secretion of the juice.

Certain facts seem to speak for an inhibitory action of the central nervous system on intestinal secretion. Thus it has been observed that extirpation of the nerve plexuses of the abdomen, or section of the splanchnic nerve, causes diarrhœa for two or three days. This might be determined by removal of inhibitory impulses normally arriving at either the muscle wall or the intestinal glands.

§ Gregory. *J. Physiol.*, 1947, **106**, 95.

There have been claims to have demonstrated the presence in the intestinal mucosa of a specific secretory hormone, called *enterocrinin*. Injection of crude (but not of pure) secretin causes a secretion of intestinal juice which may, of course, be attributed to the presence in it of "enterocrinin." It is also possible that general humoral mechanisms may play a part, though probably only a subsidiary one, in bringing about normal secretion of succus entericus.

Characters of Intestinal Juice. The intestinal juice obtained from a permanent fistula has a specific gravity of about 1,010. It is generally turbid from the presence in it of migrated leucocytes, disintegrated epithelial cells and clumps of mucus. It contains about 1·5 per cent. total solids, of which 0·8 per cent. are inorganic, chiefly sodium bicarbonate and sodium chloride. Its *p*H varies from 6·3 to 8·6 according to site, and, especially, to the amount of CO_2 lost in collection. It is less buffered than pancreatic juice. The organic matter includes a number of enzymes, but it is an open question how many of those nominated are actually present in the juice secreted under normal conditions. Some of the claims rest upon the examination of bacterially contaminated scrapings of the mucosa, others on the turbid and cell-rich juice mixed with desquamations, obtained by collection from fistulæ. While it is probable that the normal juice is always mixed with some shed epithelial cells, the relative number of these may be small compared with those set free in a fistulated loop exposed to a varying degree of mechanical insult. The fair thing seems to be to consider the enzymes found, apart from bacteria, in (*a*) centrifuged fresh juice, (*b*) fistula juice as collected, and (*c*) mucosa scrapings.

(*a*) Centrifuged fresh juice always contains *enterokinase*, the activator of pancreatic trypsinogen (p. 879), and *amylase*.*

(*b*) The turbid juice, as collected, usually contains various *peptidases*, *lactase*, *maltase*, *invertase* and *lipase*. The peptidases, formerly considered as a single enzyme called erepsin,† are distinguished by the fact that they have no power of acting on native proteins, peptones or proteoses, but only upon the polypeptides, which are rapidly split (optimal *p*H = 7·8). The juice contains several different peptidases which act on peptides of different structure, a dipeptidase acting on dipeptides, etc., and convert them into amino-acids.

(*c*) Scrapings of the mucosa contain all the enzymes mentioned above, and also, often or usually, *proteases*, *nuclease*, *phosphatase*, and *arginase*.

We may suppose that the enzymes discussed above exercise their functions in digestion in three ways. The soluble enzymes present in the juice, viz. enterokinase and amylase, exert their proper actions on trypsinogen and on starch respectively. The shed cells also present to a varying extent in the juice break down and set free their insoluble enzymes into the lumen of the gut, and these also exert their effects in breaking down polypeptides, disaccharides, or fats. The insoluble enzymes which are retained in the normal cells of the intestinal mucosa exert their actions on substances in transit through the epithelium, in the normal course of absorption, *i.e.* they are proper endo-enzymes.

The functions of the intestinal enzymes may therefore be said to be, first, the activation of the pancreatic trypsinogen, second, the further breakdown of all the constituents of the chyme, and third, the action, as, *e.g.* by phosphatase, upon substances in the course of absorption. In addition, the intestinal juice ensures a continual supply of water to the intestinal contents, thus facilitating solution and absorption of the digestion products.

8. MOVEMENTS OF THE SMALL INTESTINE

The movements of the intestines can be investigated either by direct observation of the gut or by means of the barium meal and X-ray examination.* In using the former method it is essential to exclude the many reflex influences which can play on the intestine, either by extirpation of the whole of the nerve plexuses of the abdomen, by division of the splanchnic nerves, or by destruction of the spinal cord below the mid-dorsal region. It is questionable, however, whether the movements seen under these conditions are the same as those which occur in the intact animal.

Three types of movement have been described in the small intestine, namely: (1) Pendular movements; (2) segmenting movements; (3) peristalsis. The movements may be seen in an animal treated as described above, when its abdomen is opened in a bath of warm normal salt solution.

The *pendular movements* probably only occur in the opened abdomen, where they appear as writhing movements of individual loops of the intestine. Bayliss and Starling appear to have described under this name the regular movements now called segmenting, and it is doubtful whether the pendular movements are anything more than the expression of segmenting contractions freed from the confinement of their normal surroundings.

The ***segmenting movements*** are the most constant and fundamental. They may be recorded by inserting into the intestine a balloon filled with air and connected with a piston recorder. The constriction which accompanies each contraction is then seen to be most pronounced at the middle of the balloon, i.e. in the zone of greatest distension, and the amplitude of the contractions is augmented by increasing the tension on the walls of the gut. These movements are unaffected by the direct application of drugs, such as nicotine or cocaine, which we might expect to paralyse any local nervous structures in the intestinal wall; they occur equally well in the isolated intestine, from which facts Bayliss and Starling † concluded that these rhythmic contractions were myogenic, and were propagated from muscle fibre to muscle fibre. This is confirmed by the observation of Gunn and Underhill ‡ that the contractions continue in strips of muscle completely freed from any remains of the nerve plexus. These contractions occur with considerable regularity at a frequency which varies inversely with their distance from the stomach, and in the ileum is of the order of twelve a minute. The different frequencies at different levels is due, according to Alvarez, to the existence of a "metabolic gradient" from

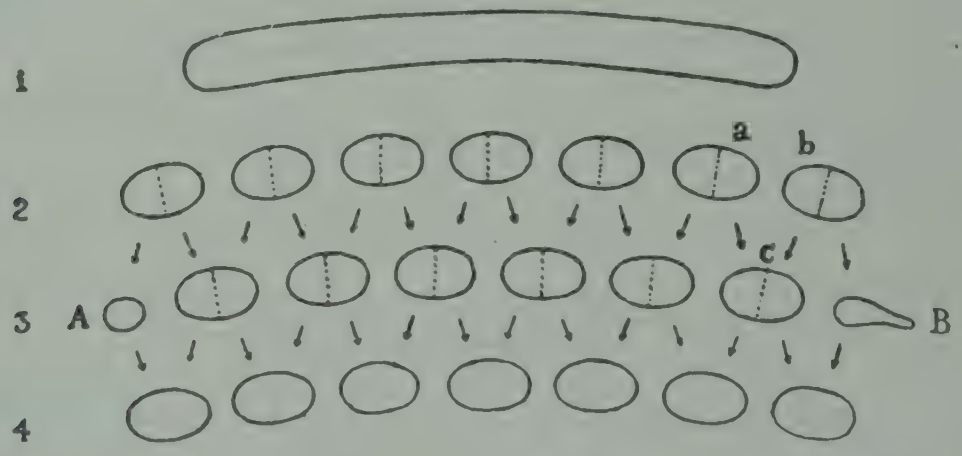

FIG. 572. Diagram of the "Segmentation" Movements of the Intestines as observed by the X-Rays, after Administration of Bismuth. (CANNON.)

2. The column broken up into segments.
3. Five seconds later, each segment divided into two, the halves joining the corresponding halves of adjacent segments.
4. Condition (2) repeated five seconds later.

---

* CANNON. *Amer. J. Physiol.*, 1902, **6**, 250.

† BAYLISS and STARLING. *J. Physiol.*, 1899, **24**, 99; 1901, **26**, 125.

‡ GUNN and UNDERHILL. *Quart. J. Exp. Phys.*, 1914, **8**, 275.

above downwards, the upper portions having a higher rate of metabolism and being also more excitable than the lower parts.

These segmentations must cause a thorough mixing of the contents of the gut with the digestive fluids. On examining under the X-rays the intestine of a cat, which some hours previously has taken a large meal of bread and milk mixed with bismuth, a length of gut may be seen in which the food contents form a continuous column. Suddenly movements occur in this column, which is split into a number of equal segments. Within a few seconds each of these segments is halved, the corresponding halves of adjacent segments uniting. Again contractions recur in the original positions, dividing the newly formed segments of contents and re-forming the segments in the same position as at first (Fig. 572). In this way every particle of food is brought successively into intimate contact with the intestinal wall. These movements have not a translatory effect, and a column of food may remain at the same level in the gut for a considerable time.

The ***peristaltic waves*** cause onward progress, possibly with a spiral rotation,* of the contents of the intestine. The classical description of peristalsis is that given by Bayliss and Starling, who described it as a wave moving slowly—generally at about 2 cm. a minute—involving contraction of the gut above the food mass, and relaxation below it. If a balloon be inserted in the lumen of the exposed gut, it will be found that pinching the gut *above* the balloon causes an immediate relaxation of the muscular wall in the neighbourhood of the balloon. On the other hand, pinching the gut half an inch below the situation of the balloon causes a strong continued contraction to occur at the level of the balloon itself (Fig. 573). Stimulation at any portion of the gut causes contraction above the point stimulated and relaxation below it (the " myenteric reflex "). The same effect is produced by introduction of a bolus of food, especially if it be large or have a direct irritating effect on the wall of the gut (Fig. 574). In this case the contraction above and the inhibition below cause an onward movement of the bolus, which travels slowly down the whole length of the gut until it passes through the ileocæcal opening into the large intestine. According to Alvarez, the direction of the peristaltic wave is determined by the direction of the metabolic gradient of the intestine. The peristaltic contraction involves the co-operation of the local nervous system, viz. Auerbach's plexus. Whereas in the œsophagus it is the central nervous system which co-ordinates, the peristaltic contractions in the small intestine continue after severance of all connection with the brain and spinal cord. On the other hand, they are absolutely abolished by painting the intestine with nicotine or with cocaine.

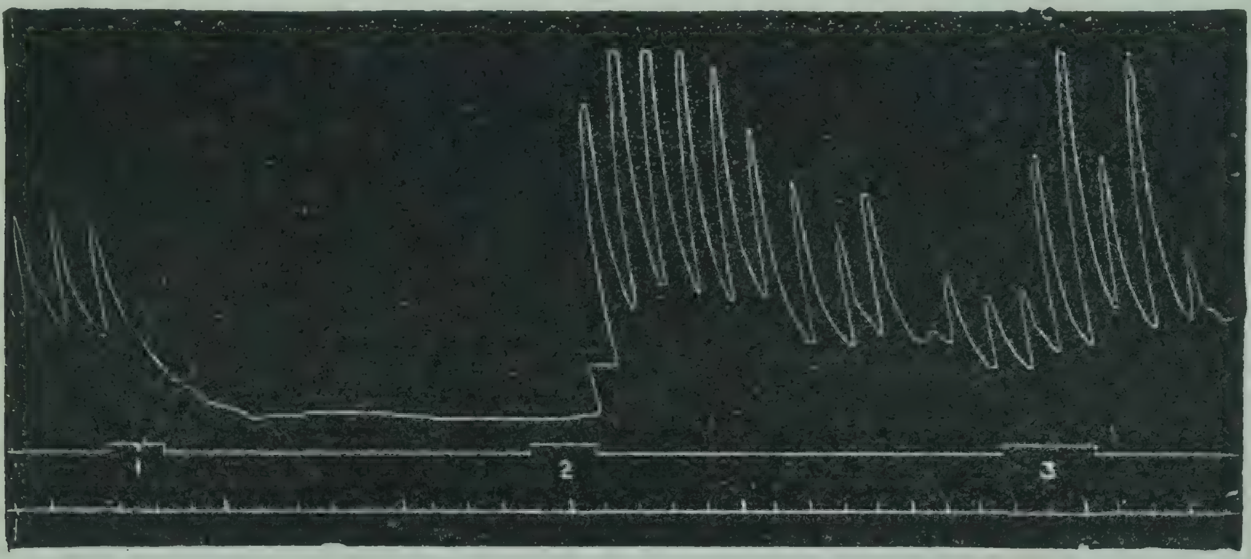

FIG. 573. Intestinal Contractions (Balloon Method).

In this dog all the abdominal ganglia had been excised, and both vagi cut. Showing propagated effects of mechanical stimulation above and below the balloon. (1) pinch above, (2) pinch below, (3) pinch below balloon.

---

* FRANKLIN and MAHER-LOUGHNAN. *J. Physiol.*, 1938, **94**, 426.

According to Alvarez, the peristaltic wave, as described by Bayliss and Starling, is abnormal, and in his opinion true peristalsis consists of a series of "rushes" traversing the whole length of the small intestine, travelling much more rapidly (2 to 25 cm. per second), and in which the constriction is less intense and not preceded by a wave of relaxation. Probably both forms occur.

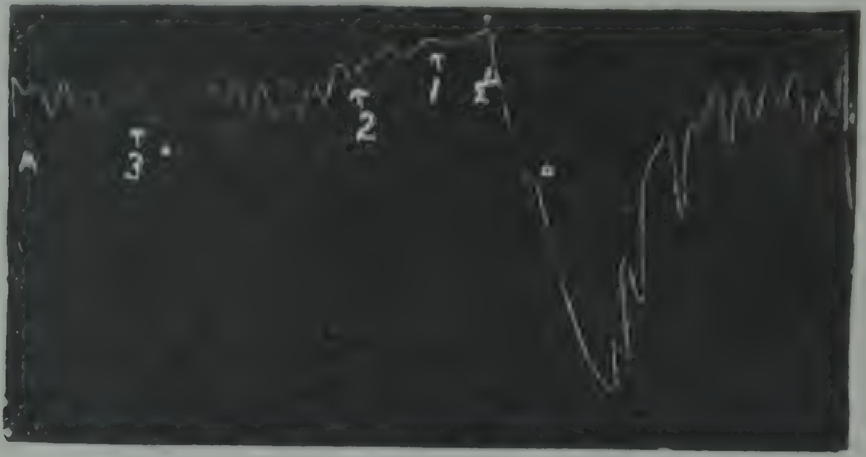

Fig. 574. Passage of Bolus. Contractions of Longitudinal Coat (Enterograph).

The bolus (of soap and cotton wool) was inserted into the intestine four inches above the recorded spot at A. The figures below the tracing indicate the distance of the middle of the bolus from the recording levers. As the bolus arrives two inches above the levers, there is cessation of the rhythmic contractions and inhibition of the tone of the muscle. This is followed, as the bolus is forced past, by a strong contraction in the rear of the bolus.

Anti-peristalsis is never observed in the lower small intestine. Mall showed that, if a short length of gut be cut out and reinserted in the opposite direction, a species of partial obstruction results, in consequence of the fact that the peristaltic waves, started above the zone of operation, cannot travel downwards over the reversed length of gut. The intestine above this level therefore becomes dilated. If, however, the reactions of the local nervous system be paralysed or inhibited, a reflux of intestinal contents is quite possible, since the contractions excited at any spot by local stimulation of the muscle have the effect of driving the food either upwards or downwards; the direction of movement of the food will be that of least resistance.

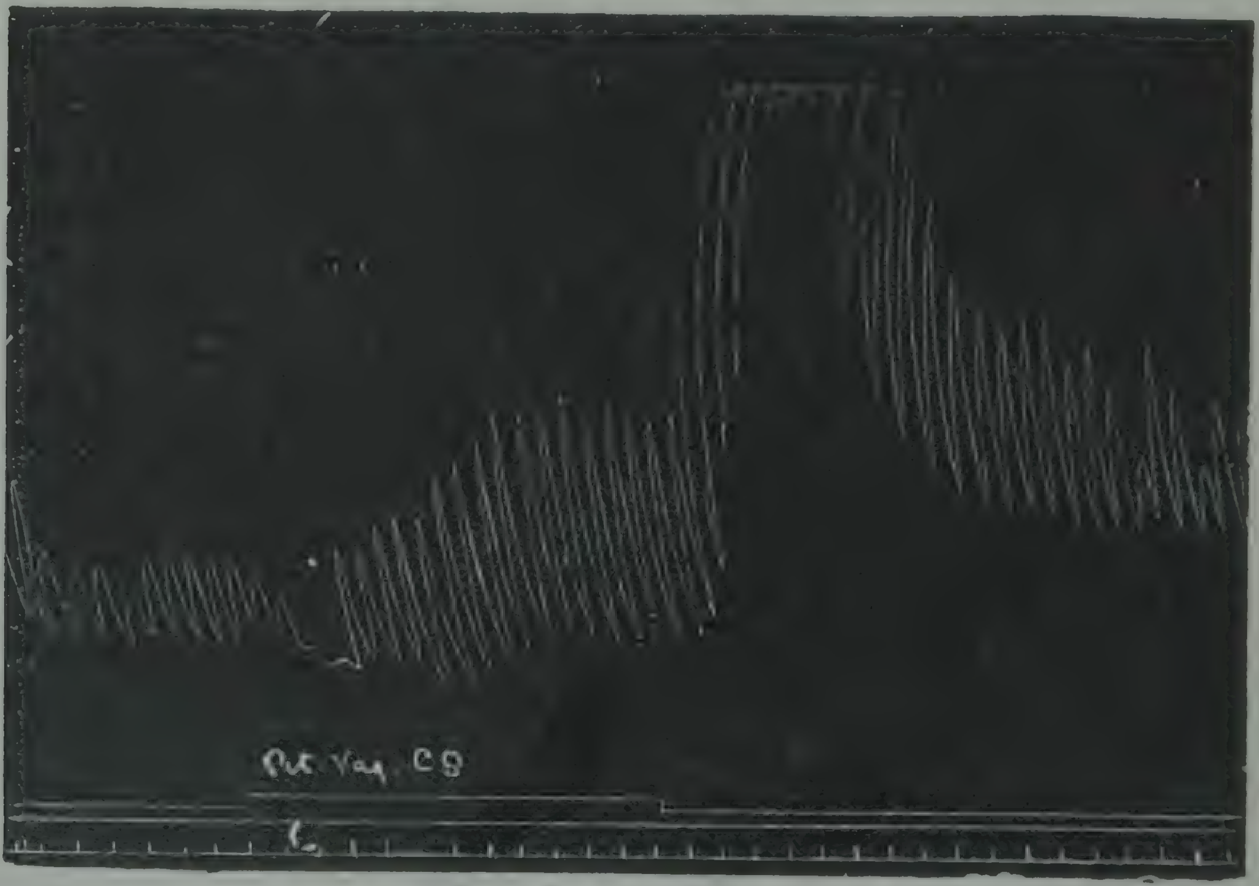

Fig. 575. Effect of Stimulation of Right Vagus on Intestinal Contractions.

The movements of the small intestine are also affected by the central nervous system. Stimulation of the vagus causes an initial inhibition of the whole small intestine, followed by increased irritability and increased contractions (Fig. 575). The ingestion of pleasant foods also increases intestinal tonus, probably by augmenting vagal impulses, while section of the vagus lowers tone. On the other hand, stimulation of the splanchnic nerves, or injection of adrenaline, causes complete relaxation of both coats of the small gut (Fig. 576). It seems that the splanchnics normally exercise a tonic inhibitory influence on the intestinal movements, which can be increased reflexly, and notably from the intestine itself: both afferent and efferent paths are in the splanchnics.* The relaxed condition of the gut, called paralytic ileus, which obtains in many abdominal affections, is probably due to reflex inhibition through the splanchnic nerves.

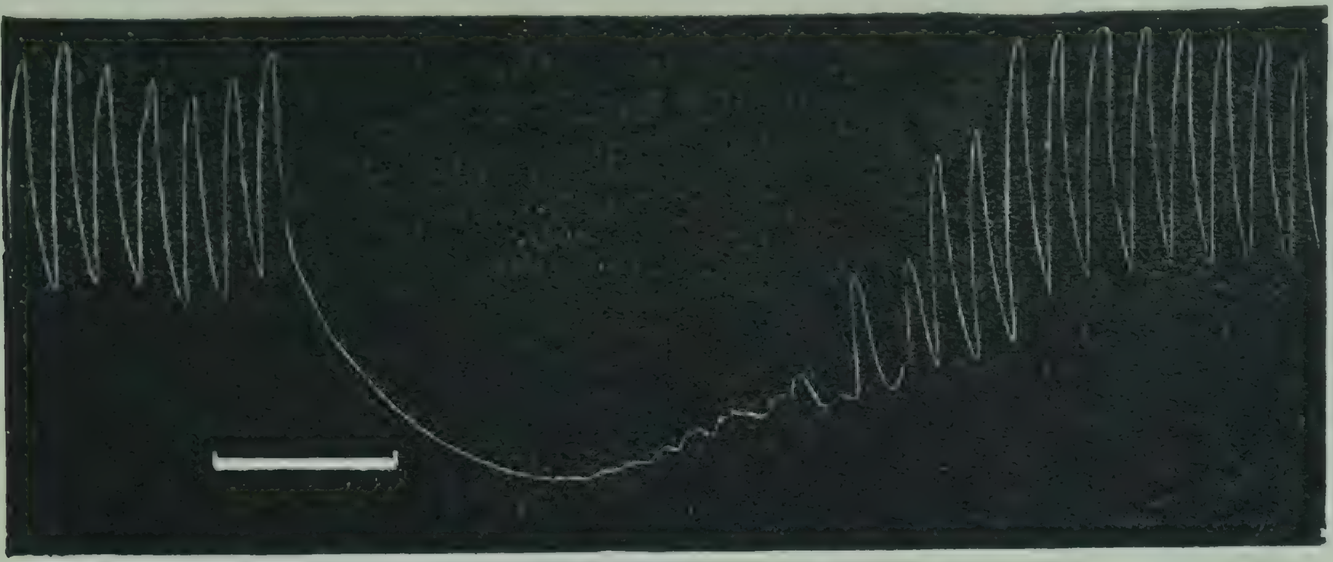

Fig. 576. Excitation of both Splanchnic Nerves. Balloon Method. Intestine returned to Abdomen.

The movements of the duodenum show some special features, viz. contraction of the first part (duodenal cap), peristalsis of the second and third parts, antiperistalsis of the second and third parts, and segmenting movements. Normally the contents are passed to and fro a few times in the duodenum before passing on to the jejunum, but once they have passed on they do not return. Antiperistalsis is most definite in the second part of the duodenum, and leads to periodic filling of the duodenal cap, or even to regurgitation into the stomach. Very rapid mixing of the contents with the digestive juices results from this to-and-fro movement.†

In man, the chyme remaining from the digestion of a meal begins to arrive at the lower end of the ileum in about three and a half hours after the meal. Here it accumulates for a while, during which time active segmentation movements occur, and further absorption of water takes place. Peristalsis is generally feeble in this part of the bowel, but is reflexly increased during or just after a meal. It is at this time, *i.e.* when the next meal is taken, that the contents are passed on by occasional peristaltic contractions through the lower end of the ileum and into the cæcum. The lowest 2 cm. of the ileum present a distinct thickening of the circular muscular coat, forming the *ileocolic sphincter*. This sphincter relaxes in front of a peristaltic wave and so allows the passage of food into the colon. On the other hand, it contracts as a rule against any regurgitation which might be caused by contractions in the colon.‡ Although thus falling into line with the rest of the muscular coat as concerns its reaction to stimuli arising in the gut above or below, it presents a marked contrast to the rest of the gut in its relation to the central nervous system. It is unaffected by stimulation of the vagus. Stimulation of the splanchnic, however, which causes complete relaxation of the lower part of the ileum with the rest of the small intestine, produces a strong contraction of the plain muscle forming the ileocolic sphincter.* According to Hurst,† an important function of the ileocolic sphincter is, by its tonic contraction, to prevent the contents of the ileum passing too rapidly into the cæcum, so as to allow more time for digestion and absorption of foodstuffs to be carried to completion in the ileum.

9. FUNCTIONS OF THE LARGE INTESTINE

Great differences are found in the size of the large intestine of different animals. In the carnivora it is short and narrow, and possesses little or no cæcum. In herbivora the large intestine is well developed, with sacculated walls, and the cæcum is very large. Man occupies a somewhat intermediate position between these two classes. The great development of the large intestine in vegetable feeders is due to the fact that all the nutritious material in their food is enclosed in cells surrounded by cellulose walls. The cellulose is dissolved either by the agency of bacteria or by means of cytases in the vegetable cells themselves. In the horse and rabbit, for instance, the chief part of the digestion of the cellulose occurs by bacterial action in the cæcum.

In carnivora the large intestine has unimportant functions to discharge in digestion and absorption. The products of digestion are practically entirely absorbed by the time that the food has arrived at the ileocolic valve. In man the importance of the large intestine will vary with the nature of his food. If, however, a large quantity of vegetable food be taken, a considerable amount of material may reach the large intestine unabsorbed. A small proportion of this may undergo absorption in the large intestine, while the rest will pass out with the fæces, increasing their bulk. About 90 per cent. of the pectin of the food is absorbed, after being broken down by bacterial action in the colon.‡

The large intestine in man is the part of the alimentary canal in which micro-organisms flourish. In the mouth these are numerous, including various species of micrococci, staphylococci, streptococci, aciduric bacilli, spirochætes and spirilla, etc., the stomach has a very restricted flora in health, since the strong acid reaction of the contents kills most of the organisms which enter it. The upper small intestine also contains few; the ileum has a rapidly increasing bacterial content, *e.g.*, enterococci, coliform bacilli, staphylococci and yeasts, as the ileo-cæcal valve is approached. So far, however, there are few anaerobic bacteria and putrefaction is slight until near to the large intestine. Bacterial flora here becomes much more complex and numerous and includes very many species of aerobic and anaerobic bacteria as well as yeasts and protozoa. The commonest bacterial species are coliform bacilli, enterococci, staphylococci, aciduric bacteria, spirochaetes, sporing aerobes, and both pathogenic and non-pathogenic species of sporing anaerobic organisms, such as *Cl. welchii* and *Cl. putrifica*.

Bacteria are said to make up from a quarter to one-third by weight of the fæces, but the greater part are dead organisms.

At birth the intestine contains very few organisms, but is rapidly colonised both from mouth above and anus below. Intestinal bacteria are probably not essential to life, but aid in digestion and may also affect the host's well-being by their activity in respect of both vitamin synthesis and vitamin destruction.

The study of the products of the activity of these bacteria, and of the protection of the body from these and from direct invasion by the organisms themselves, forms an interesting chapter in pathology.

The mucous membrane of the large intestine is lined by simple tubular glands containing many typical "goblet" cells. Investigation by the fistula method shows that, when empty, the secretion of the large intestine is extremely scanty and composed wholly of mucus, while when stimulated mechanically by introduction of a drainage tube, a slight watery secretion is further contributed.

* Elliott. *J. Physiol.*, 1904, **31**, 157.
† Hurst. *J. Physiol.*, 1913, **47**, 54.
‡ Werch and Ivy. *Amer. J. Dig. Dis.*, 1941, **8**, 101.

The secretion in the cat's colon is effected through the action of the *nervi erigentes.*[*] Reflex secretion can be obtained by stimulating the central end of one nervus erigens, the other nerve being intact. We may suppose such a secretion, often copious, to be a result of the presence of irritating substances in the fæces. Secretion is also caused by pilocarpine, inhibited by atropine, and reduced by sympathetic stimulation. The secretion has a pH of 8·4 and is rich in mucin, but almost devoid of any enzymes. In the resting state the colon reabsorbs the entire secretion. The secretion of mucus aids the passage of the fæces along the gut.

As an absorbing organ the large intestine of man is of little importance. From observations on cæcal fistulæ in man it has been calculated that about 500 c.c. of water pass the ileocolic valve in the twenty-four hours. Of this about 400 c.c., together with the water secreted in the large intestine itself, undergoes absorption in the large intestine. The absorption of food substances introduced into this part of the gut is much slower than that which takes place on introduction by the mouth. In some cases after the introduction of large enemata into the large intestine, a certain amount may escape backwards into the ileum and may there undergo absorption. The isolated large intestine of man is able to absorb only about 6 grammes of glucose per hour and about 80 c.c. of water. If egg albumin or caseinogen solutions be introduced by the rectum, no absorption can be detected after several hours. Feeding by nutrient enemata is thus of little value.

It was formerly held that the large intestine excreted a considerable fraction of the ingested calcium and magnesium salts, and also iron and heavy metals when these were administered. So far as calcium, magnesium and iron are concerned this belief has been shaken by the careful work of Nicolaysen[†] and of McCance and Widdowson,[‡] who found that when their salts were injected into the blood there was no increased output of the elements by the bowel. In earlier work allowance was not made for failure of absorption when these salts were given by mouth.

Such absorption of *iron* as takes place occurs in the duodenum and upper part of the jejunum. Only about 0·1 mg. daily appears in the urine ; all the rest of the normal intake of about 7–8 mg. daily, together with any iron compounds given by mouth, is unabsorbed and appears in the fæces, chiefly as sulphide.

Of the acid radicals, *phosphates* may pass out either with the urine or with the fæces, the exact path taken being determined by the relative amount of calcium and alkali metals present in the food. If there is an excess of calcium most of the phosphates will leave with the fæces, but this does not imply that calcium phosphate has been excreted.

The large intestine does seem to be a channel of excretion for the heavy metals, such as bismuth and mercury. If bismuth be administered subcutaneously, the fæces will be found to contain this substance, and the wall of the large intestine will be stained black from a deposit of sulphide of bismuth. This deposit stops short at the ileocolic valve.

Movements of the Large Intestine. By means of the occasional peristaltic contractions, accompanied by relaxation of the ileocolic sphincter, the contents of the small intestine are transferred into the colon. This happens most rapidly when the next meal is taken, but in any case not till about four and a half hours after the last one. When food is swallowed, or when chyme enters the duodenum, a peristaltic rush is initiated in the small intestine ; on the arrival of the wave at the ileocæcal valve, the sphincter opens and allows the passage of some of the contents of the ileum into the colon (" gastro-ileal " reflex). In man the contents are considerable in bulk, are semi-fluid, and quickly fill up the transverse as well as the ascending colon.

Innervation. The innervation of the large intestine is derived from both sympathetic and parasympathetic sources; there are some differences in the details of anatomical distribution in its different parts, and in different species of animals. In man, the *colon* in its proximal part receives fibres from the superior mesenteric plexus; these are partly sympathetic, from the lumbar roots, and partly parasympathetic from the vagus. In its distal parts the colon is supplied by sympathetic fibres, which reach it from the upper lumbar roots *viâ* the pelvic splanchnic branches, intermesenteric plexus and nerves, the inferior mesenteric plexus, in which are many ganglia, and the inferior mesenteric nerves. The parasympathetic supply to the distal colon is from the second to fourth sacral spinal roots, and then by way of the hypogastric plexus, in which are also scattered ganglia, to the wall of the colon (Fig. 577).

Regarding the action of these nerves, there are discrepancies in the results of different investigators. It has often been claimed that the sympathetic is inhibitory to the musculature of the colon, with the exception of the ileocolic sphincter, to which it is motor, while the parasympathetic is motor to all except the ileocolic and anal sphincters. But there is doubt about the action of the sympathetic, which is without doubt often motor, at all events to the circular coat. Whether the vagus is motor to the cæcum is also doubtful.

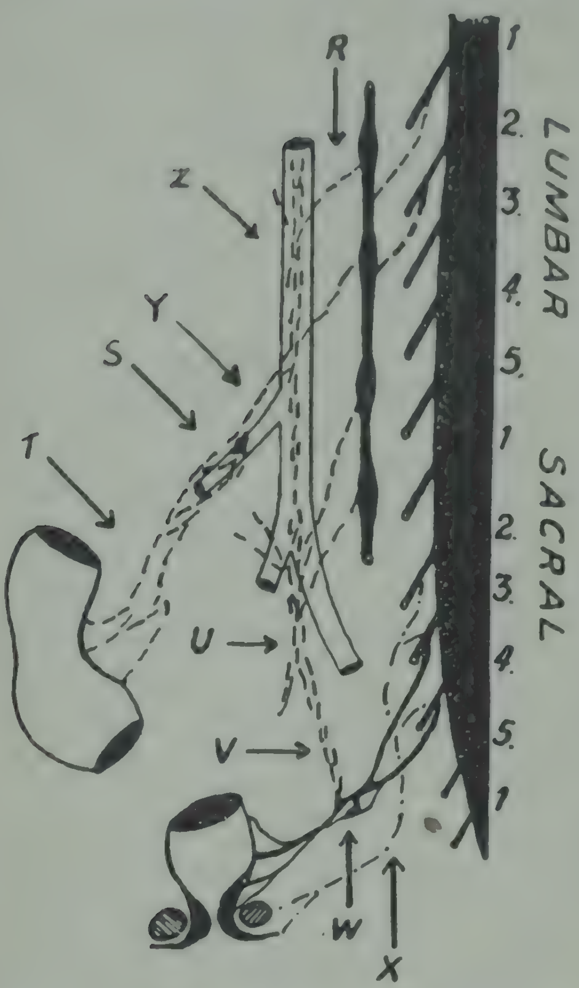

FIG. 577. The Nervous Outflow to the Distal Colon in Man. R., pelvic splanchnic nerves; S., inferior mesenteric plexus; T., inferior mesenteric nerves; U., presacral nerve; V., hypogastric nerve; W., hypogastric plexus; X., pudic nerve; Y., intermesenteric nerve; Z., intermesenteric plexus. (GARRY. *Physiol. Rev.*, 1934, **14**, 103.)

In addition to the nervous arrangements as described above, the large intestine has two intrinsic nerve plexuses, similar to those of the small intestine.

The rectum in man also receives a double nerve supply, of which the sympathetic is derived from the lumbar roots by way of the presacral nerve and the hypogastric nerves and plexus, while the parasympathetic supply from the sacral nerves also reaches it by way of the hypogastric plexus (Fig. 577). The *internal anal sphincter*, of plain muscle, has a similar supply, while the striated *external anal sphincter* receives a motor supply from the pudic nerve, which also supplies various other striated muscles of the perineum. Afferent fibres are present in the sacral and pudic nerves.

Movements. The movements of the large intestine may be observed by the X-ray method assisted, in man, by auscultation and percussion. Until about four hours after breakfast the cæcum is filled with gas, is resonant on percussion, but emits no sounds. At about the fourth hour the ileal contents begin to enter, producing characteristic sounds, and the X-ray shadow shows rapid filling of the cæcum and ascending colon; these show little peristaltic action but seem to be passively filled by the peristaltic contractions of the ileum.

The movements of the large intestine differ considerably in various animals,* according to the nature of the food and the part played by this portion of the gut in the processes of absorption. Man takes an intermediate position between herbivora and carnivora as regards his large intestine.

---

* ELLIOTT. *J. Physiol.*, 1904, **31**, 157; **32**, 401; ELLIOTT and BARCLAY-SMITH. *J. Physiol.*, 1904, **31**, 272.

In the cat there is active peristalsis and antiperistalsis of the ascending colon as it fills. The effect of the antiperistaltic waves is to force the food into the cæcum, regurgitation into the ileum being prevented by the tonic contraction of the ileocolic sphincter. The movements are rendered still more effective by the sacculation of the walls. The distension of the cæcum caused by this anti-peristalsis excites occasionally a true co-ordinated peristaltic wave which, starting in the cæcum, drives the food before it into the transverse colon. These waves die away before they reach the end of the colon, and the food is driven back again by waves of anti-peristalsis. The result of this process is the absorption of the greater part of the water of the intestinal contents, as well as of any nutrient material; and the drier part of the intestinal mass collects towards the splenic flexure, where it may be separated by transverse waves of constriction from the more fluid parts which are being driven to and fro in the proximal and intermediate portions. By means of occasional peristaltic waves these hard masses are driven into the distal part of the colon.

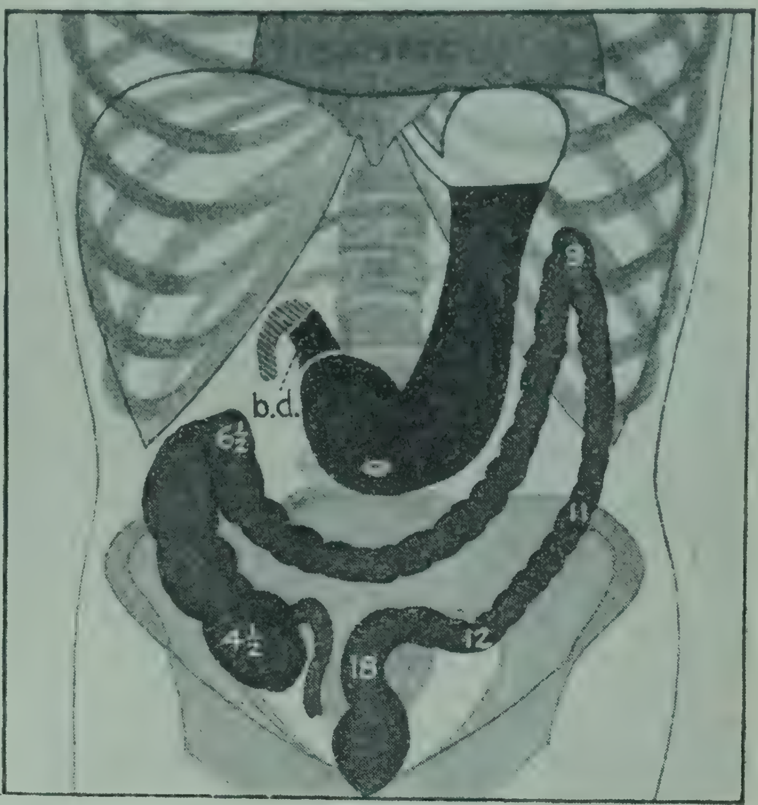

Fig. 578. Skiagram to show Normal Position of Colon in Man, and the Position attained by its Contents at different periods after a Meal containing Barium Sulphate.

The times of arrival at different levels are marked in hours after the meal on the colon. (Hurst.)

About 500 grammes of fluid chyme per day pass the ileocæcal valve in man; water and a little nutrient material is absorbed, chiefly in the cæcum and ascending colon, though the contents remain soft till they reach the pelvic colon, when they undergo inspissation, so that the average weight of fæces per day is about 135 grammes.

The contents, in man, reach the hepatic flexure on an average in about six and a half hours after the meal, the splenic flexure at about nine hours, and the pelvic colon in twelve hours, though there are great individual variations. The time taken for a barium meal to reach various levels in the colon in man is shown in the accompanying figure (Fig. 578). It should be remembered, however, that a barium meal is usually given after previously emptying the whole alimentary canal as completely as possible. In the normal course of events food residues are much slower in being completely eliminated in the fæces than these figures would indicate. Thus Alvarez and Freedlander, administering coloured glass beads with the food to normal adults, found that, even after four days, only about three-quarters of the beads had been recovered.

The progress of the contents along the large intestine is not a slow regular one, but occurs as a result of a few rather sudden, powerful contractions. These, due to what is called a gastro-colic reflex, occur especially when food is taken, and during defæcation, and are called "*mass peristalsis.*" By this means the contents of the cæcum and ascending colon may be moved bodily into the transverse colon in a few minutes, and similarly the contents of the transverse colon may be equally rapidly passed on into the pelvic colon and rectum.

Defæcation. Under normal conditions, the rectum and distal colon are subordinated to the spinal and other nerve centres, the inhibitory effect of the sympathetic supply being predominant, and leading to retention of the contents. Hence spinal anæsthesia leads to some increase of tone, whereas spinal transection in the lower thoracic region leads to complete relaxation. It would seem that the sympathetic supply has its centre in the lumbar cord, while the parasympathetic centre is higher up.

The normal stimulus for defæcation is probably the attainment of a certain distension of the rectum, which is reinforced by stimuli arising from the movement of fæces along the rectum and anal canal. These reflexly excite contraction of the colon, and relaxation of the sphincters, the former being due to the transmission of impulses along the sacral nerves. Stimulation of these nerves in an animal produces a rapid shortening of the distal part of the colon, due to contraction of the recto-coccygeus and longitudinal fibres of the gut, followed after some seconds by a contraction of the circular coat. This originates certainly as high as the splenic flexure, and possibly even higher, and spreading rapidly downwards empties the whole of this segment of the gut. In man, the pelvic colon becomes filled with fæces from below upwards, the rectum remaining empty till just before defæcation. In individuals whose bowels are opened regularly, the entry of fæces into the rectum gives rise to a sensation of fulness and acts as the call to defæcation. "Mass contractions" of the colon may occur as a reflex result of taking food into the stomach. The rectum thus becomes rapidly filled, and its distension produces the call to defæcation. Hence the act of defæcation after breakfast, or, in patients with irritable intestines, after any meal. If no response be made, the desire to defæcate passes away, since the rectum relaxes again. The minimal pressure required to produce the call to defæcate varies from 30 to 40 mm. Hg. The emptying of the rectum itself is largely assisted by the contractions of the voluntary muscles of the abdominal walls and pelvic floor. The last section of the rectum is emptied at the close of the act by a forcible contraction of the levator ani and the other perinæal muscles, and this contraction also serves to restore the everted mucous membrane.

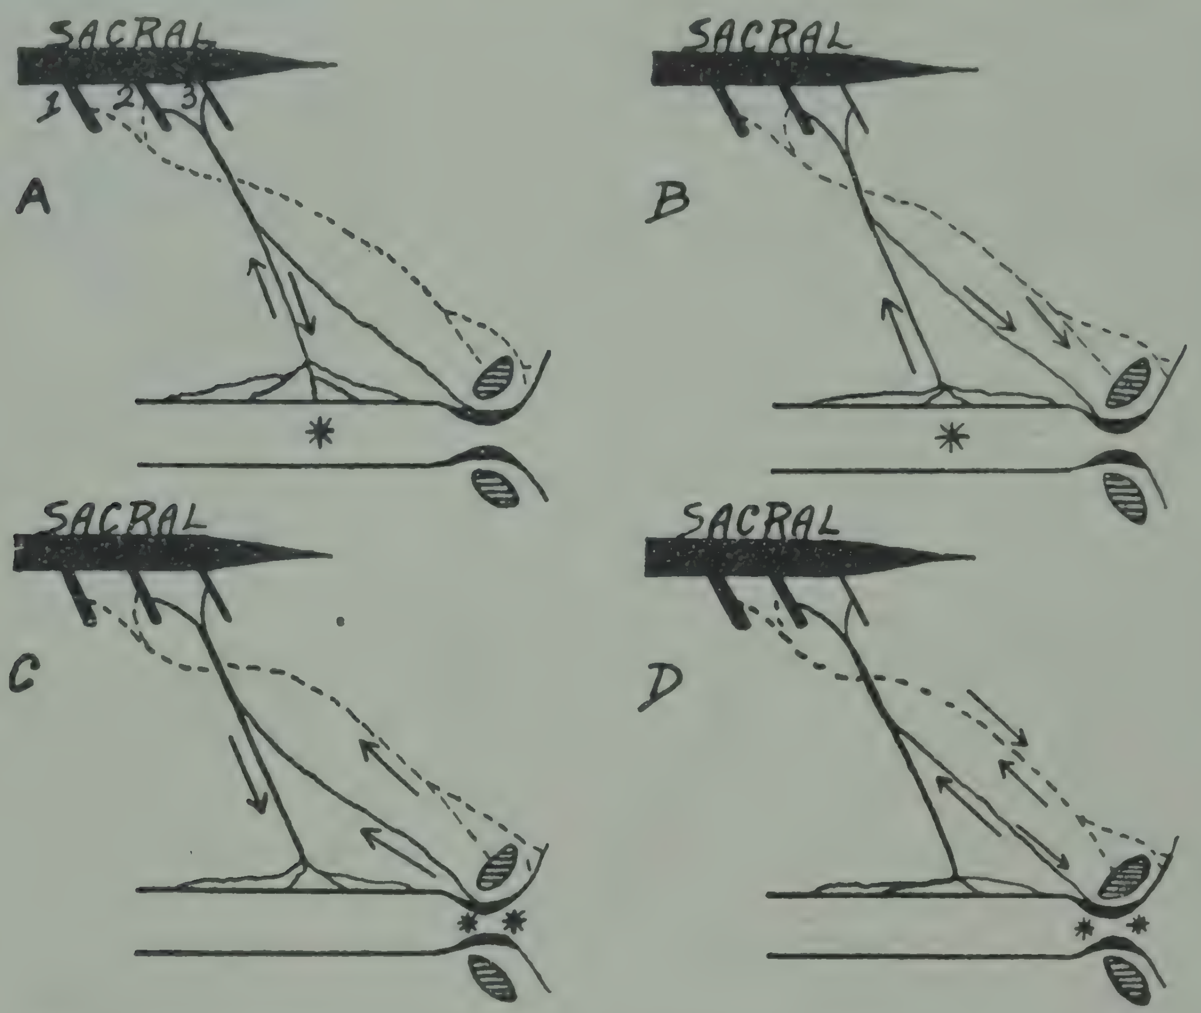

FIG. 579. Course of Impulses in Defæcation, according to Garry.
— pelvic nerve.
- - - pudic nerve.
* point of stimulation.

Stimulus to mucosa of distal colon causes (A) contraction of distal colon and (B) relaxation of both anal sphincters.

Stimulus to mucosa of anus causes (C) contraction of the distal colon and (D) relaxation of both sphincters.

The anal orifice is guarded by an internal anal sphincter of smooth muscle, and by a series of three striated external sphincters.* The internal sphincter is supplied by the sacral and hypogastric nerves, and the external anal sphincters by the pudic nerve. These sphincters are normally kept closed, even on section of the upper lumbar spinal cord. Stimuli in the colon or rectum which give rise to defæcation cause a reciprocal contraction of the lower bowel and relaxation of these sphincters.* Conversely, stimulation of the anal canal, as by movement of fæces through it, leads to reflex dilatation of the canal, and contraction of the rectum. As shown in Fig. 579, the afferent nerves in these reflexes are the pelvic nerves and the pudic nerves, the former being also motor to the colon and inhibitory to the internal sphincter, while the latter is motor to the external anal sphincter.

---

* MILLIGAN and MORGAN. *Lancet*, 1934, **227**, 1150.

The carrying out of this reflex act is normally dependent on the integrity of a certain part of the lumbar spinal cord. If this " centre " be destroyed, the tonic contraction of the sphincter muscles disappears. The centre may be either excited to increased action or inhibited by peripheral stimulation of various nerves, or by emotions such as fear. Application of warmth to the region of the anus causes reflex relaxation of the sphincter ; application of cold increases its tonic contraction.

Some time after destruction of the lumbar spinal centres a certain amount of automatic control is restored over defæcation. This has been supposed to be due to a fundamental control exerted by the local nerve plexuses,† but has not been finally explained.

The Fæces

In man or the carnivora the absorption of the constituents of a meal is practically complete by the time that the food has arrived at the lower end of the ileum. The fæces in the main are not derived from the food, but are produced very largely in the alimentary canal itself. This is shown by the fact that on analysing the fæces no soluble carbohydrates or proteins, albumoses, peptones or amino-acids are to be found. After a meal of meat, microscopic examination of the fæces reveals no trace of striated muscle fibres. Moreover, animals in a state of complete starvation form fæces which do not differ in their composition from the fæces which are found after feeding, though the amount is less. In one experiment Hermann isolated a loop of gut, joining its ends together so that a continuous ring was formed. The continuity of the gut was then restored by suturing the two free ends. After some weeks the isolated loop was found to contain a semi-solid material similar to fæces.

So long as vegetables or coarsely ground cereals are excluded from the diet, the nature of the latter does not alter the chemical constitution or appearance of the fæces. Under these circumstances the fæces have the following composition :

Water	65 to 67 per cent.
Nitrogen	5 to 9 ,,
Ether extract	12 to 18 ,,
Ash	11 to 22 ,,

The ash consists chiefly of lime and phosphoric acid with some iron and magnesia. The ethereal extract contains fatty acids and a small amount of lecithin. Neutral fat is present in very small proportions. The fæces also contain small quantities of cholic acid and its decomposition product, dyslysin, also coprosterol, a reduction product of cholesterol, and a certain amount of purine bases, consisting of guanine, adenine, xanthine and hypoxanthine. On the average the fæces contain about 0·11 gramme of purine bases per idem, about seven times as much as is contained in the urine passed in the same time. The material basis of the fæces seems to be largely inspissated mucus, bile and other secretions, desquamated epithelial cells from the intestinal wall, and bacteria, of which countless numbers, chiefly dead, are present. It has been reckoned that as much as 50 per cent. by weight of the fæces may consist of dead bacteria.

---

* Garry. *J. Physiol.*, 1932, **74,** 14P ; *Physiol. Rev.*, 1934, **14,** 103.
† Denny-Brown and Robertson. *Brain*, 1935, **58,** 256.

Very different is the composition of fæces if the food contains a large amount of cellulose. Not only does the ingested cellulose pass unchanged into the fæces, but large quantities of other substances enclosed in the cellulose walls may also escape digestion. Moreover, the increased bulk of the undigested residue stimulates peristalsis, and thus quickens the passage of the food through the gut. The influence of the character of the food is well illustrated by a comparison of the amount and composition of the fæces on different kinds of bread (RUBNER) :

Kind of bread.	Weight of moist fæces.	Weight of dried fæces.	Percentage of ingested food.	Nitrogen (g.).
Bread from fine flour .	132·7	24·8	4·03	2·17
Bread from coarse flour .	252·8	40·8	6·66	3·24
Brown bread . . .	317·8	75·79	12·23	3·80

The indigestible cellulose in the food is not without value. If the food is capable of entire digestion and absorption, the amount of fæces formed is limited to that produced by the intestinal wall itself. The small bulk exercises very little stimulating effect on the intestine, and the movements of the latter will therefore tend to be sluggish. The presence of a certain amount of cellulose in the diet may therefore be of considerable advantage by giving bulk to the fæces and ensuring the proper regular evacuation of the lower gut.

Intestinal Gas. Gas gets into the intestine from swallowed air, by diffusion from the blood, or as a result of fermentative changes. The longer it stays there the more nearly it gets to equilibrium with the blood. The total quantity of gas passed daily *per anum* is very variable ; a normal average is about 500 c.c.*

10. The Sensations of Hunger and Thirst. When the body is in need of food or water, the characteristic sensations of hunger or thirst arise and increase in intensity if the need is not satisfied. It is important to distinguish between hunger proper and appetite : the former is unpleasant or even painful, while the latter, though accentuated by actual hunger, is mainly psychological and generally pleasurable.

It is not certain what is the fundamental cause of the hunger sensations. Hunger may be specific, as well as general, as, for example, the characteristic salt-hunger which leads animals in the wild state to travel long distances in search of its relief. Indeed, the constant average dietary balance in man and in animals of all species must in the long run be due, not so much to any conscious selection of the various constituents as to an unconscious choice guided by vague specific desires, now for more carbohydrate, now for salt, or fat, or protein. We have no knowledge of the mechanisms upon which these specific hungers, or their satisfaction, depend, nor could it be denied with any certainty that general hunger is due to a summation of such specific hungers, though probably it is not. The view that general hunger is associated with a lowering of the blood sugar receives some support from the fact that the blood sugar is a common pabulum into which certain other nutritional materials are convertible, so that its concentration in the blood may well serve as an index of the nutritional needs of the body. In support of this view is the fact that a sensation of hunger is one of the first effects of lowered blood sugar resulting from the action of a dose of insulin, though against it is the fact that hunger is a very prominent symptom in diabetics in whom, however, the blood sugar is permanently raised.

---

* BEAZELL and IVY. *Journ. Dig. Dis.*, 1941, **8,** 128.

As regards the actual pangs of hunger, which are referred to the epigastric region, there is little doubt that these are caused by powerful contractions of the body of the stomach, which begin as soon as the organ is empty or nearly empty,* at first as feeble contractions at intervals of twenty to thirty seconds, but finally becoming very powerful and lasting for about thirty seconds. Each contraction is accompanied by a hunger pang, and by an increased secretion of saliva. Vagotomy and sympathectomy in man each abolish hunger pangs, the former by depressing gastric motility, the latter by interrupting the afferent path ; but vagotomy certainly does not abolish sensations of hunger due to insulin.†

The effects of deprivation of water are evident sooner than those of want of solid food, and are correspondingly more urgent. In the first stage there is craving for liquid, and a feeling of dryness in the mouth ; later the dryness increases, the air breathed seems hot and dry, and frequent and painful swallowing movements are made ; food cannot be swallowed and even sugar may not dissolve in the mouth. Delirium and death soon follow, the total duration of life without water depending on the rate of loss and so being brief (one to two days) after exertion in hot dry climates, but longer, up to two weeks or more, in cooler damper climates and under conditions of rest.

The thirst of *diabetes mellitus* and of *diabetes insipidus* is imperative : in the former case the water is lost in company with the sugar excreted; in the latter there is a primary disturbance of the normal water distribution of the body, so that water which should normally be stored, *e.g.* in the connective tissues and liver, is excreted and leads to a constant shortage.

It has often been supposed that thirst is a general sensation arising in some way from the desiccated tissues. This view received support from experiments by Claude Bernard, who found that in animals with double œsophagostomy, as for sham feeding, or animals with open gastric fistulæ through which fluid escaped on swallowing, thirst was apparently not relieved by drinking. It has certainly been found that after long deprivation of water the osmotic pressure of the blood is demonstrably increased,‡ and possibly this is the case in diabetes mellitus, yet it is not possible to show any clear change in that direction in the early stages, in which, nevertheless, thirst is well established. Probably, therefore, the changes in the blood are too small to detect by physico-chemical methods, though sufficient to produce the characteristic sensations of thirst.

The alternative view, advanced by Cannon,§ is that the sensation of thirst is, as it appears to be, due to a dryness of the mouth, from any cause whatever. Owing to the passage of the inspired air through the pharynx, this always tends to become dried, but drying is ordinarily prevented by the secretion of saliva. When the tissues are deprived of water, however, the secretion of saliva is reduced, thus leading to the slight drying of the pharynx and producing the sensation of thirst. But we do not know how this result is produced. For example, in men, intravenous injection of 300 c.c. of 5 per cent. NaCl causes thirst, and reduction of salivary flow ; but analyses showed an increase of 5–10 per cent. in plasma and extracellular volume.‖ The thirst and dry mouth were prevented if 500 c.c. water was given half an hour before the salt injection, but the plasma changes were similar to those not preceded by water drinking.

Administration of atropine, by checking the secretion of saliva, gives rise to thirst, and conversely pilocarpine when administered to thirsting animals relieves it (Pack).¶ It has been stated also that after ligature of the parotid ducts, dogs show constant thirst. But doubt has been cast on this by Montgomery,* who finds that removal of all the salivary glands from dogs does not alter the water intake. The same is true of men with no salivary glands ; they drink no more than others, but drink more often.†

CHAPTER XLV

THE ABSORPTION OF THE FOODSTUFFS

The processes of digestion result in the conversion of the insoluble constituents of the food into soluble substances of smaller molecular weight, which can pass into the blood stream, and so become available for use in the body. The transfer of the dissolved materials, together with water, into the blood and body fluids, is called absorption.

Absorption from the Stomach. The rapidity with which highly diffusible substances, such as ethyl alcohol or hydrocyanic acid, produce their physiological effects, even when the pylorus has been obstructed, shows that some absorption can occur from the stomach. The substances named, however, have definite vapour pressures, and might pass as vapours.

If we may judge by experiments with heavy water (D_2O), there may be quite measurable absorption of water from dog's stomach pouches.*

The chief absorption of water occurs in the small intestine. It is on this account that the salient symptoms of dilatation of the stomach with stenosis of the pyloric orifice can be nearly all referred to the deprivation of the body of water, and can be often relieved by the administration of water, either subcutaneously or by the rectum, *i.e.* by the channels through which absorption is still possible.

Sugars and amino-acids may perhaps also be slowly absorbed in the stomach.

Absorption from the Small Intestine. By far the greater part of the absorption of all materials takes place in the small intestine. The inner surface of the small intestine is greatly augmented by the formation of folds, the *valvulæ conniventes*, and by the protrusion of villi from the surface. It has been calculated that each square millimetre of intestine represents an absorbing surface of 3 to 18 mm.^{2}, and a total capillary surface of about the same order, though not all these capillary surfaces are superficial in position.

Structure of Villi. Each villus (Fig. 580) consists of a framework of reticular tissue containing many leucocytes in its meshes, separated from the lumen of the gut by a continuous layer of columnar cells. These surface cells, which rest on an incomplete basement membrane, are of four kinds. Much the most abundant are the *principal* or *columnar absorbing cells*. These present a striated border or fringe on their outer sides (Fig. 580). Scattered among them are numerous *goblet cells*, *Paneth cells* and *enterochrome* or *basal granular cells*.† Similar groups of cells are found lining the crypts of Lieberkühn. Apart from the fact that the goblet cells secrete mucus, the function of these various cells is a matter for speculation.

The villus offers two channels by means of which material which has passed through its epithelium may be carried away. In the middle of the villus is the central lacteal, which leads into a plexus of lymphatics placed superficially to the *muscularis mucosæ*. From the superficial plexus communicating branches pass vertically to a corresponding plexus lying in the submucosa. Valves are present in abundance in the deeper plexus, so that fluid can pass easily from the lacteal to the deeper plexus, but not in the reverse direction. From the muscularis mucosæ, unstriated muscle fibres pass up through the villus, to be attached partly to the outer surface of the central lacteal, partly by expanded extremities to the basement membrane covering the surface of the villus. Contraction of these muscle fibres might empty the central lacteal into the deep plexus of lymphatics and may also cause an expulsion of the contents of the spaces of the retiform tissue of the villus into the central lacteal. Formation of lymph is constantly proceeding, and its flow is doubtless aided by the continual movements of the muscular walls of the canal.

† Macklin and Macklin. In "Cowdray's Special Cytology," 1935, p. 283.

The other possible channel of absorption is by the capillary blood vessels of the villus. Each villus is supplied with blood from one or two arterioles which break up into a rich plexus of capillaries lying close under the basement membrane of the villus. The total surface area of the portions of the outer capillary walls which lie immediately below the epithelium is about one-third of the whole epithelial surface, so that the surface through which interchange may occur between the contents of the bowel and the blood is at least three to five times the area of the intestinal mucosa in plan. In these capillaries the blood is circulating rapidly, so that a considerable amount of material may pass into them without appreciably altering the composition of the blood. But the blood in these vessels is at a high pressure, probably not less than 30 mm. Hg. so that we shall have to place out of court any possibility of absorption occurring by a process of filtration. The return blood is collected into one or two veins, which run to a submucous plexus and then join the radicles of the portal vein in the mesentery. It will be evident that, so far as processes of diffusion are concerned, the passage of substances from the lumen of the intestine into the blood stream would be much more favoured than passage into the lymph, for the blood current is so much more swift, and its surface of exposure so much greater than that of the lymph.

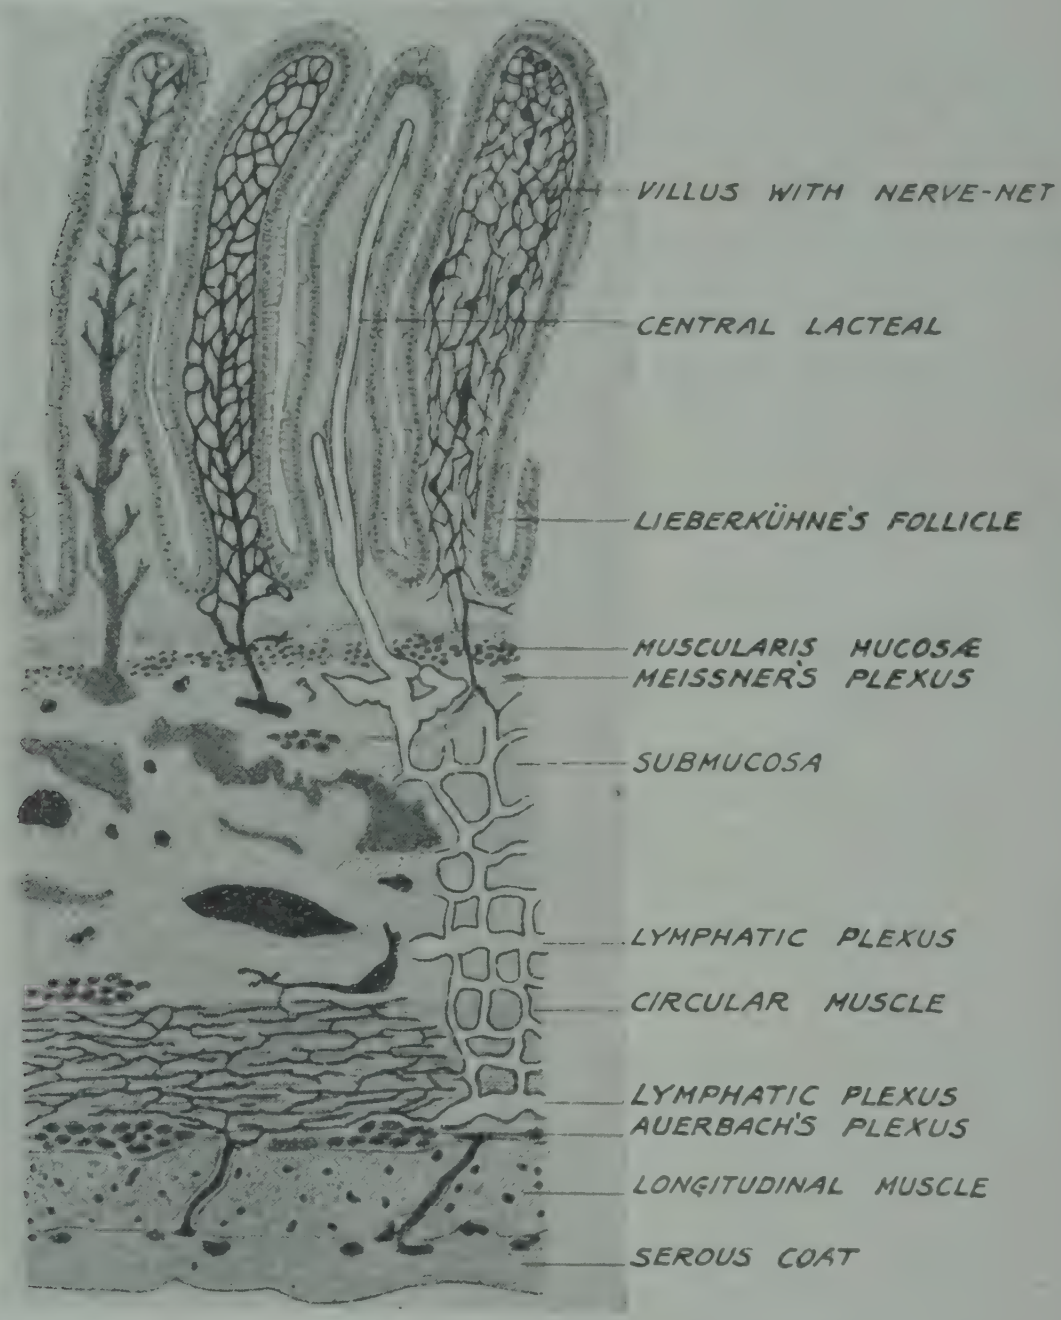

FIG. 580. Diagrammatic Section through Wall of small Intestine to show Vascular and Lymphatic Arrangements. (After SCHAFFER.) (*Lehrb. d. Histol. u. Histogenese*, 1932.)

Movements of Villi. One of the most striking facts in connection with intestinal absorption is that when it is in progress the villi are in a state of continual movement,* which, in a chloralosed dog, can easily be seen on opening the intestine opposite the mesenteric border and examining the mucosa by reflected light (Fig. 581). The movement in carnivora consists of a shortening, at rather irregular intervals of time (about six per minute) to about half the extended length, and then a more gradual extension; the cause of the shortening is no doubt the contraction of the plain muscle of the villus, but the lengthening has not been explained. The villi move quite independently of one another. In herbivorous and omnivorous animals the movements are somewhat different.

In the fasting state the villi are motionless and flattened, so as to look elliptical when seen from above, but if moistened with water or Ringer's solution they immediately swell out to a rounded cross-section and begin their pumping movements. The movements usually cease soon after removal of the intestine from the body, after loss of blood, stoppage of circulation, asphyxia or acapnia.

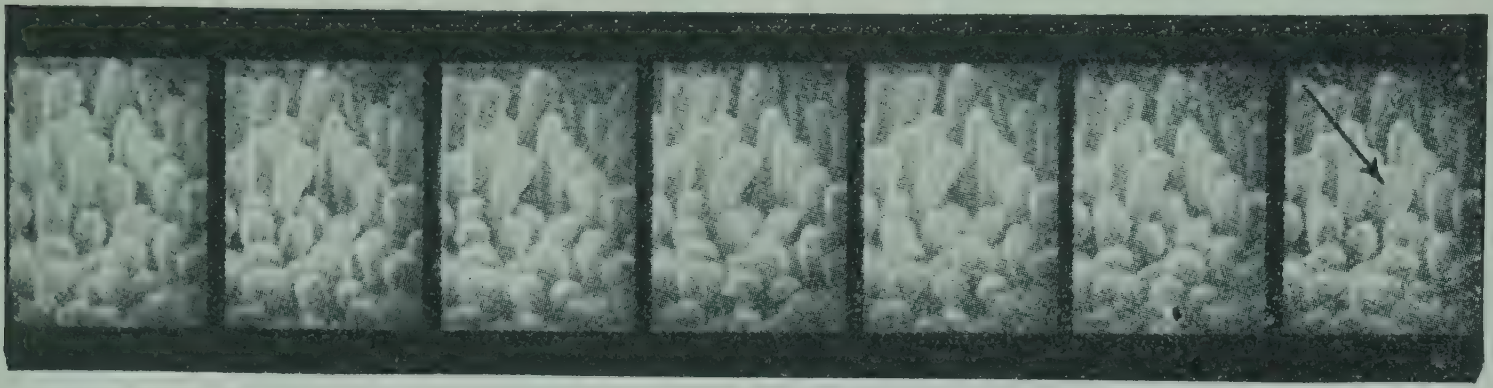

FIG. 581. Portion of cinematomicrograph film showing movements of villi in living intestine of dog during somewhat less than one second. Note the villus indicated by the arrow. (KOKAS and LUDÁNY, *Pflüger's Arch.*, 1930, **225**, 421.)

Mechanical stimuli to the base of the villus cause a contraction, probably by exciting the Meissner's plexus, which appears to be motor to the plain muscle of the villi. Chemical stimuli, *e.g.* eserine, yeast extract, amino-acids, etc., also cause rhythmic contractions of the villi. When the mucosa is stripped off from the submucosa these stimuli all fail if the muscularis mucosæ, together with Meissner's plexus, is detached, but remain effective when it is left behind. The natural stimulus for the contractions of the villi is stated to be a hormone, called *villikinin.* It is extractable from the intestinal mucosa by dilute hydrochloric acid and has been shown, by cross-circulation experiments, to be present in the blood after hydrochloric acid has been placed in the duodenum of a donor dog.†

The Absorption of Water and Dissolved Substances. The absorption of water from the alimentary canal is very little influenced by the water content of the body, the greater part of the ingested fluid being absorbed in the intestine. Thus a man may maintain the water balance of his body steady, whether he take one litre or six litres of water daily. The regulation, apart from that determined by thirst, is carried out by the kidneys.

The intestinal contents at the ileocæcal valve contain relatively nearly as much water as they do at the upper part of the jejunum. Their absolute bulk, however, is much smaller, so that only a small proportion of the water that has been taken in by the mouth remains to be absorbed in the large gut—an amount considerably less than that which has been added to the contents of the small intestine in the form of secretions.

When salt solutions are introduced into the small intestine, they are rapidly absorbed without any increase in the rate of lymph flow, whereas the absorption of large amounts of fluid may cause dilution of the plasma. This has usually been interpreted as meaning that the blood vessels at the surface of the villi are solely responsible for the absorption. But an alternative explanation is possible.

† KOKAS and LUDÁNY. *Q. J. Exp. Physiol.*, 1938, **28**, 15.

On its way through the sub-mucosa the lymph vessel comes into very close contact with special plexuses of small veins, so that it would be quite possible for transfer of water or dissolved material of the lymph to take place into the blood. Hence, in addition to absorption from the intestinal contents into the blood, there might also be reabsorption from lymph into blood.

The problem as to the forces which are responsible for the transfer of various substances from the lumen of the intestine across the " membrane " consisting of epithelial cells, together with interstitial tissue and endothelium of blood or lymph capillary, into blood or lymph respectively, is a very old one to physiology and still presents many difficulties. As regards the *rate* at which the transport occurs, it must be granted that this will be largely influenced by the contractile activity of the villi referred to above. Setting this aside, however, as likely to affect only the quantitative aspect, the problem still allows of no facile solution by reference to simple laws of physical chemistry, probably because our understanding of those laws is not yet sufficiently complete. Opinions, therefore, run in two directions ; according to one view the living intestinal membrane selects those constituents which are to be absorbed in accordance with the needs of the organism ; the other school considers that though the process of absorption may be vastly complicated by special physico-chemical properties of the membrane, yet it is not at present desirable to regard it as fundamentally different from that concerned in the passage of substances through dead membranes. Some of the factors concerned in transport through membranes in general have already been discussed in Chapter VII.

The special physico-chemical phenomena which need some further comment here may be grouped under the headings : (1) Diffusion and Osmosis ; (2) The Special Properties of the Membrane ; (3) Hydrotropy.

(1) Diffusion and Osmosis. These terms have already been explained in Chapter VII., and the reader is here only reminded of some pertinent facts which are in apparent contradiction to the accepted laws of osmosis and diffusion. As an example we may take some experiments * on the passage of water and sodium chloride from the intestine of dogs with Thiry-Vella fistulæ, during half-hour periods, after placing 75 c.c. of solution in the loop. When distilled water was placed in the gut, only 59 per cent. of it was absorbed, but when 0·4 per cent. NaCl was used, as much as 95 per cent. of the water was absorbed. With ascending strengths of NaCl solution, the water absorbed rose from 59 per cent. with pure water to a maximum of 95 per cent. between 0·4 and 0·7 per cent. NaCl, and then fell rapidly because with concentrations over 1·8 per cent. osmotic passage of fluid *into* the intestine, as well as considerable secretion, took place. The absolute amount of sodium chloride absorbed increased with the concentration of NaCl placed in the intestine, up to 1·5 per cent., *beyond which it fell* ; but the percentage of the NaCl given which was removed rose with concentration until about 0·7 per cent. and then fell. At 0·1—1·2 per cent. NaCl (when allowance for secretion into the gut was made) the fluid was absorbed without change of composition, *i.e.* water and NaCl were absorbed together ; from solutions over 1·2 per cent. NaCl, however, the chloride was absorbed faster than the water. Some of these facts might be explicable on the simple laws of osmosis, but some certainly cannot be so explained. The absorption of isotonic solutions has been supposed to be accounted for by the osmotic pressure of the colloids in the blood plasma, but the rate of absorption of 0·9 per cent. NaCl solution was not altered by the addition to it of 6 per cent. gum acacia, which provides a colloid osmotic pressure about equal to that of the plasma.

When isotonic solutions of sodium chloride and sodium sulphate are placed in an intestinal loop the sodium chloride is almost completely absorbed, although blood plasma contains at least 0·6 per cent. of that salt, whereas the sodium sulphate is unabsorbed and remains in approximately isotonic solution.

---

* Rabinovitch. *Amer. J. Physiol.*, 1927, **82**, 279.

Similarly, magnesium ions are unabsorbed.* It is clear, therefore, that osmotic work is performed by the intestine even in an apparently simple case like this one. The active intervention of the cells in the absorption of any substance can be abolished by any means which destroys their vitality, such as the addition of sodium fluoride or cyanide to the fluid to be absorbed, or destruction of the epithelium by previous temporary occlusion of the blood vessels supplying the loop of intestine: when poisoned by cyanide, the difference between the intestinal mucosa and a dead membrane disappear.

Wallace and Cushny,† as the result of their experiments on the relative absorbability of various sodium salt solutions from the gut, divide the salts into four main classes as follows: (1) Sodium chloride, bromide, iodide, formate, acetate, propionate, butyrate, valerianate, caprate; (2) Ethyl sulphate, nitrate, lactate, salicylate, phthalate; (3) Sulphate, phosphate, ferrocyanide, caprylate, malonate, succinate, malate, citrate, tartrate; (4) Oxalate, fluoride.

Of these the first class contains salts which are absorbed with great ease from the intestine. The second are absorbed with somewhat greater difficulty. The third group are absorbed so slowly, *i.e.* the salts retain the water in which they are dissolved so long, that they act as laxatives. The members of the fourth class are not absorbed at all. It is evident that this classification is independent of the diffusibility of the salts. There is, however, one character which apparently determines the non-absorbability (relative or absolute) of the members of the third and fourth classes. All these salts form insoluble compounds with calcium. This common character is not an explanation of the permeability of the cell wall, but is simply a general statement of one of the conditions which affect the power of the cells to take up salts from their solutions, this power being absent in the case of salts which furnish an insoluble calcium compound.

When sugar solutions are used, both sugar and water are completely absorbed, but again certain anomalies appear, which are not readily explained on physico-chemical grounds. Glucose disappears almost as rapidly as sodium chloride or iodide, though its physical diffusibility is less than that of these salts. Further, great differences, which are also not referable to the diffusibility of the sugars in question, are found between the rates at which different sugars are absorbed and in different species of animals.‡ In cats the order of speeds of absorption is galactose $>$ xylose $=$ glucose $>$ fructose. In rats, galactose is the most rapidly absorbed, then comes glucose, while fructose is only half, and mannose only one-fifth as rapidly absorbed as glucose,§ the actual ratios of rates being 110, 100, 43 and 19 respectively. The pentoses xylose and arabinose are very slowly absorbed (15 and 9 respectively); when the intestine is dead, and used like a dialyser, the rates are different, for then, though all substances pass more quickly, xylose passes out even more rapidly than glucose.‖ There is never any passage of glucose outwards from the blood into the lumen of the bowel.

When the rate of absorption of glucose from solutions of different strengths is studied, it is found that the most rapid absorption is from 0·75M (13·5 per cent.) solution, the rate of absorption from this strength being about 20 per cent. more rapid than from 2M solutions.¶ A still greater rate of absorption was obtained when 0·2 per cent. phosphate was added to the 0·75M glucose solution. There is considerable evidence that glucose, and probably other sugars, are absorbed in the form of combinations with phosphoric acid. Thus, serum phosphate is increased during absorption,** while if the phosphatase be poisoned, absorption of glucose from the intestine is inhibited.††

As regards the disaccharides, it would seem that unless these are hydrolysed by intestinal enzymes there is no absorption at all, though they are diffusible readily enough through dead membranes.

It is a further curious fact that some substances, *e.g.* glucose, or amino-acids, are absorbed at a constant rate from the intestine, in spite of the fact that as absorption proceeds the concentration of the substance in the gut diminishes, yet other substances, such as lactic acid and iodides, are absorbed at rates which depend on the concentration of the substance in the intestine at the time.*

When we turn from these facts to seek physico-chemical explanations in accordance with the laws of osmosis, it is necessary, if we are to make any further progress, to consider the latter in a wider sense. In the narrower sense, osmosis refers only to the passage of water through membranes impermeable to all solutes, but it is clear that we need to consider the passage of both water and solutes through membranes of restricted, but variable, permeability. These laws are complex, and have been specially studied by Schreinemakers,† who finds that the course of the interchange of water and solutes will vary, and in an unpredictable manner, according to the number of solutes, their concentration, and the nature of the membrane, so that it is quite possible, for instance, even with dead membranes, to get water or solute moving in a direction which is apparently opposed to simple laws of osmosis as deduced from semipermeable membranes. Experiments with radiosodium (Na^{24}) as a tracer ion show that sodium is constantly moving in and out of the gut, whatever the net direction may be, the total turnover rate between intestine and blood being about equal to the whole plasma sodium every eighty-three minutes.‡ It would be beyond our scope here to enter further into this aspect of the subject.

We must conclude that an active transference of water and solutes from the lumen into the blood stream is effected by the intermediation of forces having their origin partly in the metabolism of the cells themselves. This work of absorption by the cells may be aided or hindered according to the physical conditions present, though our knowledge of these physical conditions is at present too fragmentary to enable us to appraise the respective parts played, on the one hand by the physical conditions and on the other hand by the activity of the cells, which primarily results from and secondarily modifies them by introducing fresh ones. If these act against the cells, *e.g.* if the fluid be hypertonic, the absorption is effected more slowly, while with hypotonic solutions the physical conditions concur with the vital activity of the cells in bringing about a very rapid transference of fluid from the gut into the blood vessels. Among these physical conditions we must reckon the nature of the substances present in the intestine. If these can pass easily into, and through, the cells, *e.g.* ammonium, sodium, or chloride ions, absorption is carried out rapidly. If, on the other hand, the solutes in the intestinal contents are but slightly diffusible, or have very little power of penetrating into the cells, the absorption of water by the cells causes an increased concentration of the solutes, and therefore an increased osmotic pressure which offers a resistance to any further absorption.

(2) **Special Properties of the Membrane.** As already explained in Chapter VII., the results of osmotic experiments, even with dead membranes, depend very much on the properties of the membrane, and this in its turn is dependent, not only on its chemical composition, but, since the membranes with which we are concerned are essentially colloidal, also on its previous history.

Like other cells, those of the intestinal epithelium are bounded on their free surface by a " lipide " layer, permeable only by such substances as are soluble in lipides. On the other hand, the cement substance between the cells may be of a different character and possibly permeable to water-soluble substances. The question has been propounded whether the greater part of the substances which enter the blood plasma from the gut pass between the cells or through them. Water could probably pass in either way. Most of the inorganic salts, as well as the sugars, are insoluble in lipoids and would have to pass between the cells. When the question is investigated by the use of dyestuffs, soluble or insoluble in lipides, it is found that the lipide-soluble dyestuffs, such as neutral red or toluidin blue, pass into the cells, whereas the dyestuffs which are insoluble in such substances pass into the intercellular spaces. Too much stress, however, must not be laid on these experiments. The fact that absorption of these dyestuffs is determined by the physical conditions of the cell membrane is no proof that the absorption of the normal food constituents is determined in the same way. In fact, it is quite legitimate to assume that the lipide limiting layer round every cell has as its main office, not the regulation of the access of foodstuffs to the cell, but its protection from anything which it does not require. If it were not for such a membrane the assimilation of a salt would be determined entirely by its concentration in the immediate surroundings of the cell, whereas we know that assimilation by any living organism, whether uni- or multi-cellular, is regulated in the first place by the activity of the organism itself. The properties of the membranes are also liable to be altered by such phenomena as adsorption, electric charges, imbibition, Donnan equilibria, etc.

(3) **Hydrotropy.** Hydrotropy* is the property of certain substances to render other substances soluble in water, in which otherwise they would be insoluble. The increase of solubility is sometimes remarkable, as, for instance, a 100-fold increase in the solubility of sulphonal by sodium salicylate, a five-fold increase for uric acid by atophan, etc. Hydrotropic substances are usually salts of certain organic acids which powerfully lower surface tension ; the substances which are brought into solution by their agency include fats, lipides and sterols.

Verzár and Kúthy† showed that various substances, particularly fatty acids, are dissolved, and, what is much more important, rendered dialysable, by the bile salts. Thus oleic acid was emulsified in a phosphate buffer-solution, and then 5 per cent. sodium glycocholate added. The mixture was placed in a dialyser, outside which was the same mixture without any fatty acid. After sixteen hours' dialysis the contents of the dialyser and the outer fluid were analysed for fat, with the results shown :—

DIFFUSION OF OLEIC ACID DISSOLVED IN NA GLYCOCHOLATE
(Verzár and Kúthy)

No.	pH	Per cent. oleic acid.				Per cent. of fat not diffusible.
		In dialyser.		In outside fluid.		
		Beginning.	End.	Beginning.	End.	
1	6·5	0·081	0·052	0·0	0·042	—
2	6·5	0·250	0·172	0·0	0·078	37·6
3	7·0	0·059	0·033	0·0	0·027	—
4	7·0	0·220	0·142	0·0	0·069	37·3

With the more dilute solutions, the fatty acid was almost completely diffusible, but with the stronger ones, only about two-thirds of it was really dissolved.

It cannot be doubted that the phenomena of hydrotropism may play a very important *rôle* in connection with the absorption of fats, sterols,‡ calcium salts, and other substances which are normally insoluble in water.

The Absorption of Fats

At least 95 per cent. of ingested fat is normally absorbed. The processes of digestion of fat result, first, in very fine emulsification (p. 27), and second, in hydrolysis to glycerol mono- and di-glycerides and fatty acids. For the rapid absorption of fats, three factors are necessary, firstly the fat must be, at least in part, hydrolysed, secondly bile salts must be present ; these two factors provide the trinity of components—monoglyceride, fatty acid, bile salts—which most effectively promotes emulsification ; thirdly the enzyme phosphatase must be present in the gut : if any condition is lacking, absorption is delayed. Analyses of the contents of the gut after a fatty meal show § the emulsion to consist of negatively-charged particles of 0·5μ diameter, or less; some of the fats are present as mono-glycerides and fatty acids, the amount of these as compared with unchanged fat increasing as we descend the gut. Some of the fat may thus be presented for absorption in a state of true solution in consequence of the hydrotropic action of the bile salts. Very little of it can be presented in the form of a soap, since the pH of the contents is about 6·5, but soaps are unstable at reactions more acid than pH 9·0.

It is probable that some fat is absorbed without being split at all, but the means by which this is effected is unknown. One condition for this seems to be very fine emulsification (particles less than 0·5μ). Even an inert substance like liquid paraffin is absorbed if it is first artificially reduced to an emulsion of a fineness comparable with that to which the fats are reduced in the normal course of digestion.*

If an animal be examined a few hours after a meal rich in fats, the lymphatics of the intestine, the *cisterna lymphatica magna* and the thoracic duct are seen to be distended with a milky fluid—*chyle.* The opacity is due to the presence of minute granules (0·05 to 1 μ) called *chylomicrons.* These consist, not of fatty acids, but of neutral fat.† The fat in such chyle may amount to over 6 per cent., so that in a moderate-sized dog 12 grammes of fat may be carried in the course of an hour from the intestine to the blood by this means.‡ The fact that this is mainly or entirely neutral fat means that, if lipolysis occurred prior to absorption, resynthesis has taken place during absorption. The esters formed are not always glyceryl esters—sometimes cholesteryl esters are found in chyle. Chylomicrons begin to increase in the blood about thirty minutes after a standard meal containing about 30 grammes fat, and reach a peak at about two hours, the peak being higher for obese subjects than for thin ones (Fig. 582). During fat absorption the plasma and serum are therefore milky, and on standing, fat

globules may rise like cream to the surface of the serum. Fat is found in a free state in this finely divided condition in the blood plasma so long as it is being absorbed from the intestine.*

The Blood Lipides. The blood lipides consist of fats, phospholipides and cholesterol. In the post-absorptive state the plasma contains about 600 mg. lipides per 100 c.c. Of this about 100 mg. is usually neutral fat, but this may be absent; phospholipides (calculated as lecithin) amount to about 250 mg./100 c.c.; cholesterol about 150 mg./100 c.c., of which half is free and half is in the form of esters. The red cells contain about 700 mg. lipides per 100 c.c., distributed roughly as follows: neutral fat, 0–150 mg.; phospholipides, 450 mg.; cholesterol (nearly all free), 175 mg.

After a meal containing fat the blood fat and phosphatides show a rise after about two hours, and remain high as long as absorption of fat continues, say for a further two to seven hours. The cholesterol esters of the plasma also increase in fat absorption. Apparently, during absorption more of the lecithin is present in the corpuscles than in the plasma. In from six to ten hours after absorption is complete, free fat disappears, the serum becoming perfectly clear. Thus part at any rate of the fat which is absorbed from the gut is carried thence by the lymphatic channels in the form of neutral fat to the blood stream, by which it is distributed to the various tissues of the body, gradually leaving the blood stream in a manner which at present has not been determined. After a heavy meal of fat, and while the fat content of the blood is high, there appears to be engulfment of fat particles by the endothelial cells of the blood capillaries; the further fate of this fat is uncertain, but it may be passed on into the tissues.

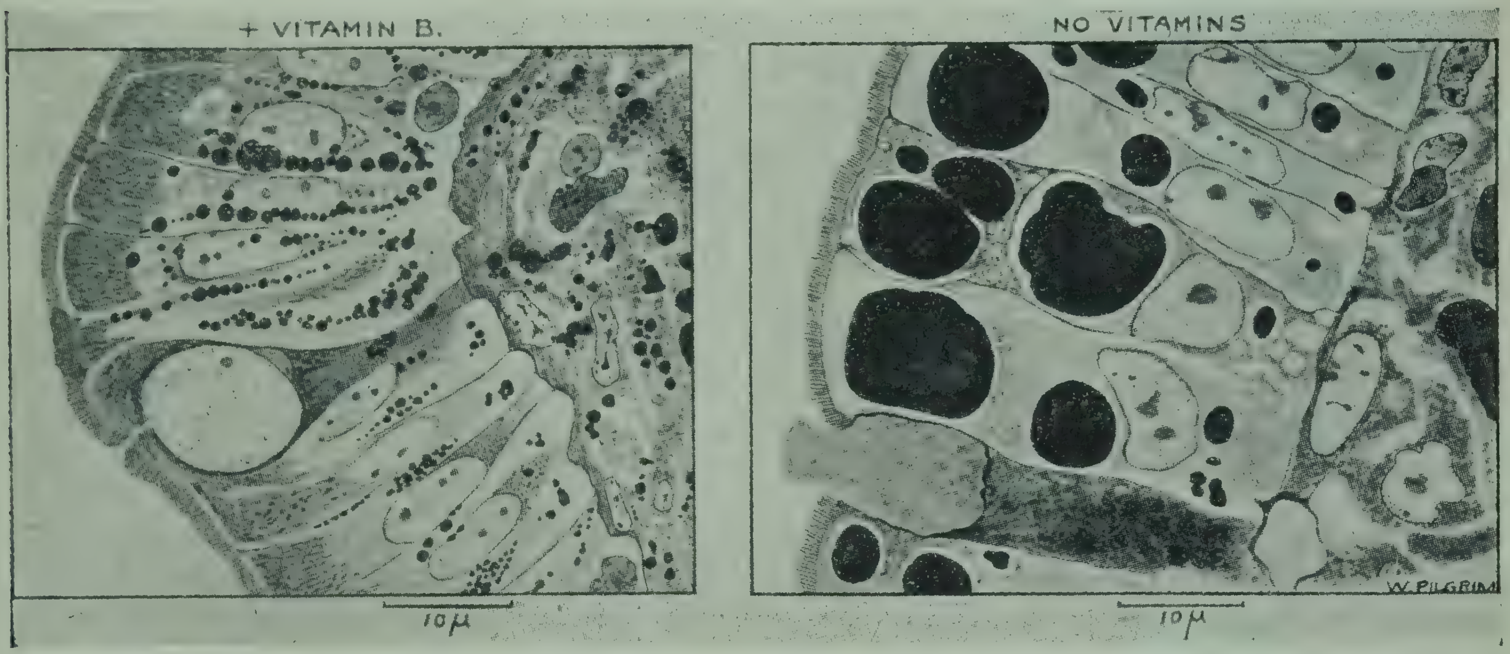

FIG. 583. Epithelium of villus during fat absorption in the rat. On left, showing absorption by streams. On right, absorption by drops. The fat is stained black with osmic acid. (MOTTRAM, CRAMER and DREW, *Brit. J. Exp. Path.*)

Complete starvation causes an increase in all the blood lipides, but the rise in neutral fats is especially great if the subject is obese.

Paths of Fat Absorption. It seems evident that much of the fat which is absorbed takes the path by way of the lymphatics and thus into the blood plasma, though certain facts have presented difficulty in the way of accepting this as a complete view of the process. Ligature of the thoracic duct certainly impedes the absorption of fat, but does not abolish it; the percentage of fat in the blood rapidly falls to a minimum which remains constant, even during starvation. If now fat be administered, although a considerable proportion of it may be absorbed, the percentage of fat in the blood is not raised. If the thoracic duct lymph be collected during the absorption of a given quantity of fat from the intestine, sometimes not more than 60 per cent. of the fat which has disappeared from the gut can be recovered from the lymph. The explanation seems to be that fat is absorbed into both blood and lymph, the fully hydrolysed products largely into blood, the unsplit fat into lymph. If fatty acid or prelipolysed fat is ingested there is lipæmia in portal blood but not in systemic blood, nor much fat in the chyle.* The blood-absorbed fatty acid is taken up from the blood by the liver, the chyle-fat probably by fat depôts.

---

* NISSEN. "Studies in Alimentary Lipæmia in Man." (1933, Copenhagen: Levin and Munksgaard.)

Microscopic examination of a section of a villus during fat absorption shows that absorption occurs through the epithelial cells, in which droplets of fat appear in abundance; they are also demonstrable within the lacteal vessels. We are thus faced with three problems: how does the fat pass into the epithelial cells, what happens to it there, and how does it pass out and into the lacteals? To none of them can an adequate answer be given.

Fatty acids solubilised by the hydrotropic action of bile salts may be provisionally accepted as capable of passing right through the epithelium and into the blood.

It has been credibly suggested that the bile salts are preferentially absorbed, or adsorbed, by the epithelial cells covering the villi, and there exert their solvent action to great advantage. The lecithin of the bile greatly augments the hydrotropic action of the bile salts.† Whereas a 5 per cent. sodium glycocholate solution dissolves 0·12 per cent. of oleic acid, the presence of 0·8 per cent. lecithin raises the solubility to 4·5 per cent.‡ We have seen that the bile salts undergo a circulation, so that the same quantity of bile salts may therefore be used over and over again. That the presence of bile in the intestine is essential for the normal absorption of fat is shown by the fact that on establishment of an external biliary fistula, the utilisation of fat sinks from about 98 per cent. to about 40 per cent., the unabsorbed fatty acid appearing in the fæces.

The absorption of insoluble, unsplit fats, presents greater difficulty. No doubt the cell surface is itself of a lipoidal nature, and fine particles of fat might melt into it: the outer striated hem has also been thought to contain fine channels through which particles might pass.

It has been claimed that absorption of fat through the cells may occur in one of two different ways.§ In the first method, called "*absorption by streams*," a stream of fine fat droplets passes on either side of the nucleus, and the outer part of the cell is free from droplets. Abundant droplets of fat are also seen in the reticular tissue of the core of the villus (Fig. 583).

In the other method, called "*absorption by drops*," the columnar cells are found closely packed with fat granules (Fig. 583) which, small at the beginning of the process of absorption, rapidly enlarge till they occupy the greater part of the cell lying between the nucleus and the striated border. No fat globules are to be seen within the border itself. Mottram, Cramer and Drew found that when vitamins A and B were absent from the food, absorption was by drops. Frazer could not confirm this, but found that addition of choline caused somewhat similar results. It has been suggested that absorption by drops occurs when unhydrolysed fat is absorbed direct.

In the process of fat absorption, the fat is collected in the first place near the Golgi apparatus of the cell, which becomes greatly enlarged during the absorption, and no doubt plays some part in it (Fig. 584); Cramer and Ludford ‖ suggest that it effects the synthesis of neutral fat from fatty acid.

Investigations by special staining methods which distinguish fatty acids from neutral fat or soap ¶ showed that no soap was histologically detectable, but there was plenty of fatty acid, as well as neutral fat, in the epithelial cells, and fatty acid was still found even in the lacteals.

During fat absorption there is some conversion of the fatty acids in the cells to phospholipid compounds by phosphorylation under the action of the intestinal phosphatase. This explains the increase in the phospholipides of the blood during fat absorption; some of the lecithin added to the blood is adsorbed by the red cells. When fat is given together with radioactive "labelled" phosphorus compounds, the phospholipides of the intestinal mucosa in a short time contain the distinctive element. The importance of the enzyme phosphatase is shown by the fact that fat absorption is inhibited by the administration of iodoacetic acid, which poisons this enzyme.

How the droplets of fat are passed from the interior of the epithelial cells into the reticular tissue of the villus, and from there onwards into the lumen of the lacteal, remains a mystery. There is definite evidence* that the fat is not transported to any extent, as was once supposed, by leucocytes. It is conceivable that, if the epithelial cells, when sufficiently charged, extruded their droplets into the reticular tissue, they might be transferred thence into the lacteal, together with lymph, by the pumping action of the villi, since we have no positive evidence that the walls of the lacteals are continuous under all conditions. In any case, the contractions of the villi may well play an important part in the process by emptying the lacteals into the submucous plexus of lymphatics, and so on into the valved lymphatics of the mesentery.

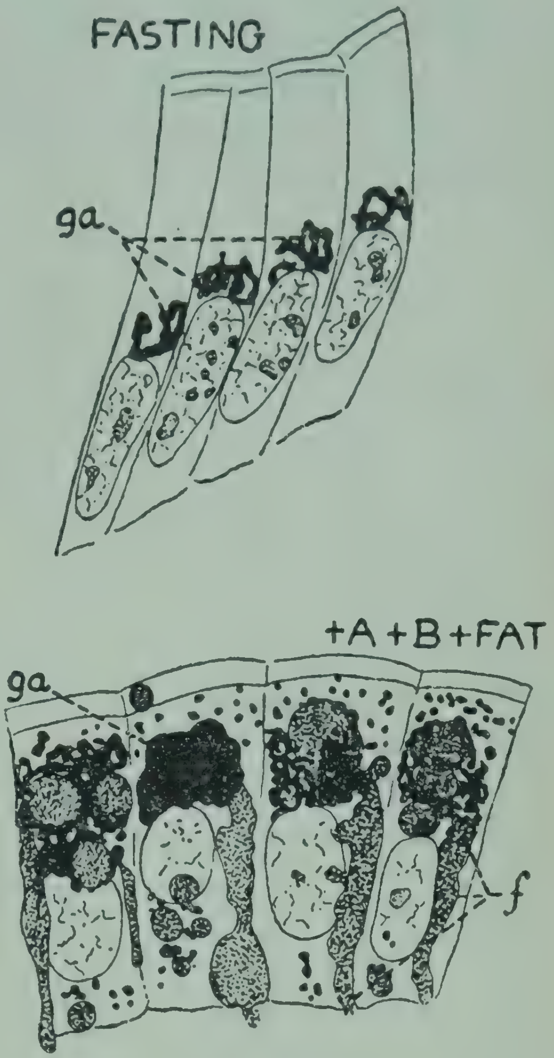

FIG. 584. Showing relation of Golgi apparatus to fat absorption. Above, fasting cells of villus. Below, cells during absorption of fat. *ga* = Golgi apparatus. *f* = fat droplet. (CRAMER and LUDFORD, *J. Physiol.*)

Absorption is interfered with by ligature of the pancreatic duct, so removing lipase from the gut. If the fæces be analysed, it is found that a large proportion of the fat has been split into fatty acids which have remained unabsorbed. This lipolysis has, however, been carried out by the agency of micro-organisms, *i.e.* in the lower segments of the gut where the greater part of the bile has been already reabsorbed. If fat, in a finely divided form, be given to animals deprived of their pancreas, a certain proportion of it is absorbed. Under these conditions some lipolysis may occur in the stomach itself, or absorption of the emulsified fat may have occurred directly.

Substances which are physically almost identical with fats, *e.g.* liquid paraffin, are almost unabsorbed, except when introduced into the intestine in the finest possible emulsion ; after prolonged feeding with liquid paraffin small amounts of it can be found in the liver.† Cholesterol and other sterols, however, are absorbed, most readily when fat is also given, and may be recovered from the liver ; the ease of absorption runs parallel with the solubility of the substance in bile salts.‡

Removal of the whole large intestine does not affect fat absorption.

The Absorption of Carbohydrates

As a result of the action of the various digestive juices, all the digestible carbohydrates of the normal diet of man are reduced to monosaccharides. In the absorption of these by far the greatest part is played by the small intestine. By the time that the food has arrived at the ileocæcal valve, practically the whole of the carbohydrate constituents of the food have been absorbed by way of the vessels of the portal system. The lymph from the thoracic duct contains no more sugar than does the arterial blood taken at the same time, whereas there is an increased percentage of sugar in the portal blood, and even in the general circulation, during the absorption of a big carbohydrate meal.

† CHANNON and COLLINSON. *Bioch. Journ.*, 1929, **23**, 676.

‡ CHANNON and COLLINSON. *Bioch. Journ.*, 1928, **22**, 391.

The problem as to the passage of these substances across the intestinal wall into the blood vessels has already been dealt with. A most striking fact is the relative impermeability of the intestinal wall to the disaccharides as compared with the monosaccharides.

The Absorption of Proteins

The amino-acids produced by protein digestion are absorbed by the blood vessels of the intestinal villi, and pass unchanged into the portal blood. There is no significant increase in the amount of lymph flow or in the amount of protein contained in this lymph during digestion. Moreover, it was shown by Schmidt Mülheim that the absorption of protein was not interfered with as the result of ligature of the thoracic duct.

During the absorption of a protein meal, changes have been described by various observers in the structure of the villus. Several observers have described changes in the epithelium as the result of protein digestion, the cells of the villi becoming swollen and vacuolated.

The first question we have to decide is whether the proteins are always completely hydrolysed before absorption. There is some evidence that serum proteins may be absorbed by the small intestine, though, unless unchanged protein can be shown to have passed into the blood, we cannot exclude the possibility that hydrolysis had occurred owing to the action of intestinal enzymes. An argument in favour of active intervention of the cells of the gut in absorption is perhaps furnished by the fact that if an animal's own serum be introduced into a loop of its intestine the whole of the serum is absorbed. It is not easy to explain this result as due to the digestion of the proteins and their conversion into diffusible products, since the intestinal loops were washed free of any trypsin, and serum has a strong antitryptic action which would prevent its being attacked by traces of trypsin. It has also been claimed by Mills[*] that tissue fibrinogens can be absorbed from the intestine and recovered unchanged from the urine. Foreign proteins, such as egg albumin, or the serum of other species introduced into the blood stream, may cause poisonous effects and albuminuria. If injected in small quantities they excite, as a reaction on the part of the organism, the production in the blood serum of a *precipitin*, and later the animal becomes anaphylactically sensitised (Chapter IV.), and the presence of the precipitin or of anaphylactic sensibility may therefore be looked upon as a test by which we may decide whether these proteins have passed through the intestinal wall unchanged. In most cases it is found that, however abundant the amount of protein administered, none of it appears in the urine, nor is any precipitin formation or anaphylactic reaction aroused. Ascoli, however, has observed such results occasionally to follow the administration of large doses of egg white, and it has been shown[†] in the sensitised human subject that "allergic" reactions may then ensue when the specific native protein is eaten, or even given per rectum. In experiments on guinea-pigs this was not the case unless there was simultaneous damage to the intestinal wall, or considerable pressure applied within the gut.[‡] There is a difference, according to age, in the behaviour of animals to the introduction of soluble protein into their alimentary canal. It seems that during the first few days of life the cellular lining of the alimentary canal is slightly permeable to foreign proteins, whereas later on little or no protein is absorbed unchanged from the gut.

The absorption of unchanged proteins can therefore play but a small part in the assimilation of protein as a whole.

When peptones and proteoses are introduced into the intestine they are rapidly broken down to amino-acids by enzymes of the intestinal juice ; this explains why, in the earlier experiments when peptone was absorbed no peptone could be found in the portal blood—a fact which led to the incorrect deduction that the peptone had, in the course of absorption, been synthesised to form native proteins of the blood plasma.

We know from the researches of Fischer and others that, although the different proteins in our food present a marvellous qualitative similitude, in that all of them yield on hydrolysis the same kinds of amino-acids, there are great differences in the relative amounts and stero-chemical arrangement of these amino-acids in different proteins. It is difficult to imagine how, for instance, muscle protein could be formed from wheat protein, a process continually occurring in the growing animal, unless we assumed that the protein molecule is first partly taken to pieces, and that its constituent molecules are then selected by the growing cells of the body and built up in the order and proportions which are characteristic of muscle protein.

[‡] HETTWER and KRIZ. *Amer. J. Physiol.*, 1925, **73**, 539.

Very little energy is lost in such transformation, *i.e.* the heat of combustion of the products of digestion would differ from that of the original protein by less than 5 per cent.

Since all the evidence shows that ingested protein undergoes complete hydrolysis before entering the blood stream, it should be possible to feed an animal on a diet in which the protein had been replaced by the corresponding mixture of amino-acids. The experimental decision of this question was first attempted by O. Loewi,* who kept a dog in a state of nitrogenous equilibrium on a diet containing fat, starch, and a pancreatic digest of protein, which contained no substances giving the biuret test. These results have been confirmed,† and it has also been found that the intravenous injection of mixed amino-acids will keep a man in nitrogenous equilibrium if equal in N-content to the requisite amount of protein ‡; the administration (plus glucose), of 2·5 to 10 per cent. enzymic protein hydrolysates, or of acid hydrolysates to which tryptophan and methionine have been added, is now a recognised clinical procedure in dealing with almost moribund patients too weak to be fed.§ For starved and declining prisoners in concentration camps in 1945, however, oral administration proved as good as injection.

The Fate of the Amino-Acids after Absorption. During starvation the protein requirements of the active tissues are met at the expense of the less active tissues. The proteins characteristic of any tissue can be taken down, removed to another part of the body, and built up into the proteins characteristic of some other active tissue. It is difficult to conceive that such a transference and transformation could occur in any other way than by a more or less thorough disintegration of the protein molecule at one place and its synthesis at the other, and we know that every tissue contains intracellular enzymes (cathepsins) which are capable of effecting the disintegration of proteins, and are responsible for the autolysis of tissues after death. There is thus no *a priori* reason to believe that the blood carries the proteins from the alimentary canal to the tissues in any other form than that of amino-acids. Strongly in support of this conclusion is the evidence ‖ that after a protein meal there is an increase in the non-protein nitrogen (*i.e.* the nitrogen not present as coagulable protein) of the blood, and particularly in the portal vein blood. The final proof was rendered possible by Van Slyke's method ¶ for the detection of small quantities of amino-acids in the blood and tissues, and ultimately by the actual isolation of amino-acids from the dialysate prepared by circulating blood from a living animal through a collodion dialyser,** and back to the animal again. Several different amino-acids have been isolated from the blood,†† though it is not known to what extent or under what circumstances the individual amino-acids are altered in amount. In sum, however, their amount does vary. The blood always contains a certain amount of amino-acids, even during fasting, but after a protein meal there is a considerable increase in the amount.‡‡ Thus the blood of fasting animals contains from 3 to 6 milligrammes of amino-acid nitrogen per 100 c.c. Blood taken after food contains from 8 to 10 milligrammes of amino-acid nitrogen per 100 c.c.

In Fig. 585 are shown the results of experiments on rats absorbing a diet of meat. The upper curve (I) shows the per cent. of absorption from the intestine; the lower curves show (II) the amino-nitrogen of the blood, and (III) the oxygen consumption of the animal. During the first three hours absorption is rapid, the amino-N of the blood rises steeply, and with it the oxygen usage—a similar increase of oxygen usage is obtained if amino-acids are injected direct into the blood (specific dynamic action).

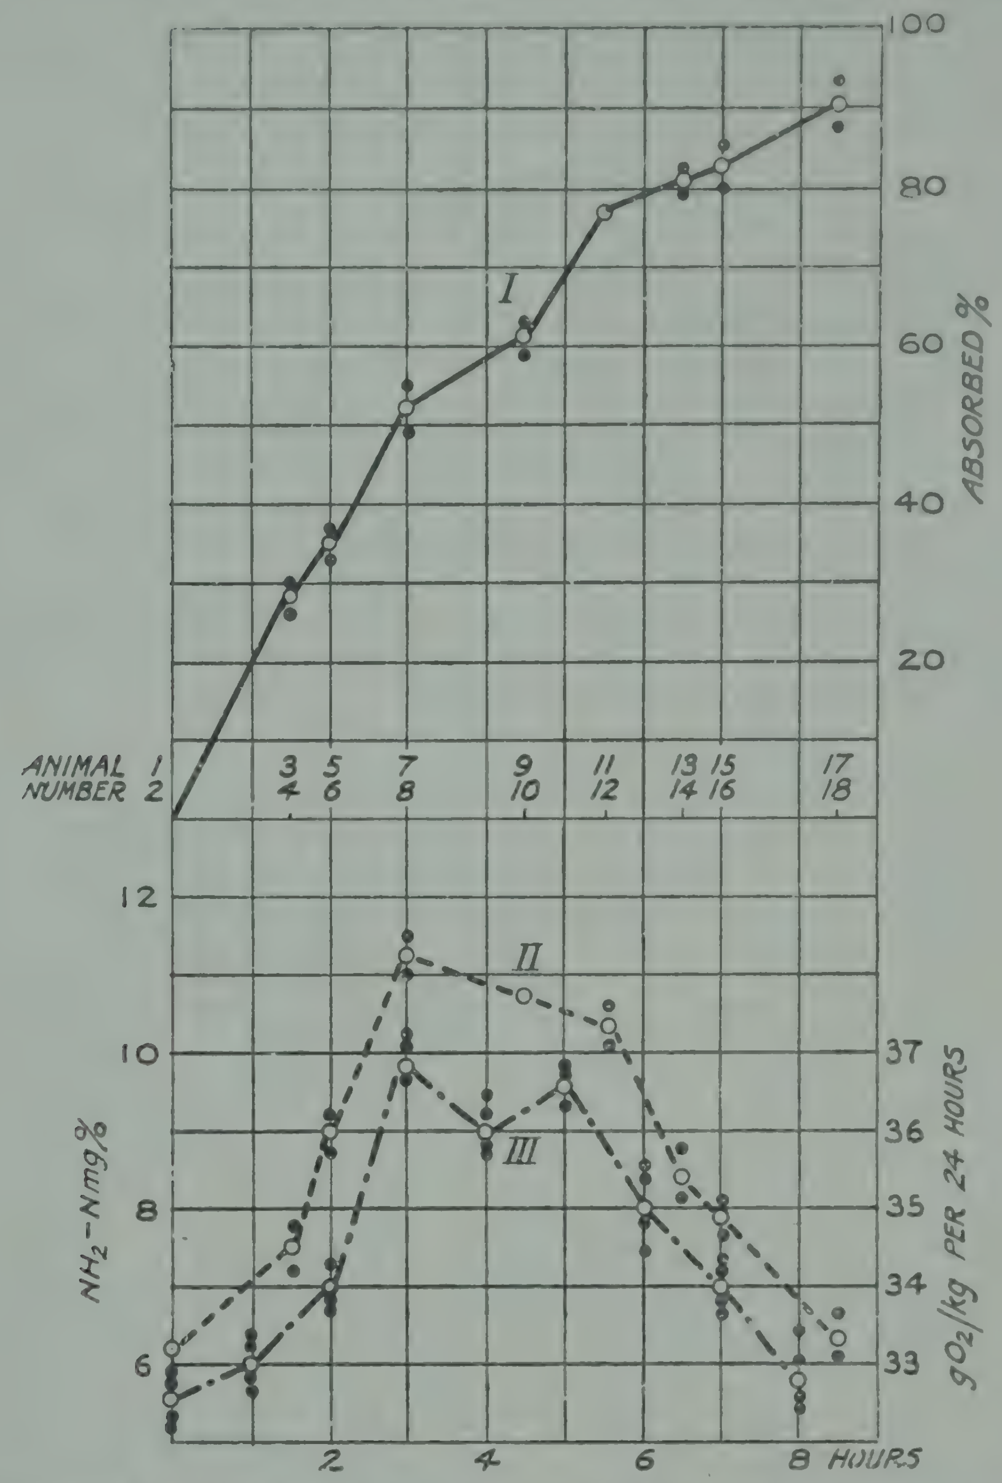

Fig. 585. Effect of feeding rats with meat. I. Rate of absorption from alimentary canal. II. Amino-N of blood. III. Oxygen usage of animals. (Kúthy.) (From Verzár, *Ergebn. d. Physiol.*, **32**, 1931.)

The question of the fate of amino-acids thus absorbed from the intestine into the blood is decided by an estimation of the amino-acid content of the blood and of different tissues at various times after the injection of amino-acids into the blood. After the injection of amino-acid, only a certain proportion is excreted in the urine, and the rest of the amino-acid rapidly disappears from the blood and is taken up by the tissues without undergoing any immediate chemical change: in certain tissues, such as the muscles, a definite saturation point exists which sets the limit to the amount of amino-acids that can be absorbed, but the capacity of the internal organs, and especially of the liver, for the absorption of amino-acids is much greater.

It is worthy of note, however, that the abstraction of amino-acids by the tissues from the blood is never complete, *i.e.* the amino-acids of the blood must be in a state of equilibrium with those of the tissues, although the concentration in the latter may be much greater than in the former. If several hours be allowed to elapse after the injection of amino-acids before the analysis of the tissue is undertaken, it is found that the amino-acid nitrogen content of the liver may have returned to normal, although the concentration in the muscles has suffered no appreciable fall. We know that this difference is due to the fact that the liver is the main site of amino-acid breakdown.

We therefore conclude that the amino-acids produced by protein digestion are absorbed without further change into the blood stream. They then circulate throughout the body, as a result of which an equilibrium concentration is established for each amino-acid between the blood and the several tissues, a certain proportion of them finally being built up in each tissue into the proteins characteristic of that tissue in order to replace the waste caused by wear and tear. The rest, probably the major part of the amino-acid, is taken up by the liver, where most of it undergoes deamination, the nitrogen moiety being rapidly converted into urea which is excreted by the kidneys, while the non-nitrogenous moiety is carried to the working tissues, which it serves as a ready and immediate source of energy.

The distribution of the amino-acids in fasting, starving and during absorption has been studied in cats by Bolton and Payling Wright.* They estimated the amino-nitrogen in blood and in plasma coming from the intestine by the superior mesenteric vein, in that leaving the liver by the hepatic vein, in blood going to the tissues by the carotid artery, in blood leaving the tissues by the inferior vena cava, and in the lymph.

Some of their average results are given below :—

Condition.	Average amino-N (mg/100 cc.) in blood plasma of				Lymph.
	Carotid.	Sup. Mes Vein	Hepatic vein	Inf. ven. cava	
Fasting . . .	5·0	5·3	4·8	5·3	5·9
Starving . . .	4·9	4·9	4·4	5·4	6·1
Fed peptone 20 g. 5 hrs. before . . .	15·2	19·5	15·9	14·9	17·1

These experiments bear out the current view that absorption of the amino-acids into both the capillaries and the lymphatics of the villi is in accordance with the laws of diffusion. The blood capillaries being more superficial, and the lymph being diluted by the tissue fluid derived from the afferent blood stream, the amino-acids reach a higher level in the portal blood than in the lymph during absorption. Always there is a lower level of amino-acids in the hepatic vein blood, showing that the liver is constantly removing amino-acids from the blood. Also, in fasting, the blood from the tissues and intestine has the same content of amino-acid, while in starvation the venous return from the tissues has a raised content as compared with the arterial blood, which shows that the muscles and other tissues are undergoing a process of breakdown, yielding amino-acids to the blood and lymph.

The fact that not only the blood but also the tissues contain amino-acids, even after complete starvation for some days, shows that these substances are intermediate steps not only in the synthesis but in the breaking down of body proteins. Free amino-acids are thus the protein currency of the body, just as glucose is the carbohydrate currency. The fact that high protein feeding does not appreciably increase the amino-acid content of the tissues shows that any storage of nitrogen in the organism must take place, not in the form of amino-acids, but as tissue protein.

The Plasma Proteins. The plasma proteins, serum albumin and serum globulin, probably play an important *rôle* in protein metabolism. The plasma proteins are almost certainly formed, in the liver, from the amino-acids derived from digestion of protein ; they then act as a reserve of readily available protein in case of need. In prolonged protein starvation, the plasma proteins are lowered, and when, in man, the level drops below 5·5 per cent., hunger œdema may occur, because of the lowered colloidal osmotic pressure of the plasma.

---

* Bolton and Payling Wright. *J. Physiol.*, 1937, **89**, 269.

The plasma proteins can be experimentally lowered by the process called *plasmapheresis*. In this, blood is drawn daily, and the corpuscles washed with isotonic salt solution and reinjected. By suitable, steadily diminishing, daily plasmaphereses the serum proteins can be lowered, say, from 6 per cent. to a certain low level, say, 4 per cent. The plasma protein that must be removed per week in order to maintain this level reaches a constant figure, called the basal output. If anything is done to upset the balance, more or less plasma protein must be removed in order to keep the constant low level. Feeding with different proteins, for instance, will alter it. Thus, 100 grammes ox serum protein will form 38 grammes serum protein in a dog, 100 grammes meat forms about 20 grammes, and 100 grammes gelatin only 5 grammes.

Plasma protein can be formed also from reserve stores in the body, and fasting animals can replace 40 to 60 per cent. of the circulating plasma protein within twenty-four hours, and even after an extensive hæmorrhage up to 25 per cent. of the original plasma protein is reinstated in about twelve hours. The plasma proteins so added are apparently not drawn from a preformed stock, but are constructed within a few hours.* Conversely, plasma protein can be utilised for general purposes. Thus a protein-starved dog can be kept in nitrogenous equilibrium by frequent injections of dog plasma. This accession of protein appears to benefit the tissues directly, for it is not followed by an increase of nitrogen output as dietary protein intake would be, nor does it raise the blood amino-acids, although the injected plasma protein has all disappeared in less than twenty-four hours. Starved people in prison camps benefited by intravenous serum injections.

It seems probable, therefore, that the tissue proteins are supported by amino-acids and/or plasma proteins. Part of the tissue protein forms a reserve and is readily and quickly depleted. Depletion occurs in protein starvation, illnesses due to infections, burns, fractures, etc. Supplies of amino-acid from without, and demand for protein within, are in a condition of dynamic equilibrium with protein reserves. If the need for protein for cells or plasma exceeds the supply from amino-acids, the reserve stores, including plasma proteins, will be depleted, and if less it will be replenished. It seems probable that tissue proteins can be built from plasma proteins without loss of nitrogen.

THE ACTUAL COURSE OF DIGESTION. London † described the course of digestion of meals in dogs which had been provided with fistulæ at various points along the alimentary canal.

We may take as an example the digestion of 200 grammes of bread. This evoked the secretion of 20 grammes of saliva, about 10 grammes of mucus from the coats of the stomach, and about 315 grammes of gastric juice. In the animal with a pyloric fistula, the first admixture of the food with the outflow from the fistula occurred at eight to twelve minutes after the completion of the meal, and after this time the pylorus continued to open at regular intervals, discharging each time a small amount of fluid composed of particles of undigested bread mixed with gastric juice. The following Table shows the percentage amount of food taken which had left the stomach at the end of each hour after the meal :

First hour	32·6 per cent.
Second hour	17·9 ,,
Third hour	29·5 ,,
Fourth hour	1·87 ,,
Fifth hour	6·66 ,,
Sixth hour	4·21 ,,

The outflow from the duodenum, being mixed with the pancreatic juice and the bile, is yellow in colour and increased in amount. With a meal of 200 grammes there are secreted on the average 130 grammes of bile and 140 grammes of pancreatic juice.

---

* EBERT *et al.* *Amer. J. Physiol.*, 1942, **136**, 299.

† LONDON. *Z. f. Physiol. Chem.*, 1907, **53**, 246 ; 1908, **56**, 378 ; 1909, **60**, 191, 267.

On deducting the amount of juices which have been added to the food, it is found that even in this short length of intestine absorption of about one-sixth of the ingested food has taken place, about one-fourth of the carbohydrates having been absorbed and about one-eighth of the proteins.

In a dog with a fistula about the middle of its small intestine, the material obtained was quite different in character from that flowing from the duodenal fistula. The pasty character had disappeared, the material forming a frothy, orange-yellow, even jelly-like mass with practically no trace of undigested bread.

From a fistula in the ileum the outflow was much scantier than that obtained from the jejunal fistula, consisting of a thick jelly-like, orange-coloured mass. Both proteins and carbohydrates were entirely digested.

From a fistula in the cæcum there was no outflow until four or five hours after the meal. The material from the gut was then extruded in fæcal-like masses at intervals of one half to one hour. This regular outflow lasted for about six hours. The reaction of the contents was strongly alkaline, with no food particles, and the material contained merely débris of cells, with small traces of sugar, dextrin and unaltered starch. The absorption of the foodstuffs is thus practically complete by the time that the food has reached the lower end of the small intestine.

The following Table gives the total amounts obtained in a series of experiments from the different fistulæ after administration of 200 grammes of bread, and also the percentage amount of foodstuffs which had been absorbed at each level :

	Total amounts obtained from 200 grms. of bread.	Absorbed per cent.
Pyloric fistula	691 grammes	0
Duodenal fistula	691 ,,	17·45
Jejunal fistula	585 ,,	37·77
Ileal fistula	412 ,,	67·65
Cæcal fistula	80 ,,	94·34

CHAPTER XLVI

THE HISTORY OF THE FOODSTUFFS

The absorbed products of the foodstuffs have varied histories in the body; for a while some of them, after modification, may linger on in new guises as component parts of the living framework, but sooner or later all of them suffer ultimate oxidative breakdown to relatively simple compounds, which are got rid of by excretion. The physiological history of these chemical transformations is called *metabolism*, or *intermediary metabolism*.

For purposes of description the subdivision of the subject under the headings of protein, carbohydrate or fat metabolism is retained. But it should be realised that such subdivision is largely artificial, and that actually these various metabolic highways have crossroads in common, and so are interrelated. Moreover, the distinction between the materials of the living machinery and the non-living fuel which it uses are less sharp that was once supposed.

The Use of Isotopes in the Study of Metabolism

An important aid in following the fate of a substance in the body is provided by the use of elements in isotopic form. There are two types of isotopes which may be used. The first of these are the naturally occurring ones.

When an element occurs in both normal and isotopic forms, these differ only in atomic weight, and physical properties which depend on it, but are otherwise indistinguishable. The proportion of an isotope in a given element is constant, whether the element be free or in combination. Thus nitrogen, whether in air, in an amino-acid, ammonia, urea or protein, always contains 1 part of N^{15} (*i.e.* nitrogen of atomic weight 15) to 269 parts of the normal nitrogen N^{14}. Similarly, heavy hydrogen, or deuterium (D), of atomic weight 2, occurs with normal hydrogen in the proportion of 1/6,000, and heavy oxygen, O^{18} with O^{16} in the ratio 1/530, and heavy carbon C^{13} with C^{12} in the ratio of 1 : 90. The reason for this is that none of the agencies of nature can discriminate between the mixtures of elements and isotopes. Depending on differences in physical properties, however, an artificial separation can be effected, and so the element or its compounds can be prepared which will contain the isotope in a higher proportion than that found naturally. The amount of an isotope in such an element or compound is capable of determination with accuracy by physical methods, such as determination of density, mass spectrographic analysis, etc. Thus the concentration of N^{15} in nitrogen can be determined to within 0·003 per cent.

As an example of the use of natural isotopes we may mention the employment of N^{15} in the study of the fate of the amino-group of amino-acids. When amino-acids, the nitrogen of which has been "labelled" by the addition of the N^{15} compound, are given with the diet, most of the nitrogen is recoverable in combination in the tissue proteins, and some in the excreta.

The other type of isotope is the artificially prepared radioactive form of the element; thus carbon, phosphorus, calcium, sulphur, sodium, iron, iodine, etc., can be rendered radioactive, and, since the active element can readily be identified and estimated by this property,* the element, whether free or in a compound, can be traced through the body. These forms of elements are also biologically indistinguishable from the normal forms.

As an instance of the use of a radio-active element, we may quote experiments with labelled phosphorus, prepared from sulphur by neutron bombardment. When this was injected subcutaneously into rabbits, as sodium phosphate, it was found that within twenty-seven days 45 per cent. of it was excreted into the urine, and 11 per cent. in the fæces, and the element was shown to be present even in the calcium phosphate of the bones for a few weeks.

Study of the Metabolism of Tissue Slices

In the study of the metabolic changes which occur in tissues, much may be learnt by the study of tissue slices. Slices of fresh tissues weighing 20–100 mg., and of about 0·3 mm. thickness, cut by hand with a razor, continue to live for some time if kept supplied with oxygen. This is done by placing the tissue slices in Ringer's solution kept supplied with oxygen by shaking. It is easy to determine the rates of oxygen utilisation and CO_2 production of such tissue slices by the use of the Warburg manometer, one pattern of which is shown in Fig. 586.

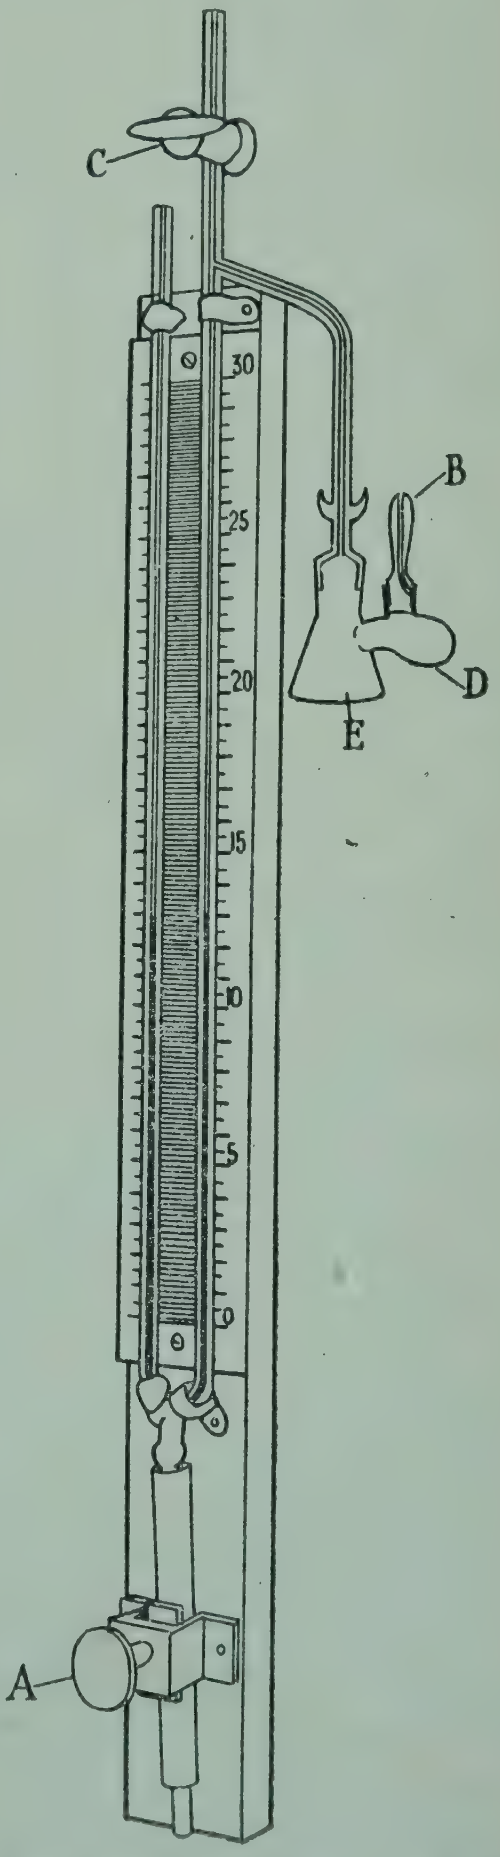

FIG. 586. Diagram of the Warburg type of manometer.

This consists of a long narrow U-tube graduated in millimetres ; one arm of the U is open to the atmosphere, the other leads to a tap C and a flask E of special construction as shown in the figure. The manometer is filled with water containing some bile salts, and opens at the bottom of the U into a rubber reservoir provided with a screw arrangement A for adjusting the amount of liquid in the U-tube. The manometer is to measure changes in the amount of gas contained in the flask and other of the closed parts of the apparatus ; these changes are measured, not by observing alterations in volume at constant pressure, but by noting alterations in pressure at constant volume. For this purpose the liquid in the U-tube starts off with a certain reading on the two sides (*e.g.* they may be at the same level). If gas is evolved or absorbed in the flask this will tend to push the liquid down on the proximal limb and up in the distal limb, or *vice versa* ; the reservoir screw is so adjusted by adding fluid to or abstracting it from the manometer, as to bring the reading in the proximal limb to the level at which it began. If gas has been absorbed, for instance, fluid would have to be withdrawn from the manometer in order to expand the gas in the flask to its initial volume ; if gas has been evolved, fluid would have to be added to the manometer to compress the gas in the enclosed space. By the application of suitable factors and corrections the amount of gas evolved or absorbed can then be calculated.

In use, the flask is filled with a gas of known composition, *e.g.* oxygen, or oxygen and CO_2, by passing oxygen in at the tap B and out by the tap

C. These taps are then closed, so confining the gas within a closed space. The apparatus is then placed in a thermostat at suitable temperature and shaken in a horizontal direction to and fro by a suitable motor. Readings of the pressure changes are then taken at suitable intervals of time.

The tissue slices are placed in the lower part of the flask, and are suspended in Ringer's solution which, as the result of the shaking, soon becomes saturated with oxygen ; subsequent oxygen absorptions then represent oxygen utilisation by the tissues. The CO_2 evolved by the tissue is absorbed by a little KOH solution placed in the inner receptacle F. The side tube D is made to contain any reagent which it may be desired to add to the contents of the flask at any subsequent stage, without having to open the apparatus to the air.

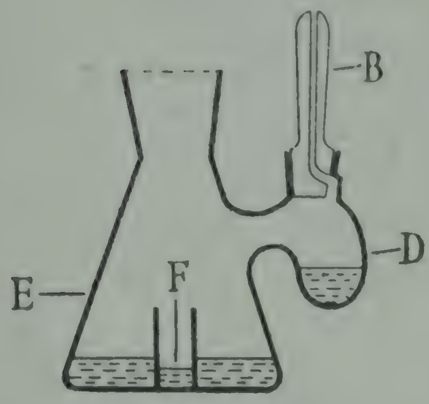

FIG. 586A.

By micro methods of analysis of the Ringer's solution and of the tissue slices many chemical processes can be followed ; by slight modification of the technique the evolution of CO_2 as well as the absorption of oxygen can be determined, and in general a valuable picture may be obtained of the kind of metabolic processes which such surviving slices of tissue are capable of carrying out. It is true, of course, that any such findings cannot be applied without some reservation to explain all the changes which may take place in the intact organ in the body, but the possibilities which the tissue slice technique provides have certainly been found to furnish valuable information.

The results are frequently expressed in terms of so-called Q values which are given in cubic millimetres of gas, *e.g.* Q_{O_2} means the cubic millimetres of oxygen utilised per milligramme dry weight of tissue per hour. Similarly Q_{CO_2} would be the volume of CO_2 similarly evolved. Absorptions, *e.g.* oxygen usages, are given a negative sign and evolutions of gas a positive sign.

1. PROTEIN METABOLISM

The protein of food has a twofold destiny. Of the absorbed amino-acids, a part, usually the greater, is broken down and yields energy, while the smaller part ultimately forms an indispensable constituent of the living substance. This part cannot be replaced by other foodstuffs, and we will consider its history first.

A. Protein Synthesis

The formation of the proteins of the living protoplasm from the proteins of the food is no question of mere translation of a substance from one place to another. For the ingested proteins are broken down into their constituent amino-acids before being absorbed into the blood stream. Furthermore, the tissue proteins are different from those which are ingested, varying from tissue to tissue and from one species to another.

It has been shown that amino-acids are abstracted from the blood by the tissues. In general terms, the synthesis of protein must be effected by the action of enzymes, such as tissue cathepsins, which bring about condensation between different amino-acids. But we have no idea how, under the influence of genes for instance, the constituent amino-acids are assembled always in the correct order and proportions, to produce proteins characteristic of the tissue and of the animal species concerned. The essential amino-acids must be supplied in the diet ; the non-essential ones can, if necessary, be synthesised in the body, so that finally the jig-saw molecule may be duly built up.

A method of studying tissue protein synthesis is that of "repletion" in depleted animals. Rats are given for two to three months a diet low in protein, but otherwise adequate. They lose weight and show hypoproteinæmia. If the protein, or all its essential amino-acids, is now restored there is rapid resynthesis of tissue protein and weight is regained. If only one of the essential amino-acids, *e.g.* lysine is omitted, the resynthesis does not take place. For adequate protein synthesis the total calorie value of the diet must be above a certain minimum, but above this level fat is laid down. Of the vitamins necessary for protein synthesis, riboflavin seems the most essential. This method also indicates that for tissue protein synthesis to occur all the essential amino-acids must be available simultaneously, since no stores of these are carried in the body.

By administration of marked amino-acids, in which the N is N^{15} and one of the H atoms is replaced by deuterium, new light has been shed on the fate of amino-acids in the body.* Much of the added acid is found to be present in protein, and there is reason to suppose that the new amino-acid has been introduced into the protein molecule in exchange for an identical molecule which leaves it. Continuous deamination and re-amination of the amino-acids in protein is also indicated by the use of this method. The proteins of the tissues thus appear to be highly labile and dynamic and not mere static compounds, as once supposed.

The Synthesis of Amino-Acids. The body can not only effect deamination of an amino-acid, but, by reversal of the enzyme action, can synthesise an amino-acid from its corresponding ketonic acid and ammonia. Knoop † found that the next higher homologue of phenyl alanine, namely phenyl-α-amino-butyric acid, when administered to an animal, was excreted in large quantities in the urine as an acetyl derivative, which was easily isolated in a state of purity. The administration of phenyl-α-keto-butyric acid led to the excretion of the same acetyl derivative in the urine. Since keto-acids are ordinary products of the breakdown of amino-acids, it is evident that the animal body can add ammonia and form amino-acids from them.

If the phenyl derivative of the corresponding hydroxy-acid, α-hydroxy-butyric acid, was administered, this was also excreted as the acetyl amino-compound. This and other evidence suggests that amino-, keto- and hydroxy-acids are interconvertible in the body, the connecting link being the keto-acid, *e.g.*

$$\underset{\textbf{Alanine}}{CH_3.CHNH_3COOH} \rightleftarrows \underset{\textbf{Pyruvic Acid}}{CH_3CO.COOH} \rightleftarrows \underset{\textbf{Lactic Acid}}{CH_3CHOH.COOH}$$

These changes can be effected by the perfused liver as readily as by the whole body.‡

The keto- or hydroxy-acids need not be derived from proteins at all but, like pyruvic acid, may result from carbohydrate metabolism. Thus, part of the nitrogen set free by protein disintegration might be recombined with the formation of amino-acids, without appearing in any way in the nitrogen balance-sheet of the body.

Glycine and alanine can be easily manufactured in the body, and the organism is capable of synthesising amino-acids from ammonia and the corresponding keto-acid. For these reactions the ammonia is derived from glutamine. Further, by transamination, one amino-acid can be converted into another.

Transamination.§ This is the name given to a reaction in which a $CHNH_2$ group of one compound can be exchanged for a keto-group of another. One of the bodies must be a *dicarboxylic* α-amino-, or α-ketonic acid (*e.g.* glutamic, aspartic, oxaloacetic or α-ketoglutaric acid) and the other an α-amino or α-ketonic acid (*e.g.* alanine, pyruvic acid). The following is an example :—

$$\underset{\textbf{Glutamic Acid}}{COOH.CH_2.CH_2.CHNH_2.COOH} + \underset{\textbf{Pyruvic Acid}}{CH_3.CO.COOH} \rightleftarrows$$

$$\underset{\alpha\textbf{-Ketoglutaric Acid}}{COOH.CH_2.CH_2.CO.COOH} + \underset{\textbf{Alanine}}{CH_3.CHNH_2.COOH}$$

§ Braunstein. *Nature*, 1939, **143**, 609.

The reaction is catalysed by enzymes called *aminophorases* or transaminases (in which the vitamin pyridoxol is the prosthetic group), and is an important means by which one amino-acid can be converted into another. It has also been found that, by the subsequent action of dehydrogenases, with co-enzyme I α-ketoglutaric acid and NH_3 can be reversibly converted into glutamic acid while at the same time a donator of hydrogen is oxidised. Glutamic acid may thus exert a catalytic effect in the oxidation of amino-acids to keto-acids and NH_3, as mentioned above.

B. Protein Catabolism

In the body, proteins ultimately become broken down into simple molecules and are excreted. Of these end-products the most characteristic are compounds of nitrogen, and of sulphur, which are almost entirely eliminated in the urine.

Animals are divisible into three groups, according to the form in which they excrete most of their nitrogenous end-products. The first group excretes it mostly as ammonia, and is called *ammonotelic*, the second, called *uricotelic*, excretes chiefly uric acid, and the third, or *ureotelic*, excretes urea. Each group may excrete smaller amounts of nitrogen in the other two forms. The explanation of the distinction, according to Baldwin, is that ammonia is highly toxic, but very diffusible, and so can only be used as an excretory form in aquatic invertebrates. When the supply of water is liable to fluctuation the nitrogen must be handled in the less toxic form of urea, as in mammals, or uric acid, as in birds and terrestrial invertebrates.

One of the facts which is revealed by urine analysis is that the distribution of nitrogen in the form of the various substances differs according to whether the subject is on a high or low protein diet. Not only is there a larger total nitrogen output when the subject is on a high protein diet, but we also find evidence of a qualitative difference as in the Table given here.* In the first place, in a normal protein diet the urea accounts for 87 per cent. of the total nitrogen of the urine. On an excessive protein diet this percentage may rise to

Distribution of Nitrogen in Urine on Various Diets

	July 13 Ordinary diet	July 20 Low protein diet
Vol. of urine	1170 c.c.	385 c.c.
Total nitrogen	16·8 grm.	3·60 grm.
Urea	14·70 grm. = 87·5 %	2·20 grm. = 61·7 %
Ammonia	0·49 grm. = 3·0 %	0·42 grm. = 11·3 %
Uric acid	0·18 grm. = 1·1 %	0·09 grm. = 2·5 %
Creatinine	0·58 grm. = 3·6 %	0·60 grm. = 17·2 %

* Folin. *Amer J. Physiol.*, 1905, **13,** 45, 66, 117.

90 or 95. On a low protein diet, not only is the total amount of nitrogen in the urine much less, but the percentage of nitrogen appearing as urea is reduced to 60. On the other hand, ammonia suffers little absolute diminution, so that its percentage of total N is considerably increased. Also, practically identical *amounts* of creatinine are obtained under the two conditions.

The interpretation which was placed upon these facts was that on high protein diets much of the nitrogenous bodies of the urine were derived almost directly from the food, while on low protein intake a relatively greater part of the substances came from the breakdown of tissue protein. Thus there were two sources of nitrogen of the urine, *exogenous, i.e.* that from the food, and *endogenous, i.e.* that derived from the tissues, but we must regard the implied classification of the nitrogenous derivatives as of the nature of a convenient fiction, in view of the facts which have since been brought to light, and which show that there is a continual interchange of amino-acids, or of atomic groups, between the tissue proteins and the fluids of the body.

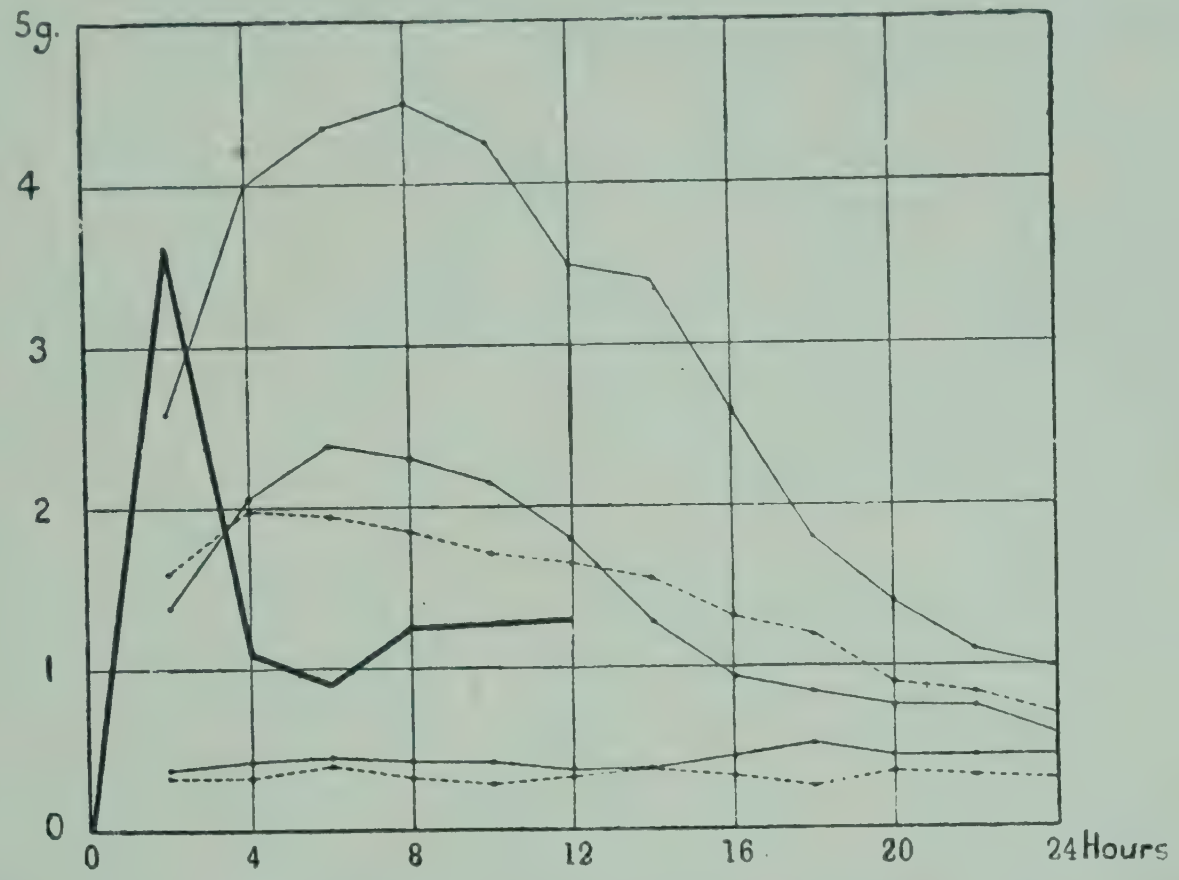

FIG. 587. The Hourly Variation in the Excretion of Nitrogen after a Meal.

The meal was given at 0. The thick line represents the average absorption of the food from the alimentary canal. The thin-lined curves, in order from above, represent the N excretion (1) after a meal of 1,000 grammes meat ; (2) after 500 grammes meat and 150 grammes fat ; (3) after a meal of 500 grammes meat ; (4) and (5) both represent the excretion in a fasting animal. (From TIGERSTEDT after FEDER.)

Urea Formation. It is evident that urea is the principal nitrogenous end-product of protein metabolism, both absolutely and relatively. On giving a large protein meal to a dog, the urea in the urine rapidly rises, and at the end of four or five hours 50 per cent. of the total nitrogen ingested with the food has appeared in the urine as urea (Fig. 587). Hence by far the greater portion of the protein nitrogen taken with the food is excreted as urea almost directly after absorption.* Urea is therefore to be regarded in the first place as an index to the amount of protein absorbed. That the nitrogen of the amino-acids is the immediate source of the urea is shown by the fact that the administration of these bodies is followed very rapidly by the appearance of the whole of their nitrogen in the urine as urea †: also, feeding with isotopic (N^{15}) amino-acids leads to excretion of isotopic urea.

It has long been known that the formation of urea from arginine is accomplished by the action of the enzyme *arginase*. It is abundant in th liver, and by its action arginine is split up into urea and ornithine *:

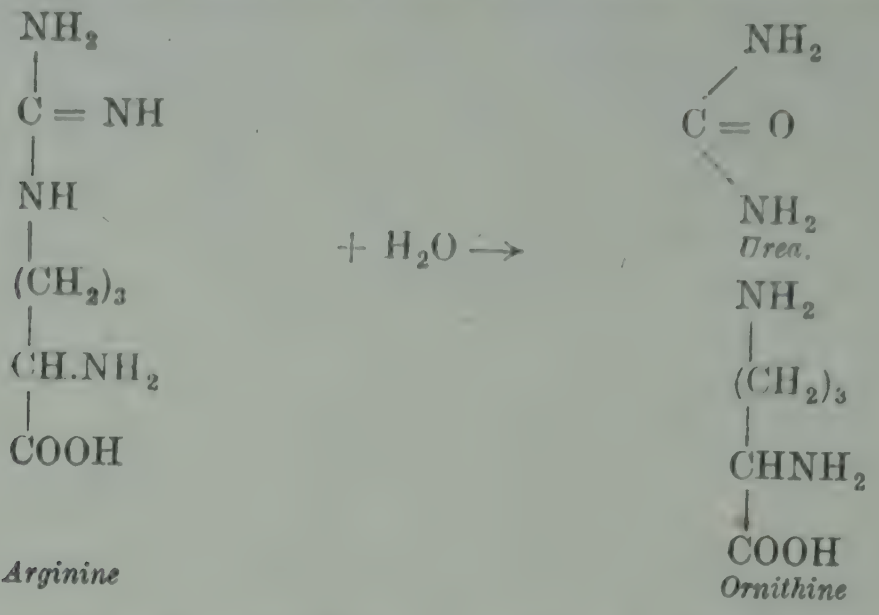
* PETTENKOFER and VOIT. *Ann. Chemie*, 1862, **52**, 361.

† LEVENE and MEYER. *Amer. J. Physiol.*, 1909, **25**, 214.



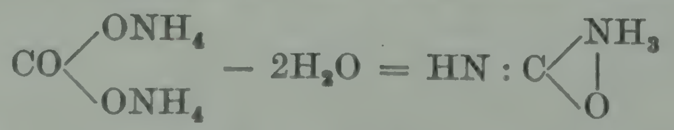
$$NH_2{-}C({=}NH){-}NH{-}(CH_2)_3{-}CH.NH_2{-}COOH + H_2O \longrightarrow NH_2{-}C{=}O{-}NH_2 + NH_2{-}(CH_2)_3{-}CHNH_2{-}COOH$$

In other instances the formation of urea is less simple than had been formerly supposed. The first stage is the formation of ammonia by *deamination* of the amino-acids, as previously described. In this change, oxygen is absorbed, and a keto-acid produced :—

$$R.CHNH_2.COOH + O \longrightarrow R.CO.COOH + NH_3$$

Tissue slice experiments confirm this, and show that liver and kidney are the tissues most active in deamination : the enzyme *l*-amino-acid oxidase, is a dehydrogenase. That ammonia can be a precursor of urea is shown by the fact that administration of isotopic NH_3 is followed by excretion of isotopic urea.

Although there is normally a small amount of ammonia in the urine, there is little if any in blood, and the urinary ammonia is not increased by injection or administration of ammonium carbonate which gives rise simply to a corresponding increase in the urea.† A large body of evidence points to the liver as being the chief seat both of deamination of amino-acids, and of conversion of ammonia into urea. Thus, if defibrinated blood be mixed with ammonium carbonate and passed for one hour through a surviving liver, the ammonium carbonate disappears and its place is taken by urea ‡ :—



$$CO\begin{cases}ONH_4\\ONH_4\end{cases} - 2H_2O = HN : C\begin{cases}NH_3\\O\end{cases}$$

though, as shown, below, the change is not so simple as this.

Extirpation of the liver in mammals is difficult, but by indirect procedures Mann § has succeeded in removing the liver from dogs.

After extirpation of the liver, both the deamination of the amino-acids and the formation of urea cease completely, indicating that under normal conditions both these processes are carried out in the liver. The animals only survive the completed operation for a few hours, but during that time the urea content of the blood and urine steadily falls. If the kidneys are also removed, the urea of the blood remains constant. In the normal animal, amino-acids are rapidly changed to urea, but when amino-acids are injected into the blood after hepatectomy, the greater part is recoverable from the blood and tissues, and there is no rise in urea or ammonia.

The actual steps by which ammonia is converted into urea, according to Krebs, depend upon the catalysing action of small amounts of ornithine, and on the presence of arginase.* In the liver, ornithine combines with ammonia and carbon dioxide to form first citrulline, and then with a molecule of ammonia to form arginine ; the arginine is then decomposed into urea and ornithine as explained above, and the ornithine thus set free can repeat the cycle, the reactions being :—

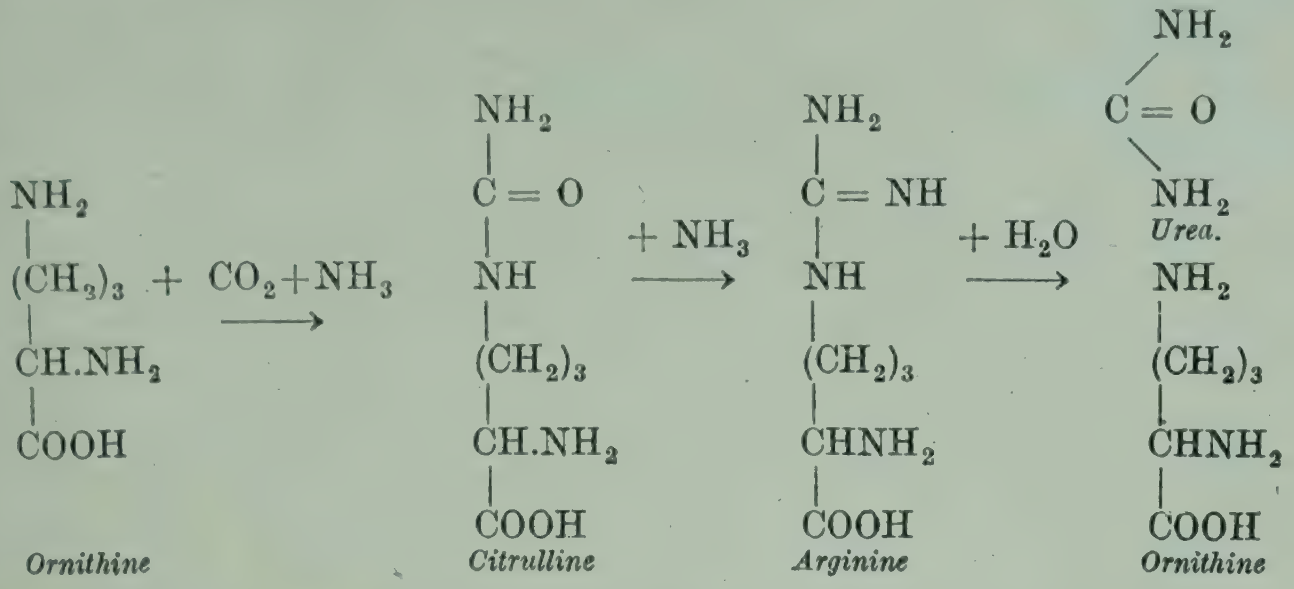
‡ Schröder. *Arch. f. exp. Path.*, 1882, **15**, 364; Löffler, *Bioch. Ztschr.*, 1918, **85**, 230.

§ Mann, *Amer. J. Physiol.*, 1921, **55**, 285; Mann and Magath, *Ergebn. d. Physiol.*, 1924, **23**, 212; Soskin, *J. Lab. Clin. Med.*, 1931, **16**, 382 (simplified).



The presence of oxygen, and some energy-yielding oxidative processes, *e.g.* oxidation of glucose or lactate, is essential, in order to provide the energy for the formation of urea.

There are possibly other paths by which urea can be formed.

Fate of the Amino-acids. The formation of urea does not signify a total disintegration of the amino-acid molecule, but is merely the result of its deamination.

The investigation of the disintegration of aliphatic derivatives generally, is rendered difficult by the fact that all the intermediate products undergo further change and leave the body in a state of complete oxidation as carbon dioxide and water. Much of our knowledge of these intermediate products is derived from the study of pathological conditions, in which they cannot be further oxidised, or by artificially converting the aliphatic intermediaries into derivatives, *e.g.* isotopic derivatives, or phenyl derivatives, which can be subsequently traced. If an amino-acid group be conjugated with an aromatic compound, *e.g.* forming a side chain of the benzene ring, it is protected from complete oxidation by this ring. The oxidation of the fatty side chain may only proceed to a certain degree, so that intermediate products of metabolism may be excreted still attached to the benzene nucleus.

In the α-amino acids the point where disintegration first occurs is the α-group. Deamination is most usually associated with oxidation.† The primary product is therefore an α-keto-acid. Thus from alanine the body would produce pyruvic acid :

$$\underset{\textbf{Alanine}}{CH_3.CHNH_2.COOH} + O = HN_3 + \underset{\textbf{Pyruvic acid}}{CH_3.CO.COOH}$$

This mode of deamination has been demonstrated to occur with slices of liver, or kidney, suspended in solutions containing various amino-acids and exposed to air,‡ keto-acids and ammonia being produced. Kidney tissue has the advantage that the ammonia is not converted to urea, as it is by liver. The enzyme concerned is an *l*-amino-acid oxidase. The keto-acid may afterwards undergo reduction to a hydroxy-acid, or oxidation to a lower fatty acid, but *in vitro* these changes can be inhibited by adding an arsenite.

The loss of nitrogen from the molecule diminishes little the energy value of the products derived from the amino-acids of the body. Thus, after deduction of the heat of combustion of urea, the heat of combustion of alanine is 349 Cal per g. molecule, while that of pyruvic acid is 279.

The important problem in the *energy* metabolism of protein is thus the nature and fate of the substances left after deamination. We have seen that protein exerts a high specific dynamic action (30 per cent.). This specific dynamic action of protein is possessed also by certain of the amino-acids. The action is not due to complete oxidation of the amino-acid, as is shown by giving glycine to a diabetic animal. The glycine is converted quantitatively into glucose, which is excreted in the urine, but yet produces the same augmentation of metabolism as in a normal animal. According to one theory, the specific dynamic action of protein is due to the amino-acids stimulating the cells of the body. But it cannot be that the amino-acids themselves are stimulants. This is shown by the fact that, when amino-acids are built up to form new tissues, as in the baby, or in the animal recovering from starvation, they exert no specific dynamic action. This action occurs only *when the amino-acids are deaminated and then undergo conversion to urea*, and, in proof of this, it remains in abeyance after removal of the liver. The interesting fact that ammonium salts also cause an increased heat production,* and are also converted to urea in the liver, lends further support to the opinion that the heat of specific dynamic action is set free in connection with this conversion. It probably represents the heat of concurrent oxidations which are coupled with the formation of urea.

The molecule which remains after removal of the amino group is, as we have shown, probably the corresponding α-ketonic acid : the subsequent history of this differs according to its nature. Ultimately it is fully oxidised to CO_2 and water, but in its intermediary changes it may be merged in the stream of the intermediaries of either carbohydrate or fat metabolism.

The amino-acids are divisible into three groups, according as they form, as intermediate compounds, sugar, aceto-acetic acid, or neither of these substances. Thus, of the amino-acids formed by the digestion of proteins, glycine, alanine, serine, cysteine, aspartic acid, glutamic acid, hydroxy-glutamic acid, ornithine, arginine, proline and hydroxy-proline can under appropriate circumstances be converted quantitatively into glucose. Probably those residues which ultimately form glucose are converted first into pyruvic acid, from which glucose is readily formed in the liver. Since the formation of glucose reduces the formation or appearance of ketone bodies, these amino-acids are classed as *antiketogenic* amino-acids. On the other hand, leucine, isoleucine, phenyl alanine and tyrosine yield no glucose, even in the diabetic animal ; but may in the liver undergo conversion into aceto-acetic acid, which is also a stage in the oxidative disintegration of fats. This group is therefore classed as *ketogenic* amino-acids. Tryptophan, valine, lysine and histidine do not form either product.

The Cyclic Amino-acids. The chief of these amino-acids are tyrosine, phenyl alanine and tryptophan, and we may assume that they participate in the labile equilibrium between the tissue proteins and the free amino-acids.

Ultimately they can all be completely destroyed, with the production of urea, carbon dioxide and water. In this respect they present a contrast to almost all other compounds of the aromatic series. Thus phenyl propionic acid, when administered, is passed in the urine as hippuric acid (benzoyl glycine). But the ketonic acids corresponding to tyrosine or phenyl alanine (*p*-hydroxy-phenyl-pyruvic acid or phenyl pyruvic acid) when given to phlorrhizinised animals yield aceto-acetic acid.

Tyrosine and phenyl alanine are not only constituents of many proteins, but are also starting points in the body for the formation of two important hormones, *adrenaline* and *thyroxine*. Adrenaline is possibly formed by the action of appropriate enzymes, tyramine being an intermediate stage. Thyroxine is probably formed, in the thyroid, from diiodotyrosine, which is formed from tyrosine. Tyrosine is also the starting point for the formation of *melanin*, the pigment of hair and skin, which is formed by the action of an oxidase called tyrosinase.

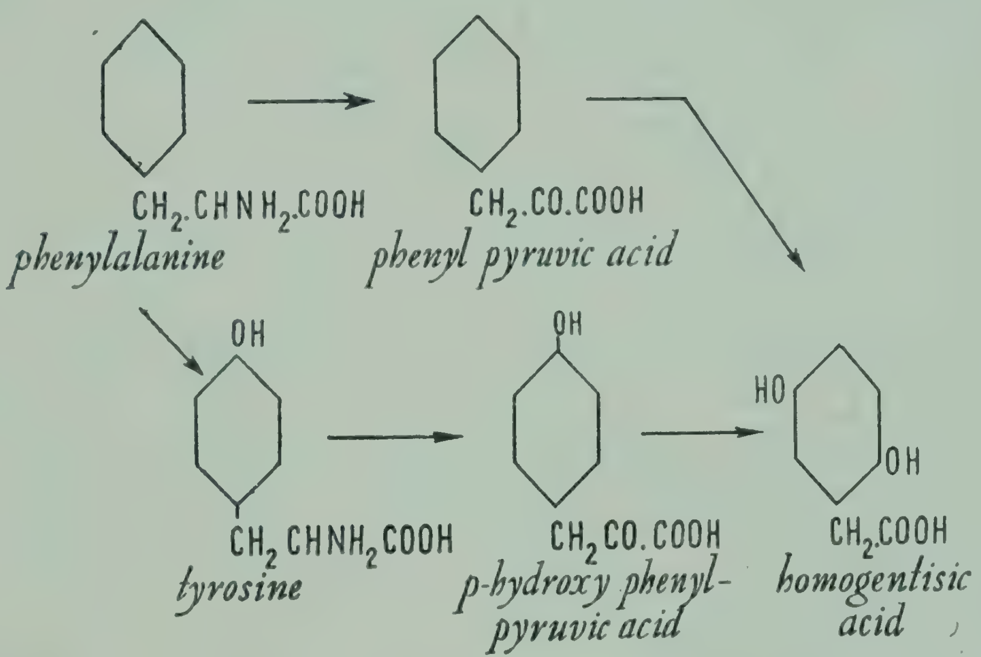
---

* LUNDSGAARD. *Skand. Arch. f. Physiol.*, 1931, **62**, **243**.

Phenyl alanine containing D when given by mouth yields tyrosine containing D in the liver, but the reverse change does not occur. Hence, phenyl alanine is essential, tyrosine is not.

The stages in the normal metabolism of tyrosine are not known. Some light is thrown on the subject by the study of a rare disorder in metabolism, known as *alcaptonuria*. In this condition, which is congenital, the urine darkens when made alkaline and exposed to the air, and reduces Fehling's solution. The peculiarities of the urine are due to the presence in it of a substance known as *homogentisic acid*, or 2,5-dihydroxyphenyl acetic acid.

If tyrosine or phenyl alanine be administered to an alcaptonuric it is quantitatively excreted as homogentisic acid. The constant ratio of this acid to the total nitrogen indicates that the whole of the tyrosine and phenyl alanine set free in the body is converted into homogentisic acid. It is probable that phenyl alanine and tyrosine are first oxidatively deaminised to phenyl pyruvic and *p*-hydroxyphenylpyruvic acid respectively, and these further oxidised to homogentisic acid :—



In a rare form of insanity, *imbecillitas phenylpyruvica*, phenylpyruvate oxidation is deficient and the acid is excreted. Phenyl pyruvic acid is also converted in alcaptonuric patients to homogentisic acid (instead of into aceto-acetic acid as it presumably is in the normal).

It is possible that under normal circumstances tyrosine and phenyl alanine are first oxidised to homogentisic acid, as in the alcaptonuric patient. Against this is the fact that *p*-hydroxyphenyl-pyruvic acid is converted into aceto-acetic acid in the liver. In the normal individual, however, the introduction of two hydroxyl groups into the benzene ring leads to an enzyme action which breaks up the ring. This enzyme is absent from the alcaptonuric, so that the transformation of the phenyl derivatives stops short at the stage of homogentisic acid.

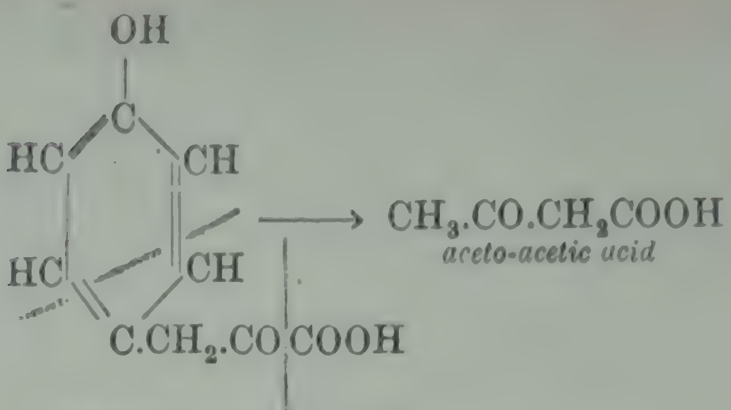
In the opinion of Dakin,* however, the formation of homogentisic acid from tyrosine is abnormal, and he considers that normally the benzene ring is split immediately after the formation of hydroxyphenyl-pyruvic acid, the side chain and parts of the ring forming aceto-acetic acid, while the rest of the ring is oxidised, as shown overleaf.

In another pathological condition (only once reported), the excreted product was *p*-hydroxyphenyl-pyruvic acid, and homogentisic acid if given was destroyed as it is by normal subjects. This supports Dakin's view.

Tyrosine in the intestine may undergo deamination by the action of bacteria, to form hydroxyphenyl-propionic acid and hydroxyphenyl-acetic acid. These

---

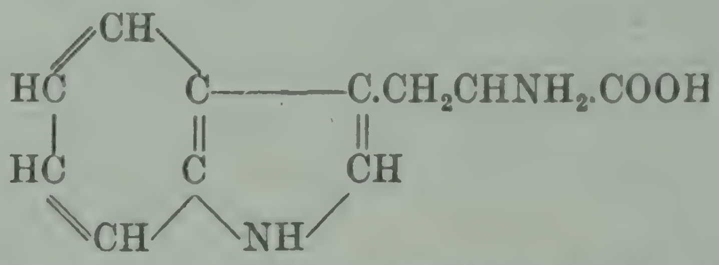
* DAKIN. *J. Biol. Chem.*, 1911, **9**, 151.



p-hydroxyphenyl-pyruvic acid

cannot be further oxidised, but appear in the urine as such or, after conversion into cresol or phenol, as sulphuric acid esters.

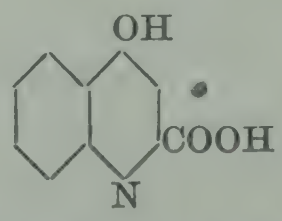
Tryptophan * is indol amino-propionic acid :—



It undergoes, like tyrosine, complete oxidation in the body, being probably first converted to the corresponding ketonic acid, indol-pyruvic acid, which can, therefore, replace it, in diets. The further stages are unknown.

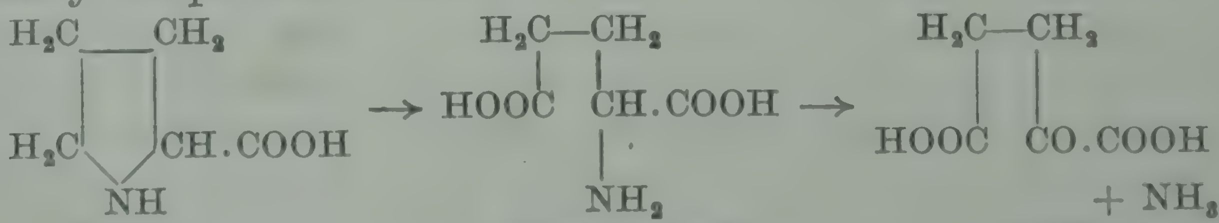
A very slight alteration in the molecule renders it incapable of this change. Thus some of the tryptophan may, under the influence of the bacteria of the intestine, be converted to indol acetic acid, and this by decarboxylation into skatol, or, by oxidation and further loss of carbon dioxide, into indol. Of these products, indol acetic acid may be found in the urine, and indol and skatol are oxidised to the corresponding phenols and pass into the urine conjugated either with sulphuric acid to form "urinary indican," or with glucuronic acid. The amount of the indol and skatol esters serves therefore as an index of bacterial decomposition in the alimentary canal. If putrefaction be prevented by an intestinal antiseptic, these esters may entirely disappear from the urine. On the other hand, a partial obstruction to the onward passage of food increases the indican excretion twenty or thirty-fold.

In the dog, tryptophan is converted into *kynurenic acid*, a quinoline derivative



which is excreted in the urine,† but this is probably not a stage in its oxidation in man.

THE PYRROL RING, which occurs in proteins as proline and hydroxyproline (*i.e.* pyrrolidine carboxylic acid and hydroxypyrrolidine carboxylic acid) appears to undergo complete disintegration in the body, by way of the tricarboxylic cycle.‡ Glutamic acid and α-ketoglutaric acid are probable intermediary compounds.



Proline *Glutamic acid* *α-ketoglutaric acid*

Both substances readily yield carbohydrate in the body.

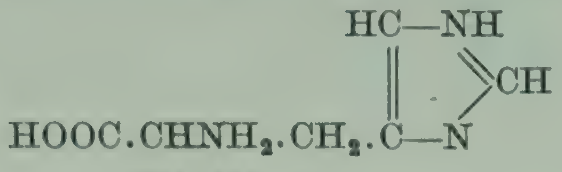
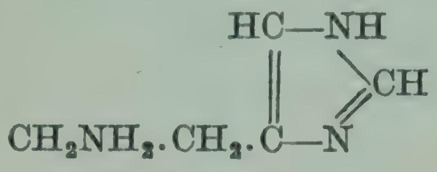
HISTIDINE is iminazol α-amino-propionic acid : ergothioneine and carnosine are derivatives of it. Histidine undergoes complete oxidation in the human body. The stages are unknown, but isotopic research suggests that the amino group of the alanine residue is very labile. The important derivative *histamine* is formed from it by the action of the enzyme histidine decarboxylase. In dogs, administration of histidine leads to excretion of urocanic acid in the urine. This is perhaps formed from histidine by the action of bacteria in the intestine.*



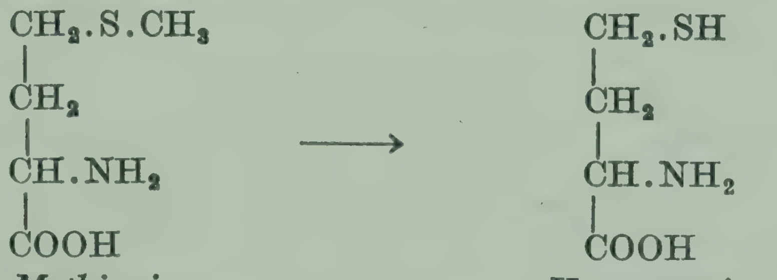
Histidine



Histamine

Amino-acids containing Sulphur. The normal source of sulphur is in the cystine and methionine links in proteins : it also exists in cysteine, glutathione and insulin, and in ergothioneine. Its ultimate fate is by excretion as the taurine of taurocholic acid in bile, by shedding of hair and nails (as keratin) and by excretion in the urine as sulphates, etc.

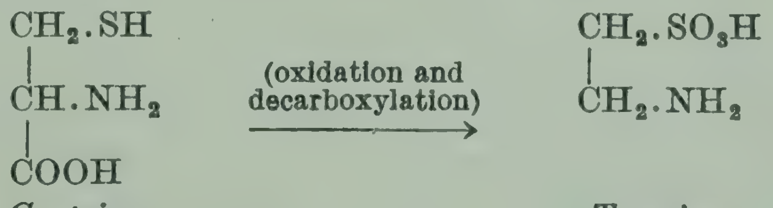
Methionine must be supplied to the body : the other ones need not be, and can be made from methionine, but we do not know by what changes. Methionine readily yields up its methyl group, and is converted into homocysteine : in the body this probably often happens, the CH_3 group being introduced into another molecule (*transmethylation*), and the homocysteine being then converted into cysteine by way of an intermediary reaction with serine. It is uncertain whether methionine can be converted into keto-bodies or sugar except *viâ* cysteine.



$$\begin{array}{l} CH_2.S.CH_3 \\ | \\ CH_2 \\ | \\ CH.NH_2 \\ | \\ COOH \end{array} \longrightarrow \begin{array}{l} CH_2.SH \\ | \\ CH_2 \\ | \\ CH.NH_2 \\ | \\ COOH \end{array}$$

Methionine *Homocysteine*

Cystine and cysteine are glycogenic. In the course of metabolism, the SH group is easily oxidised to a sulphonic group, *e.g.* :



$$\begin{array}{l} CH_2.SH \\ | \\ CH.NH_2 \\ | \\ COOH \end{array} \xrightarrow[\text{decarboxylation)}]{\text{(oxidation and}} \begin{array}{l} CH_2.SO_3H \\ | \\ CH_2.NH_2 \end{array}$$

Cysteine *Taurine*

From such compounds, sulphuric acid would most probably be set free.

Certain individuals have an inborn error of metabolism, and excrete relatively large amounts of cystine in the urine. Feeding them with cystine does not increase the amount secreted, but increases the sulphur excretion as in normal subjects : the explanation of this anomaly has not been found.

Sulphur occurs in the urine in three forms : as inorganic sulphates, as ethereal sulphates (indoxyl- and skatoxyl-sulphates), and in an unoxidised condition often termed neutral sulphur. This last consists of cystine, thiocyanates, and, in some animals, mercaptan compounds. The excretion of sulphur rises *pari passu* with that of the urea so that, with the throwing off of the NH_2 group, there must be also a removal of the greater part of the sulphur of the protein molecule. The sulphur does not necessarily appear in the urine simultaneously with the nitrogen derived from the same protein. If, for instance, there is a positive N-balance, *i.e.* if protein is being built up more rapidly than broken down, the excretion of S lags behind, and in the reverse condition of excessive

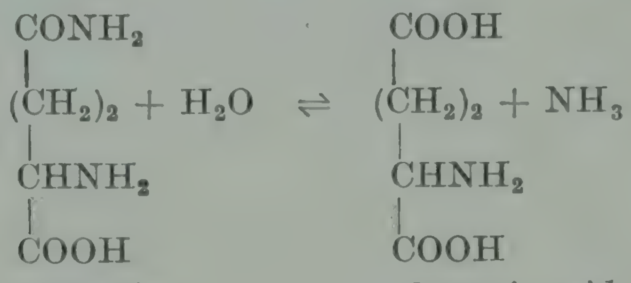
---

* RAISTRICK. *Bioch. J.*, 1916, **11**, 71.

N-catabolism the N lags behind. On the whole, however, the N : S excretion ratio is the same as that of the protein consumed, or, in starvation, as that of muscle proteins, viz., about 14.

The ethereal sulphates are excreted in varying quantity, according to the extent of the decomposition processes which are occurring in the intestine, whereby tryptophan is converted into indol and skatol, which are then detoxified by conversion to their sulphates, as already explained. On the other hand, the fact that the neutral sulphur undergoes no decrease on starvation suggests that this part of the sulphur output may be connected with tissue metabolism. Neutral sulphur excretion amounts to about 100 mg. daily, but varies widely ; about 8 per cent. of it is in the form of cystine, of which an average of about 30 mg. is excreted daily.*

The Excretion of Ammonia. A small proportion of the nitrogen in the urine occurs in the form of ammonia. The ammonia of the urine is formed not in the liver, but in the kidneys, and is not derived from ammonia in the plasma. Hence, feeding with isotopic ammonia or urea, leads to the excretion of isotopic urea, but no isotopic ammonia. Its precursor is glutamine of the plasma, and the kidney contains the enzyme glutaminase, which effects the conversion :—



$$\begin{array}{lcl} \mathrm{CONH_2} & & \mathrm{COOH} \\ | & & | \\ \mathrm{(CH_2)_2} + \mathrm{H_2O} & \rightleftharpoons & \mathrm{(CH_2)_2} + \mathrm{NH_3} \\ | & & | \\ \mathrm{CHNH_2} & & \mathrm{CHNH_2} \\ | & & | \\ \mathrm{COOH} & & \mathrm{COOH} \end{array}$$

glutamine *glutamic acid*

By this reversible reaction, ammonia, which is a very toxic substance, can be stored or released as required. The factor which determines the proportion of ammonia in the urine is the relative proportion of acid and base, i.e., of $H^{\cdot}$ and OH' ions, which has to be eliminated from the body, and this also determines the ratio of dibasic to monobasic phosphates excreted. If the fixed alkalies in the food are sufficient to combine with the whole of the acids excreted from the body, then the urine is neutral and ammonia will be absent. If, however, a dose of mineral acid be administered to an animal, this must be excreted in combination with some of the base ; the urine will then be acid, owing to a preponderance of monobasic phosphate, but some of the acid will be excreted in combination with ammonia. The ammonia of the urine is therefore an index to the amount of acids excreted. These acids may be introduced directly with the food, as when mineral acids are administered by the mouth, or may be the product of metabolic processes. Thus, if ammonium chloride be given to a starving rabbit much of it is *apparently* excreted ; actually, the ammonia is converted to urea, leaving HCl behind, and new ammonia is made in the kidney as a result. In carbohydrate starvation, hydroxy-butyric acid and aceto-acetic acid are produced in the body in large quantities, but cannot undergo further disintegration. It is therefore essential that the acids formed should be neutralised and excreted in combination with some base. When the alkalies of the food and of the tissues do not suffice for their neutralisation, ammonia is formed in the kidneys and is then utilised for this purpose, and the acids appear in the urine in combination with ammonia. The ammonia of the urine therefore gives valuable information as to the formation of acids in abnormal quantities during the processes of metabolism (" acidosis ").

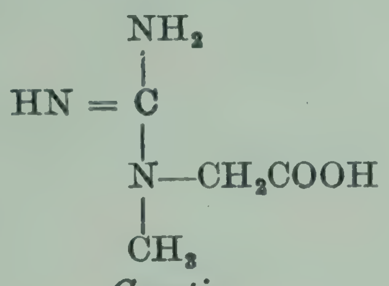
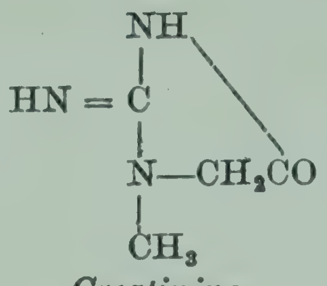
Creatinine and Creatine. On comparing the output of the various nitrogenous excreta given in Folin's Table quoted above (p. 924), we see that on a low protein diet the only substance which does not undergo simultaneous diminution is the creatinine. At one time this led to the belief that creatinine might be regarded as an index of tissue metabolism of protein.

Creatinine is derived by dehydration from creatine (methyl guanido-acetic acid).



$$HN=C(NH_2)-N(CH_3)-CH_2COOH$$

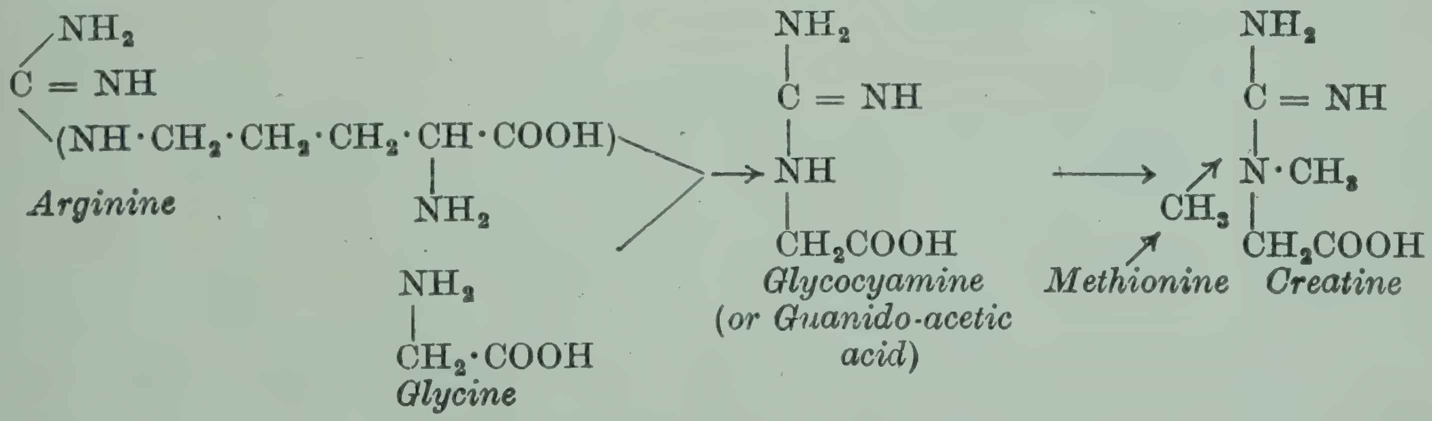
Creatine



Creatinine

Both are said to be present in the blood, creatine to the extent of about 3–5 mg./100 c.c., mostly present in the red cells, and "creatinine" about 2 mg./100 c.c. Most of the apparent creatinine of blood, however, is some other, unidentified, substance. Muscle contains about 10 mg. creatinine and about 200 mg. creatine (as creatine phosphate) per 100 grammes, so that the body of a man contains about 100 g. of this substance.

How or where creatine is formed in the body is uncertain, though its most probable site of formation is in the muscles and perhaps in the liver. By the use of compounds containing isotopic nitrogen it has been shown that, in the formation of creatine, arginine, glycine, and probably methionine play parts, the last providing CH_3 :—



In progressive muscular dystrophy, in which creatine is always present in the urine, the creatine excretion is increased by the administration of either glycine or arginine.* Creatine is also excreted by many normal persons after administration of glycine.†

Creatinine is certainly to be regarded as a waste product. About 1–1·5 grammes per day is excreted. When given *per os* it is excreted in the urine. Since isotopic creatine given *per os* leads to excretion of isotopic creatinine, it seems certain that the urinary creatinine is derived from creatine. But creatinine is excreted in considerable quantities even when a creatine-free diet is given. It has been found, moreover, that creatine administered in moderate amount by the mouth disappears in the body. It would seem probable that this is due to its conversion into creatine phosphate, which is stored in the muscles, of which it forms an invariable and essential constituent. If a large amount be given, creatine appears as such in the urine. In most cases also a certain small proportion is excreted in the form of creatinine.* After repeated administration of creatine by mouth, steadily increasing amounts of creatine and creatinine are excreted in the urine.† This would make it appear that excretion as creatine only occurs when the creatine store of the body exceeds a certain limit : it may be stored for a long time in the muscle. Hence, if isotopic creatine is given for a considerable time, and followed by a creatine-free diet, the excretion of isotopic creatinine continues.

* Brand *et al.* *Amer. J. Physiol.*, 1929, **90**, 296; *J. Biol. Chem.*, 1930, **87**, ix.; 1932, **92**, lix.; Beard and Barnes, *J. Biol. Chem.*, 1932, **94**, 49.

† Adams, Power and Boothby. *Amer. J. Physiol.*, 1935, **111**, 596.

Creatine is normally present in the urine of children before puberty,‡ and of women, especially in pregnancy, but not in that of normal adult men, except when they are starved, or deprived of carbohydrate. It also appears in hyperthyroidism and in various diseases, *e.g.* progressive muscular dystrophy and myasthenia gravis associated with muscular atrophy or weakness. Probably in most cases the excretion is due to failure of storage.

With creatinine it is different : once this substance is introduced into the body it is promptly excreted. The amount formed certainly bears some relation to the amount of muscle present, though not to the amount of muscular work done, when long periods are considered. Thus a muscular man may excrete up to 30 mg. creatinine per kg. body-weight per day (creatinine coefficient), whereas in women it is usually about 18 mg. and in children about 15 mg.

The excretion of creatinine was investigated under various conditions by van Hoogenhuyze and Verploegh, and supports the view expressed above as to the intimate relation of creatinine with the tissue metabolism. During and immediately after muscular exercise, there is an accelerated output of creatinine in the urine, but there is a corresponding drop during recovery, so that the daily excretion is but little affected. Since we know that during muscular contraction there is a conversion of creatine phosphate into creatine and inorganic phosphate, both of which are diffusible, it is reasonable to suppose that some of the creatine escapes into the general circulation, is converted into creatinine, and excreted as such. During recovery any available creatine would be taken up again, as creatine phosphate is re-formed.

2. NUCLEIN METABOLISM

An outline of the chemistry of nucleoproteins has already been given in Chapter IV.

The nucleoproteins are especially abundant constituents of nuclei, and therefore occur to a greater or less extent in all the ordinary animal foods, eggs and milk excepted. Other important purine derivatives are the mononucleotides, adenylic acid and guanylic acid, which occur in the cytoplasm of many tissue cells, *e.g.* in muscle, where adenylic acid is present as adenosine triphosphate and plays an important part in its metabolism. The metabolism of the nucleoproteins and nucleotides is essentially comprised in the history of their characteristic constituents, the purines and pyrimidines. The protein portion of the molecule, which contains a high proportion of diamino acids, shares the common fate of other protein.

‡ Rose. *J. Biol. Chem.*, 1911, **10,** 265.

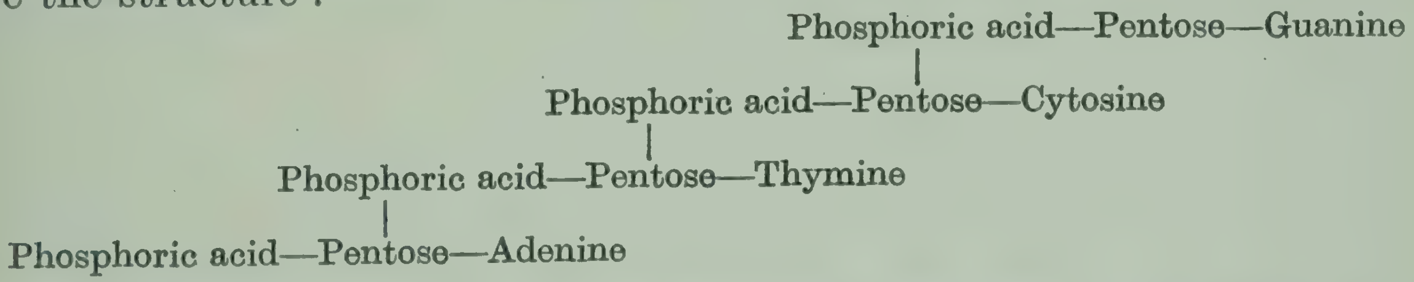
Formation of Nucleins in the Body. We have seen that, in the higher animals proteins are built up from their constituent amino-acids, some of which can be synthesised in the body. The nucleotides also can certainly be synthesised by the animal. This is shown by the fact that the hen's egg before incubation contains practically no nuclein or purine bases. During incubation there is a rapid increase in the number of nuclei, so that the chick just before it is hatched contains a considerable amount of nuclein. These must have been formed by synthesis from the phosphoproteins and phosphatides which form so important a constituent of the egg-yolk.* In the same way, in the young infant there is a rapid increase in the nucleoprotein of the body, although the only food ingested is milk, which contains but an insignificant amount of purine compounds. Confirmation of the synthesis of purines in the body has also been given by Benedict: he fed a Dalmatian hound on a purine-free diet, yet was able to extract 100 grammes of uric acid from its urine.†

Experiments with isotopic N-compounds show that the purines and pyrimidines are formed, not from amino-acids, but from ammonia, and indicates the site of formation to be the liver, and perhaps other sites, such as kidney.‡

Fate of Nucleoproteins in the Body. Nucleoprotein metabolism may be exogenous or endogenous, *i.e.* the nucleoprotein broken down in the body may be derived either from the food or from the tissues. Most of our knowledge on this subject relates to the purine portions of the molecule, the pyrimidine part having been much less explored. We will first deal with the exogenous nucleoprotein.

In the alimentary canal, nucleoproteins are acted upon by the pepsin of the gastric juice and trypsin of pancreatic juice, the protein being digested away and nucleic acid remaining.

The nucleic acids are compounds of very high molecular weight, formed by aggregation of molecules of tetranucleotides, in which four mononucleotides are linked together. Thus, a tetranucleotide of animal origin would probably have the structure :—



Phosphoric acid—Pentose—Guanine
Phosphoric acid—Pentose—Cytosine
Phosphoric acid—Pentose—Thymine
Phosphoric acid—Pentose—Adenine

The intestinal mucosa contains an enzyme, *nuclease*, which splits up the nucleic acid into its four constituent mononucleotides,§ *e.g.*

Phosphoric acid—Pentose—Adenine (= *Adenylic acid*)

is a purine nucleotide, and

Phosphoric acid—Pentose—Cytosine

is a pyrimidine nucleotide ; it is likely that some at least of these products are absorbed as such, since an adenine nucleotide has been recovered from human blood.‖ However, further changes can be effected by the intestinal juice, or by the cells of the intestinal mucosa. The latter contain the enzyme *nucleotidase*, a phosphatase, ¶ by which the phosphoric acid is split off from the nucleotides, with formation of nucleosides, *e.g.*

Phosphoric acid—Pentose—Adenine ——→ Pentose—Adenine (= *Adenosine*, a nucleoside).

§ Levene and Dillon. *J. Biol. Chem.*, 1932, **96**, 461.
‖ Jackson. *J. Biol. Chem.*, 1924, **59**, 529.
¶ Levene and Dillon. *J. Biol. Chem.*, 1930, **88**, 753.

The nucleosides are further acted upon by another enzyme, also present i the intestinal mucosa, and called *nucleosidase* *; this breaks up the purine nucleosides into purine base and carbohydrate, *e.g.* :—

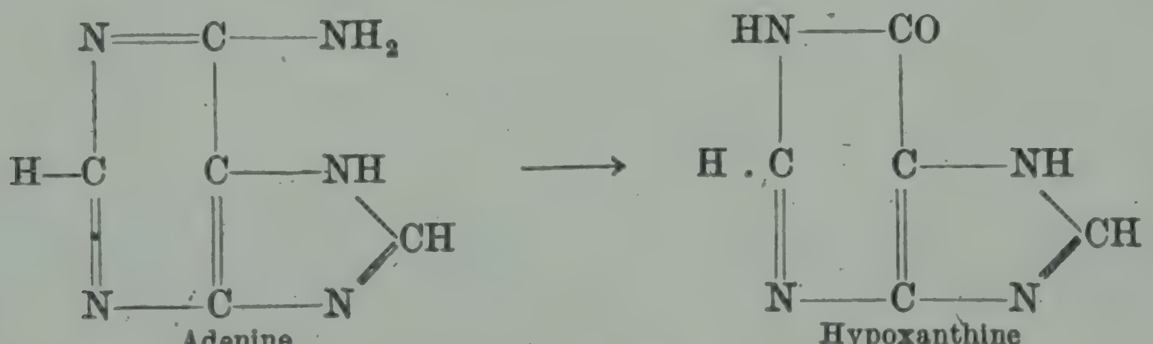
$$\begin{tikzcd} & \text{Adenosine} \arrow[dl] \arrow[dr] & \\ \text{Carbohydrate (Pentose)} & & \text{Adenine} \end{tikzcd}$$

There may therefore be present for absorption in the intestine, nucleotides, nucleosides, purine bases (guanine and adenine), carbohydrate and phosphoric acid. These products presumably may all enter the blood and be dealt with, together with similar products formed, we know not where or how, in endogenous purine metabolism, which we must now discuss.

The chief ultimate purine end product excreted in man is uric acid. In some animals it is allantoin. Ingestion of nucleoprotein, nucleic acid or purine bases is, in man, followed by an increased excretion of uric acid in the urine. It is evident that the uric acid of the urine may be derived either from the nucleins, etc., of the food, or from those of the tissues. By digestion of nucleic acids with animal tissues or their extracts under varying conditions, it is possible to bring about all the changes mentioned above, and also those further ones involved in the conversion of the purine bases contained in them into uric acid. Probably by no means all the purine bodies involved in metabolic changes are excreted as such, a good deal being lost in some unknown way.

Tissue-nucleotidases are of different kinds, phosphonucleotidases splitting off the phosphoric acid and leaving the nucleosides, while the purine nucleotidases split off the purines, leaving the phosphoric acid combined with the carbohydrate. (This could then be split into its components by a phosphatase.)

The purines set free in these various ways undergo further changes. One of these is deamination. Thus, guanine and adenine, acted upon by the enzymes guanase and adenase, are converted respectively into xanthine and hypoxanthine by loss of their amino groups, *e.g.*



Adenine
Hypoxanthine

But deamination can also occur before the purines are liberated, *i.e.* in the nucleosides. Thus adenosine can yield inosine by the action of an appropriate deaminase. By a similar change even the nucleotide can be deaminated, *e.g.* adenylic acid can be converted to inosinic acid, and from this a purine nucleotidase can split off hypoxanthine.

The hypoxanthine is converted under the action of an oxidase (xanthine oxidase) first into xanthine and then into uric acid. This was one of the earliest facts discovered in the metabolism of purines. If spleen pulp be digested with blood, it is possible to extract xanthine from the mixture.† If, however, oxygen be bubbled through the fluid, the xanthine disappears, its place being taken by uric acid. All these changes occur in the living body, though not necessarily in the order just set out. Thus a pulp of dog's liver is able completely to deaminise the adenine group of nucleic acid, converting it into a hypoxanthine group; but it is without effect on free adenine. It is evident, therefore, that the various enzymes which have been described act partly on the whole nucleotide molecule, partly on the products of its decomposition, and that the results of the action of the body enzymes are not the same in the two cases.

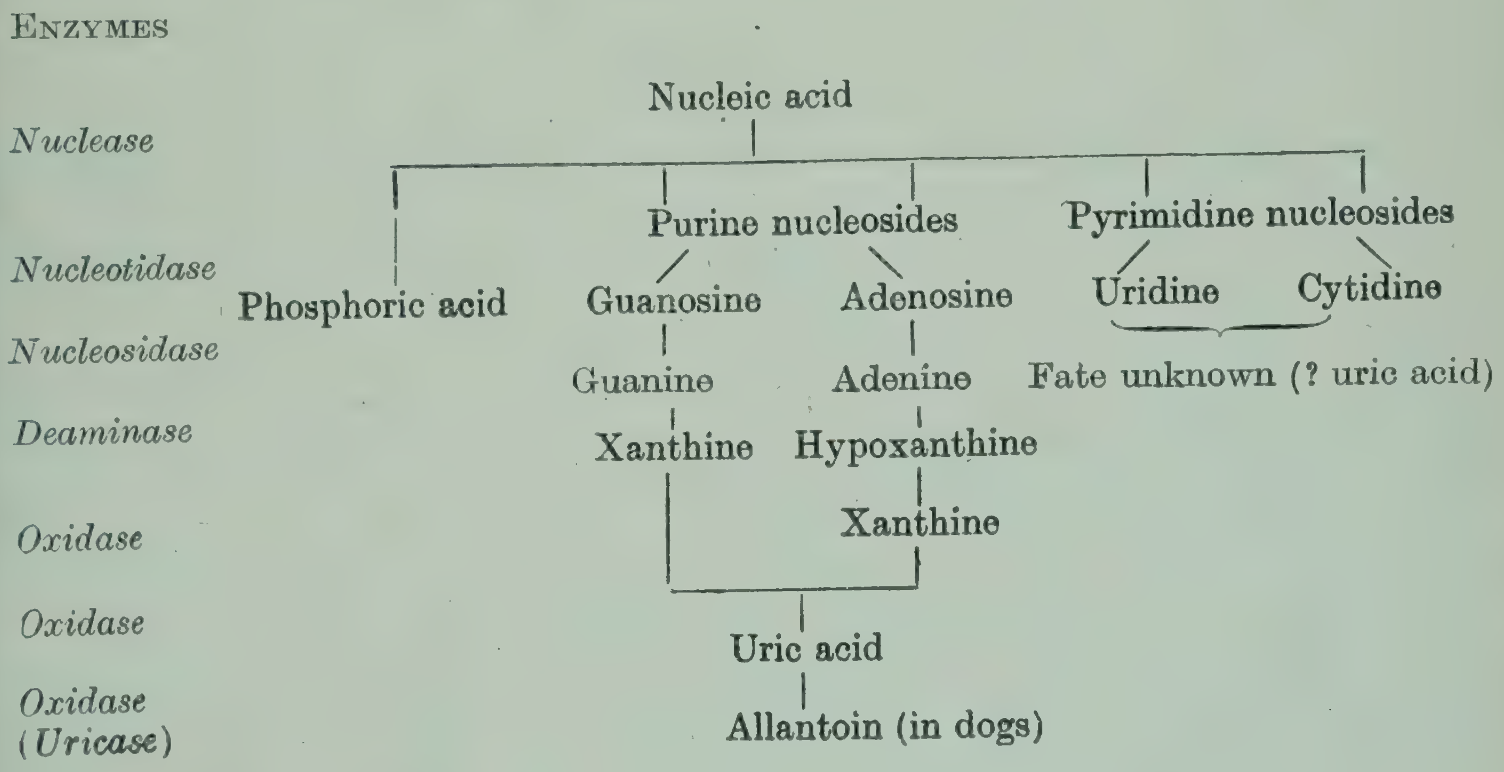
---

* Levene and Dmochowski. *J. Biol. Chem.*, 1931, **93**, 563.

† Horbaczewski. *Monat. f. Chem.*, 1891, **12**, 221.

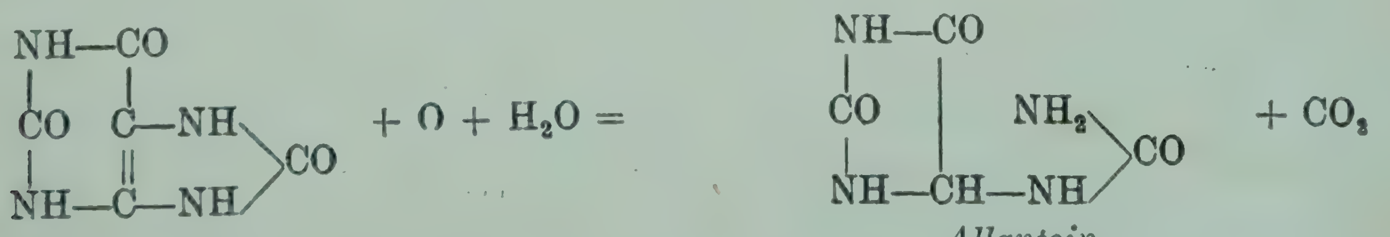
These various enzymes are not all present in all tissues, nor are the same ones present in the same tissues of different animals. Thus human liver contains guanase and xanthine oxidase; guanase is present in one or other tissue of most animals, except in those of the pig. Adenase is absent from human tissues *; guanase is present in human kidney, liver and lung, but not in spleen or pancreas. Xanthine oxidase is present in the human liver but not in other human tissues. For these reasons there are species differences in the way in which the purines are dealt with; for instance, the muscles of the pig often contain deposits of guanine because this cannot be destroyed, while adenine is present in human urine in small amounts. Yet not all the adenine present in the compounds ingested is excreted in man, because much of this purine is deaminised, by enzymes other than adenase, while still a part of the nucleotide or nucleoside molecule.†

If we make this reservation that the constituent parts of the nucleic acid molecule may undergo changes while still bound to the other parts, we may represent diagrammatically the formation of uric acid from nucleic acid as follows:—



ENZYMES
Nuclease
Nucleotidase
Nucleosidase
Deaminase
Oxidase
Oxidase
Oxidase
(Uricase)
Nucleic acid
Phosphoric acid
Purine nucleosides
Pyrimidine nucleosides
Guanosine
Adenosine
Uridine
Cytidine
Guanine
Adenine
Fate unknown (? uric acid)
Xanthine
Hypoxanthine
Xanthine
Uric acid
Allantoin (in dogs)

The question arises whether the uric acid excreted by a man represents the whole of the purines which have been destroyed in the body. Although complete equivalence has been found between the amount of hypoxanthine ingested and the amount of uric acid excreted, the same equivalence has not been established in the case of nucleic acid; and the important question arises whether uric acid once formed is stable or whether it may undergo further changes before being excreted. In many animals, such as the dog, the amount of uric acid in the urine is only minute, the chief purine derivative in this fluid being allantoin—an oxidation product of uric acid:



NH—CO
CO
C—NH
CO
NH—C—NH
+ O + H₂O =
NH—CO
CO
NH₂
CO
NH—CH—NH
+ CO₂

Allantoin

---

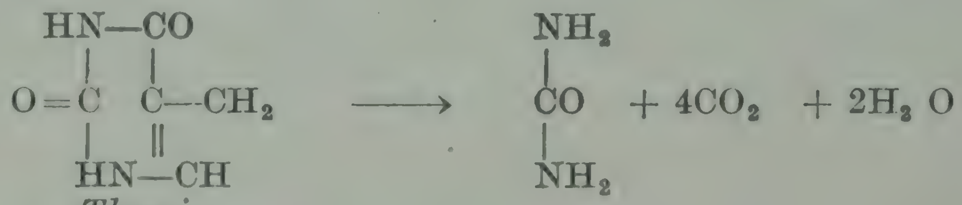
* JONES. *J. Biol. Chem.*, 1911, **9**, 129, 169.

† JONES and WINTERNITZ. *Z. f. Physiol. Chem.*, 1905, **44**, 1; 1909, **60**, 180.

This transformation can be effected by extracts made from the liver of the dog and various other animals.* The enyzme carrying out this change is known as uricase. No such enzyme is found in any human organs.†

If we add together the amounts of allantoin and uric acid excreted, and express the allantoin as a percentage of this sum, we get a figure called the *uricolytic index*. It is a measure of the extent to which uric acid is converted in the body into allantoin (by the enzyme uricase). In dogs of most species it is 98, *i.e.* most of the uric acid is oxidised to allantoin before excretion, but in the Dalmatian hound it is only 32. In the chimpanzee it is 0, and in man only 2. In man and the higher apes, therefore, practically all the uric acid formed in the body would appear to be excreted as such in the urine. The small trace of allantoin which may occur in human urine is directly derived from the food.

So far we have not considered the fate of the pyrimidine portion of the nucleotide molecule. It would seem that the human body is able completely to destroy these compounds, since they are absent from the urine. If a large amount of thymine or uracil is administered to dogs, some of it passes out in the urine unchanged, though, if given slowly it can be destroyed so that none is recoverable from the urine. Since in this condition the output of urea is increased, it would appear that the pyrimidines are converted into urea. Though we have no knowledge of the site or mode of this transformation, it is, chemically speaking, a simple one, as shown :



Thymine

Excretion of Uric Acid. Normal human blood contains 2 to 3 mg. of uric acid per 100 c.c., but the bloods of animals which do not excrete it contain very small amounts. When given intravenously, as lithium urate, to man, a variable fraction is excreted during the next few days ; the kidney does not seem able to deal with it at all rapidly. Under ordinary circumstances a man excretes about half a gramme of uric acid per day. In addition the urine contains a small amount of purine bases. From 10,000 litres of human urine Krüger and Salomon ‡ succeeded in isolating xanthine (10·1 grams), hypoxanthine (8·5 grams), adenine (3·5 grams). These are probably derived from the uric acid metabolism. In addition there are various methylated purines, derived from such constituents of the diet as caffeine, etc.

An attempt has been made to arrive at the amount of uric acid produced endogenously from a study of the quantity of uric acid in the urine of subjects on different diets. During starvation, when a man is living on his own tissues, one might expect the uric acid to be increased in consequence of disintegration of the tissues. It has been suggested that the amount of the endogenous uric acid in the urine would be obtained by an analysis of the urine from subjects taking a diet free from purine bases, but containing sufficient nitrogen to maintain nitrogenous equilibrium. Even in these circumstances, however, the amount of uric acid increases with the total nitrogenous metabolism, and, in fact, increases after each meal (Fig. 588).

There are three conditions which give rise to a definite increase in the output of endogenous uric acid. These are (1) severe muscular activity, (2) febrile states accompanied by increased nitrogenous metabolism. In both these conditions we may regard the uric acid as derived especially from the adenylic acid contained in the muscle. (3) In maturation of red cells, as, *e.g.* when a pernicious anæmia subject has an induced reticulocyte response resulting from the administration of liver extract. Presumably the increased uric acid is derived from the destroyed nuclei of the erythroblasts.

The foods which are especially effective in causing increase in the exogenous

3. FAT METABOLISM

The study of fat metabolism entails that of the metabolism of all compounds which contain fatty acids, and we shall begin therefore with a consideration of depôt fat.

Depôt Fat. We have seen that the amount of fat in the body is the main factor governing the length of life during starvation, because it is then the only material which can serve as a source of energy for a sufficient length of time. This reserve material, which is chiefly neutral fat, is found widely distributed in the body and in greatly varying amounts; the body of the average person contains some 12 per cent. of its total weight as fat, nearly all of which can act as an energy reserve. Its distribution in the body varies considerably, but we may say that the *panniculus adiposus* under the skin may account for, roughly, 50 per cent., and the perirenal, mesenteric and omental fat for about 15 per cent., 10 and 5 per cent. respectively, while some 5 per cent. or more may occur in the intermuscular connective tissue. In this adipose tissue the fat is enclosed within distended connective tissue cells, the protoplasm of which is reduced to a thin pellicle round each fat globule.

Composition of Depôt Fat. This reserve fat occurs in the form of triglycerides of various fatty acids the chief of which are stearic, palmitic and oleic acids. Ordinary depôt fat contains 75 per cent. of oleic acid, with 20 per cent. of palmitic acid and 5 per cent. of stearic acid, combined as mixed triglycerides, although often small amounts of more unsaturated acids also occur. There are also present small amounts of lecithin and cholesterol, which we may ignore for the moment.

The degree of saturation of depôt fat depends on its position in the body, there being a decreasing iodine value from the surface inwards. Thus, in a pig fed on barley the iodine values of the subcutaneous fat at increasing distances from the surface were 60, 57, 52 and 51 respectively; this is to be correlated with the increase of temperature as the distance from the skin increases,[*] and depends in part on the fact that the more unsaturated fats are liquid at lower temperatures than are the saturated ones. The same phenomenon is shown in the fact that the subcutaneous fat of the new-born infant has an iodine value of 47, which increases during the first year to the adult figure of 70.[†] This again is to be correlated with the internal position of the fœtus and the gradual adaptation during the first year of life to the fall in temperature of the subcutaneous tissues.

The Origin of Depôt Fat. (*a*) *The Food Fat.* It is a familiar experience that the fats of different species of animals usually have characteristic appearances, *e.g.* the hard fat of mutton, compared with the soft fat of beef. This relative constancy of composition within a species depends to a considerable extent on the similarity of the food of its members. But food fat may also undergo some modification during assimilation, which again will tend to make the fat of a particular animal of a constant nature. Although the nature of the depôt fat is capable of modification by the provision in the food of fats unusual in amount or nature, profound changes in its nature are usually only observed in experimental conditions so severe as to be unphysiological. The most graphic method of demonstrating such changes is to starve an animal until its fat reserves have been largely exhausted and then to fatten it on a particular fat; it is then found that the depôt fat approximates closely in composition to that of the fat given. In experiments of this type linseed oil caused in dogs an adipose tissue containing fat which was liquid at 0° C., while mutton fat resulted in a depôt fat having a melting point greater than 50° C.[‡] Similarly, abnormal acids such as erucic acid have appeared in depôt fat as a result of feeding oils containing it under similar conditions.[§] Another way of showing changes of this nature is to feed animals on diets in which fat constitutes a very high proportion of the food energy. The following Table illustrates the length to which this process can be carried.[||] Rats were fed on a basal diet with the addition of various fats in amounts such that these fats constituted 60 per cent. of the total calorie intake. The iodine value of the food and depôt fats which were determined are recorded in the following Table :—

	Iodine values.	
	Food fat.	Depôt fat.
Soya bean oil	132	122
Corn oil	124	114
Cotton seed oil	108	107
Lard	63	71
Butter fat	36	55

In more physiological conditions, in which unusual fats are given in normal amounts, the depôt fat usually shows a relatively slight change in composition. Since fat is only deposited when food in excess of the energy requirements is ingested, this is to be expected, for the fat of the food will tend to be used for immediate energy purposes. Usually the lower fatty acids are not deposited in the depôt fat, but are either oxidised immediately or built up into higher fatty acids; this again illustrates the ability of the animal to maintain the depôt fat reasonably constant in composition.[¶]

It would be expected that the composition of milk fat would also be markedly affected by the addition of fat to the diet, for a cow may be producing daily several pounds of fat in its milk, while its normal food contains a relatively small amount of fat. Such is the case. In one experiment, when a cow was fed on linseed oil, the iodine number of the milk fat rose from 30, its normal figure, to 70·4. Further, after the introduction of iodised fat subcutaneously, iodised fats are found in the milk. In another experiment a bitch, which had been fed with mutton suet and had deposited in her tissues a fat of high melting point, produced a milk the iodine number of which was the same as that of the mutton suet. In this case the fat of the milk had evidently been derived from the food *viâ* the tissues, since during lactation the animal was being fed on meat which was poor in fat.

[¶] Eckstein. *J. Biol. Chem.*, 1929, **81**, 613; Powell. *J. Biol. Chem.*, 1930, **89**, 43.

This question of the effect of feeding with fat on the composition of depôt and milk fats is one of great importance in stock raising, since food concentrates, often the bye-products of other industries, are much used for fattening purposes. The question of flavour has also to be considered, because particular food fats may readily cause the appearance in the fat, or in the milk, of any flavour present in them.

(*b*) *The Formation of Fat from Carbohydrate.* It has long been known to farmers that animals may be fattened on a diet rich in carbohydrate and relatively poor in fat. The classical experiment demonstrating the conversion of carbohydrate into fat in the animal body was that of Lawes and Gilbert.* In this experiment one of two pigs taken from the same litter was killed and completely analysed. The other pig received a diet for a given period and the total intake of fat, carbohydrate and protein in the diet was measured. At the end of the experiment this animal also was killed and analysed and a balance sheet drawn up, in which the essential points are as follows :—

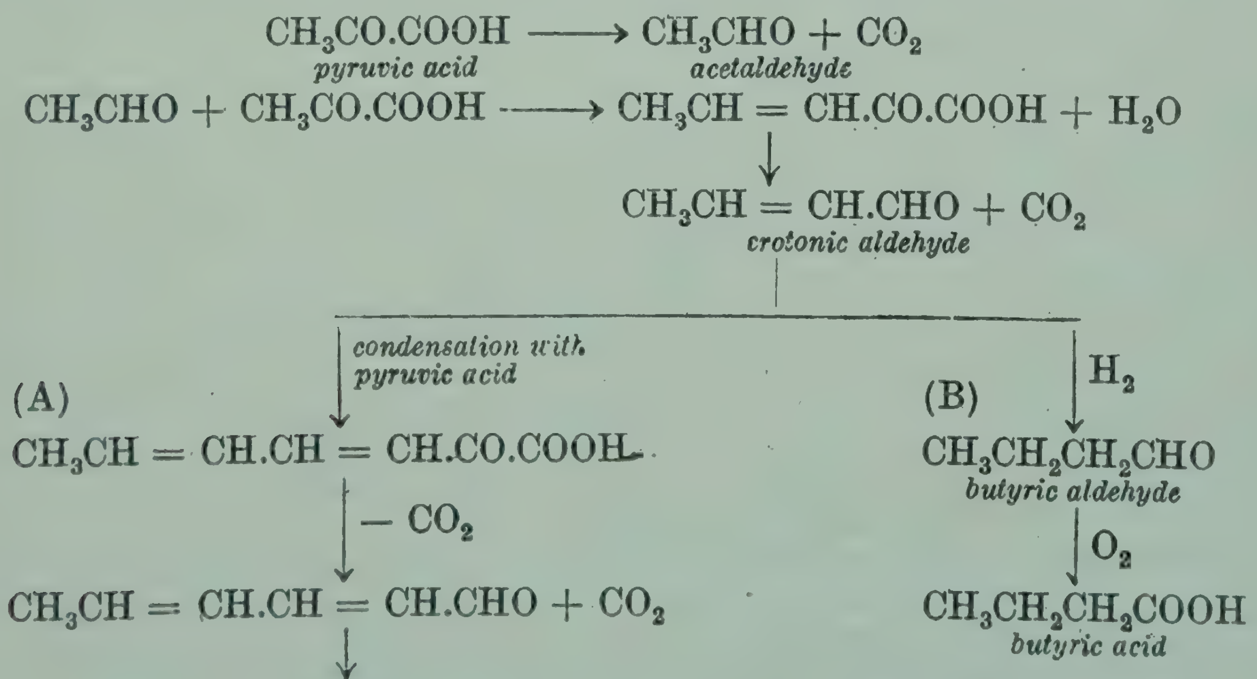
Total body fat increase .	71·2 lbs.	Protein in food . . .	64 lbs.
Fat in food	12·4 ,,	Body protein increase . .	6·5 ,,
Fat synthesised . . .	58·8 ,,	Protein available for fat synthesis	57·5 ,,
Carbon in fat synthesised .	45·3 ,,	Carbon in 57·5 lb. protein .	27·4 ,,

From these figures it is seen that whereas the synthesised fat contained 45·3 lb. of carbon, that available from protein was only 27·4 lb., *i.e.* 17·9 lb. of carbon had appeared as fat and must have been derived from carbohydrate.

Fattening of animals on a high carbohydrate diet causes the production of a harder fat than is normal,† with a corresponding decrease in its iodine value, which illustrates again the influence of food on depôt fat composition.

The means whereby sugar is converted into fatty acids is not known, although it is almost certain that it is not converted to a fatty acid by direct condensation ; an initial breakdown and a resynthesis is the probable path. Since carbohydrate metabolism both in the animal and in alcoholic fermentation passes through the three carbon stage of pyruvic acid, it is very probable that this compound forms the starting point from which fat is synthesised. It is significant that phosphate and vitamin B_1, the pyruvate co-carboxylase, are essential for conversion of carbohydrate to fat, as well as for decarboxylation of pyruvic acid to form acetaldehyde. Aldehydes possess the property of condensing together to form aldols, which may lose water with the production of double bonds. Pyruvic acid can also condense, either with itself or with an aldehyde.

Various schemes to explain the formation of fatty acid from carbohydrate have been postulated, based on this property. One such is briefly outlined below : ‡



$CH_3CO.COOH \longrightarrow CH_3CHO + CO_2$
pyruvic acid
acetaldehyde
$CH_3CHO + CH_3CO.COOH \longrightarrow CH_3CH = CH.CO.COOH + H_2O$
$CH_3CH = CH.CHO + CO_2$
crotonic aldehyde
condensation with pyruvic acid
(A)
$CH_3CH = CH.CH = CH.CO.COOH$
$- CO_2$
$CH_3CH = CH.CH = CH.CHO + CO_2$
H_2
(B)
$CH_3CH_2CH_2CHO$
butyric aldehyde
O_2
$CH_3CH_2CH_2COOH$
butyric acid

---

* *Phil. Trans. Roy. Soc.*, 1859 ; *J. Anat. and Phys.*, 1877, **11**, 577.

† Ellis and Zeller. *J. Biol. Chem.*, 1930, **8**, 185.

‡ Lubrzyrska and Smedley. *Biochem. J.*, 1913, **7**, 375.

In the above scheme a molecule of acetaldehyde derived from pyruvic acid condenses with a further molecule of pyruvic acid with the production of an unsaturated keto acid, which loses carbon dioxide to yield the unsaturated crotonic aldehyde. This latter by reduction would yield butyric aldehyde, which on oxidation would yield butyric acid (B). (It should be noted that no unsaturated aldehyde intermediaries have yet been detected.) Instead of following this path, crotonic aldehyde could condense with a further molecule of pyruvic acid and by the same procedure an unsaturated aldehyde with six carbon atoms is produced (A). This compound could either be reduced and oxidised to produce hexoic acid, or condensed further. By similar processes fatty acids containing any *even number of carbon atoms* could be synthesised and they would be saturated or unsaturated dependent on the extent to which the double bonds took up hydrogen. The fatty acids so produced would then be coupled with glycerol formed in the body from glucose, by way of glyceric aldehyde.* Such a theory would satisfy the fact that a whole series of even numbered saturated fatty acids may be produced from carbohydrate, together with unsaturated acids. Oleic acid is quantitatively by far the most important unsaturated acid synthesised from sugar, the amounts of other unsaturated acids being very small.

Adipose tissue contains a variable amount of glycogen, and it has been suggested that this represents a stage in the local conversion of carbohydrate into fat.†

(*c*) *The Formation of Fat from Protein.* The proteins are absorbed as amino-acids and we know that some 60 per cent. of the amino-acids in the food can be converted to carbohydrate in the body. It might reasonably be thought, therefore, that some of this might be converted to fat. There are, however, two limitations which make it certain that fat does not normally arise from protein. The first of these is that amino-acids can only be converted to glucose after their deamination in the liver. This is a relatively slow process, so that there is never made available at any given moment a large amount of sugar derived from amino-acids ; hence, after a high protein meal there is no pronounced rise in blood sugar. Secondly, it is difficult to satisfy the normal energy requirements of the body by ingestion of protein only. Hence any carbohydrate produced from protein would be at once oxidised for immediate energy purposes. In particular conditions, nevertheless, fat may be formed from protein, as was shown by the experiment of Atkinson, Rapport and Lusk,‡ in which large amounts of protein were given to a well-nourished animal resting in a warm environment. Some lower forms of animal life normally form fat on an exclusively protein diet, as was shown by Weinland for certain fly larvæ.

Utilisation of Depôt Fat. The power of the organism to store up reserve carbohydrate is strictly limited and probably 400 grammes represents the extreme limit of storage of carbohydrates in the body. On the other hand, in most animals there is practically no limit to the amount of fat which can be laid down by overfeeding, since the amount of reserve fat deposited will clearly depend on excess of income over expenditure. As soon as the energy expenditure exceeds the income, this fat store is drawn upon, so that adipose tissue is the one which presents the greatest loss during starvation, during which as much as 97 per cent. of it may disappear.

(*a*) *Functions of Depôt Fat.* As a reserve material, fat possesses very great advantages over carbohydrate or protein. In the first place its calorific value, 9·3, is more than twice as great as that of these other foodstuffs, 4·1. Secondly, the storage of either protein or carbohydrate entails the presence of much water, while adipose tissue is virtually pure fat (95 per cent.). Thus an enormous energy reserve may be laid down in a relatively small space. This fat in the depôts is not a static dump of material, but is constantly being turned over, even when the total amount is unchanged, or increasing. This can be shown by feeding with " labelled " fats, *e.g.* with fat containing deuterium.

Besides this function as reserve material, fat serves as a protection against temperature change and against mechanical injury, a simple illustration of the former being the apparent immunity of women, as compared with men, to

[†] Tuerkischer and Wertheimer. *J. Physiol.*, 1942, **100**, 385 ; Wertheimer, *J. Physiol.*, 1945, **103**, 359.

[‡] *J. Biol. Chem.*, 1922, **53**, 155.

exposure to cold surroundings; an immunity which women in a normal state of nutrition owe to the fact that nature has been more liberal, as art is more tolerant, of subcutaneous fat in the female than in the male.

(*b*) *The General Utilisation of Fats in the Body.* After a few days' starvation the sole sources of the energy which is available must be fats and proteins, and it is possible by an estimation of the nitrogen output to determine what fraction of the total energy evolved is to be ascribed to protein metabolism. Thus in the case of Cetti, the professional faster, it was found that the nitrogenous metabolism per unit of body weight between the fifth and tenth days of starvation corresponded to an average of 1 gramme of protein per kilogramme body weight daily. In order to oxidise this amount of protein about 1 c.c. of oxygen per minute would be required. Cetti's total oxygen consumption was 5 c.c. per kilogramme per minute, so that four-fifths of the oxygen absorbed was required for the oxidation of non-nitrogenous substances and these could only have been fats. In animals with a large store of fat the proportion of the energy obtained at the cost of the fats may be still greater.

How the fat leaves the depôts is uncertain, but there is some evidence that it leaves, as it enters, in the form of fine particles of neutral fat in the blood. During fasting these are called "*lipomicrons*"; they show periodic bursts of increase at five-hourly intervals during starvation.

The oxidation of fats supplies energy, not only for the production of heat, but also for the performance of mechanical work. Fat is found as a normal constituent of all muscle fibres and the amount of this substance is greater in proportion to the activity of the muscles concerned. Thus the heart muscle and the red muscle of the diaphragm contain larger amounts of fat than the pale voluntary muscles which have to undertake only short periods of activity.* In the human heart muscle 15 per cent. of the solids are soluble in ether and more than one-half of the ether extract is composed of fat; this would be sufficient to supply the energy of the contracting heart for six or seven hours' work. Evidence from various sources suggests that the heart does use fat to provide energy. In most instances, however, it seems that the tissues use carbohydrate in preference in order to supply energy.

In prolonged moderate exercise the respiratory quotient is the same as during rest, provided that the diet remains the same. The respiratory quotient under these conditions depends merely on the nature of the food oxidised, and it makes no difference what intermediate changes take place, such as that of fat to carbohydrates or *vice versâ*, so long as all the food used finally undergoes complete oxidation. This is well shown in the following Table, in which the oxygen consumption and respiratory quotient are compared in a man resting and working on three different diets—one principally fat, one principally carbohydrate, and the other principally protein.

Diet principally	Resting		Working		kg. m. of work done	Per kg. m. of work	
	c.c. oxygen used per min.	Resp. quotient	c.c. oxygen used per min.	Resp. quotient		c.c. oxygen used	Cal.
Fat . . .	319	0·72	1029	0·72	354	2·01	9·39
Carbohydrate .	277	0·90	1029	0·90	346	2·17	10·41
Protein . .	306	0·80	1127	0·80	345	2·38	11·35

During short bouts of severe exercise, as we have seen in Chapter X., the respiratory quotient of the *excess* metabolism is about unity, which might be interpreted as meaning that the extra energy is derived by the oxidation of carbohydrate. This is the case even when the subject is on a fat diet. But in that case after the exercise, or if hard exercise is prolonged, the quotient falls and this is interpreted as indicating that the muscle (and liver) are replenishing their stores of glycogen at the expense of fat.

* Leathes. *J. Physiol.*, 1904, **31**, Proc. ii.

(*c*) *The Possible Conversion of Fat into Sugar.* When a starved rat is fed on a fatty acid containing an *odd* number of carbon atoms (*e.g.* propionic acid), an accumulation of glycogen is demonstrable in the liver. But natural fats only contain fatty acids of even carbon numbers and do not produce this effect. Although the evidence is conflicting, it has been claimed that constant production of glucose is normally proceeding in the liver, even during fasting, and this glucose might arise from fat.[*] Further, the perfusion of livers with blood containing butyric acid leads to the production, not only of ketone bodies, but also, it is claimed, of glucose.[†] Also, the evidence that the energy of muscular contraction is derived largely from carbohydrate requires, as a logical necessity, the possibility, at all events during fasting, of the conversion in the body of fat into carbohydrate.

During hibernation, as Pembrey showed, the marmot has a very low respiratory quotient, which may be as small as 0·3 or 0·4. The excess intake of oxygen can be explained only by assuming that there is going on in the body a conversion such as that of fats into carbohydrates. The same conversion, accompanied by a very low respiratory quotient, has been alleged to take place in certain cases of diabetes. In many cases, when the diabetic animal is fasting, or is receiving a purely protein diet, a uniform ratio has been found to exist between the glucose and the nitrogen excreted; this ratio, $\frac{G}{N}$ generally equals 2·8. This represents a conversion into sugar of 45 per cent. of the protein used. In a few cases, however, even during complete starvation, the G : N ratio has been stated to amount to as much as 10 or 12. These animals are stated to be practically free from carbohydrates, so that the sugar excreted in the urine can come only from the breakdown of fats, since the protein could not provide all of it.

Various suggestions have been made as to the path by which fat could be converted to carbohydrate.

The Oxidation of Fatty Acids

The normal animal combusts fat to carbon dioxide and water and generally, therefore, no oxidation products are excreted in the urine. Any theory of fatty acid oxidation must account for the fact that fatty acids with any number of carbon atoms up to 20, both saturated and unsaturated, have to be oxidised. Secondly, it should be remembered that all the natural fatty acids contain an even number of carbon atoms. Possible hypotheses would be (i) direct and complete oxidation in the tissues generally, or (ii) stagewise oxidation begun in the liver and finished in tissues generally. For various reasons (ii) is most favoured. It may occur in various ways.

(*a*) *β-oxidation.* Evidence as to the nature of the intermediate steps has been obtained by administering to animals the phenyl derivatives of fatty acids and examining the urine for the end products. The tissues cannot readily disrupt the benzene ring, which must therefore be excreted, and which may carry with it a partially oxidised residue of the fatty acid molecule to which it was attached. Knoop [‡] found that when a series of phenyl fatty acids, beginning with phenyl acetic acid, were given to animals, one of two products only appeared in the urine, either phenyl formic acid (benzoic acid), or phenyl acetic acid, in accordance with the following scheme :—

---

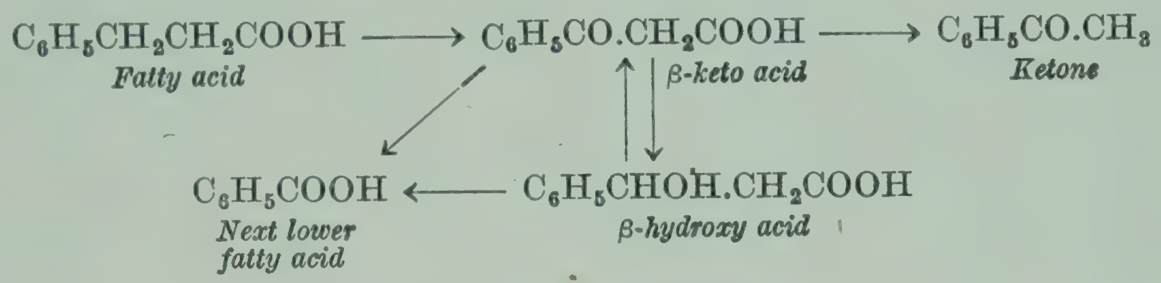
[*] Young. *J. Physiol.*, 1936, **87**, 11 P.; Soskin *et al.* *Amer. J. Physiol.*, 1935, **114**, 110.

[†] Blixenkrone-Møller. *Z. f. Physiol. Chem.*, 1938, **252**, 137.

[‡] Knoop. *Beit. Z. Chem. Physiol. Path.*, 1905, **6**, 150.

Acid administered.		No. of C atoms in fatty acid chain.	Product excreted.	No. of C atoms lost.
Phenyl formic acid (benzoic acid)	C_6H_5COOH	1	C_6H_5COOH	0
,, acetic acid	$C_6H_5CH_2COOH$	2	$C_6H_5CH_2COOH$	0
,, propionic acid	$C_6H_5(CH_2)_2COOH$	3	C_6H_5COOH	2
,, butyric acid	$C_6H_5(CH_2)_3COOH$	4	$C_6H_5CH_2COOH$	2
,, valeric acid	$C_6H_5(CH_2)_4COOH$	5	C_6H_5COOH	4

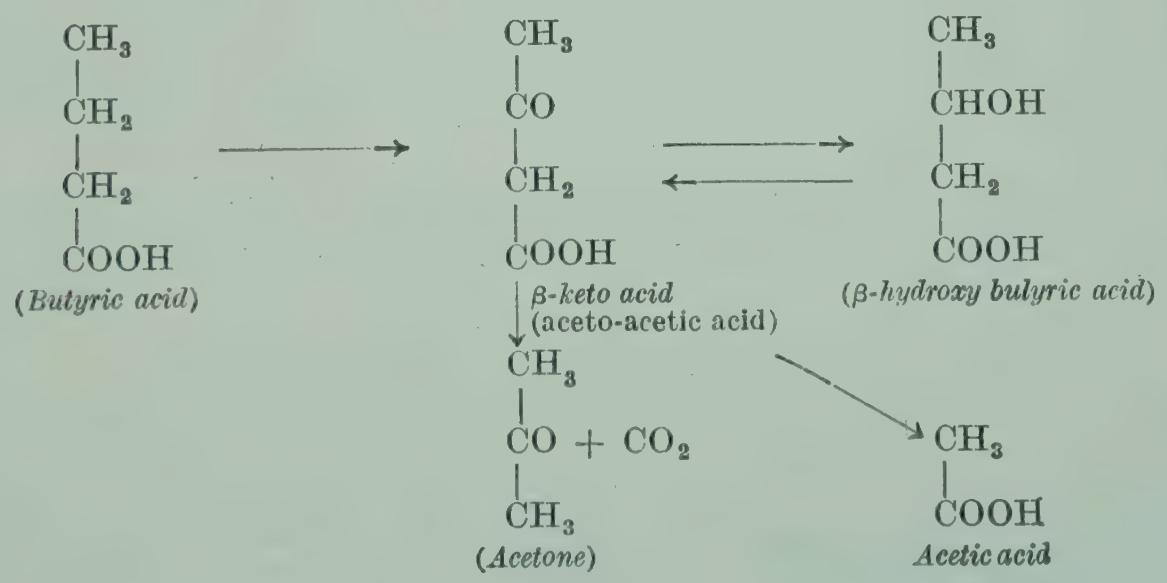
Since the number of carbon atoms lost was always an even number, this suggested that the fatty acids lost their carbon atoms two at a time, the odd-numbered acids giving rise to benzoic acid and the even-numbered to phenyl acetic acid. Dakin * showed that further intermediate products could be obtained in accordance with the following scheme :



$C_6H_5CH_2CH_2COOH$
Fatty acid
$C_6H_5CO.CH_2COOH$
β-keto acid
$C_6H_5CO.CH_3$
Ketone
C_6H_5COOH
Next lower fatty acid
$C_6H_5CHOH.CH_2COOH$
β-hydroxy acid

These two lines of evidence are the basis on which the theory of successive β-oxidation of fatty acids has been evolved. When a fatty acid is oxidised, the first product is a β keto acid, which is then oxidised at the carbonyl group to the fatty acid with two carbon atoms less. The two-carbon fragment split off may be presumed to form acetic acid. Thus, in the normal oxidation of a saturated acid like stearic acid, $C_{18}H_{36}O_2$, after the corresponding intermediate products had been first produced, palmitic acid, $C_{16}H_{32}O_2$, would be formed by loss of two carbon atoms. This process of losing two carbon atoms at a time is repeated with the production next of myristic acid, $C_{14}H_{28}O_2$, and similarly through successive stages of C_{12}, C_{10}, C_8, and C_6 to butyric acid, $C_4H_8O_2$. The higher intermediate products have not been isolated, probably because the further oxidation is rapidly and completely achieved, so that these products never accumulate.

The butyric acid, by further β-oxidation would yield aceto-acetic acid, and this then can undergo one of three further changes, reduction to β-hydroxy butyric acid, decarboxylation to acetone, or conversion to acetic acid :—



CH_3 CH_2 CH_2 COOH
(Butyric acid)
CH_3 CO CH_2 COOH
β-keto acid (aceto-acetic acid)
CH_3 CHOH CH_2 COOH
(β-hydroxy butyric acid)
CH_3 CO + CO_2 CH_3
(Acetone)
CH_3 COOH
Acetic acid

The oxidations in question appear to be carried out by the liver, and liver perfusion investigations bear this out. If fatty acids are added to blood used for perfusing a liver, there is an increased amount of acetone bodies produced

---

* Dakin. *J. Biol. Chem.*, 1908, **4,** 419 ; **5,** 173, 303.

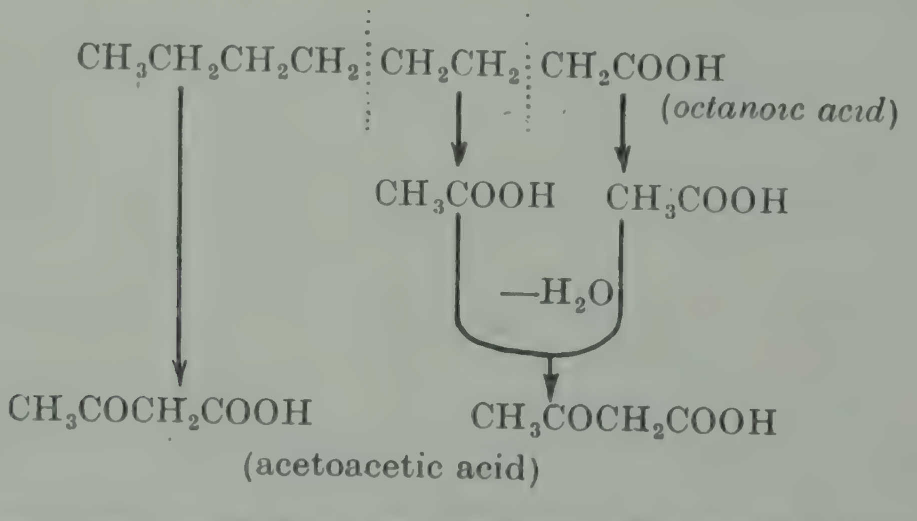
when even-numbered fatty acids are used, but not in the case of odd-numbere ones.* If aceto-acetic acid is added, β-hydroxybutyric acid is formed.

Further confirmatory evidence has come from studies of the oxidation o fatty acids added to liver slices. When lower fatty acids were added to live slices, only those which possessed an even number of carbon atoms gave ris to additional aceto-acetic acid and, further, in the liver, aceto-acetic acid wa the final oxidation product.†

There is much evidence in support of the view that β-oxidation is one of th normal mechanisms by which fatty acids are oxidised. But for the oxidatio to be normal and complete, there must be concurrent oxidation of carbohydrate In any state in which carbohydrate cannot be adequately used (diabete mellitus), or in which there is insufficiency of carbohydrate for oxidatio (starvation), excess of fat has to be burnt in order to supply sufficient energy. In this condition a state of *ketosis* occurs in which there is excretion in the urin of aceto-acetic and β-hydroxy butyric acids and acetone. These are precisely the products which, as we have seen, should be obtained on the β-oxidation theory, if, as in these conditions, fatty acid oxidation were incomplete.

The exact origin of the ketone bodies is important. According to the original β-oxidation theory the two-carbon fragments (? acetic acid) split off at each stage are oxidised to CO_2 and water, and aceto-acetic acid only arises when, at the four-carbon stage, butyric acid is in turn subjected to β-oxidation. Therefore, each molecule of fatty acid should yield only one molecule of aceto-acetic acid.

The amount of ketone bodies produced is, however, often greater than this, *e.g.* the C_8 octanoic acid can all be converted into aceto-acetic acid (two molecules). There is evidence that this is effected by β-oxidation followed by condensation of the two-carbon fragments to form aceto-acetic acid, thus :—



Proof of this condensation of 2-carbon fragments is that if octanoic acid containin C^{13} in the COOH group was incubated with liver slices, the aceto-acetic acid produced contained labelled carbon equally in the CO and COOH groups ; also, acetic acid with C^{13} in the COOH incubated with kidney tissue produced the same doubly labelled aceto-acetic acid.‡

(*b*) *Multiple Alternate Oxidation.* Another way in which ketone bodies could arise has been proposed. In successive β-oxidation, the end-products would be, from each molecule of fatty acid, one of ketonic acid, and several of acetic acid, *e.g.* from palmitic acid :—

$$\text{Palmitic acid} + 6{\cdot}5\ O_2 = 1\ \text{ketone} + 6\ \text{acetic acid.}$$

But there is the possibility that the fatty acid molecule may be simultaneously attacked at different points, with the production only of several molecules of ketone bodies, *e.g.* :—

$$\text{Palmitic acid} + 1{\cdot}5\ O_2 = 4\ \text{ketone.}$$

By determining the oxygen consumed, and the ketone bodies produced per molecule of fatty acid destroyed, it should be possible to decide between these possibilities. This was done by Stadie, and it was found that 1·1 ± 0·2 moles oxygen were used, and that about 4 moles of ketone resulted, when the experiment was carried out on liver slices. Moreover, no acetic acid, or any C_2 to C_8 acid could be found : the low R.Q. (0·3) showed that these had not been first formed and then oxidised.

‡ WEINHOUSE *et al.* *J. Biol. Chem.*, 1944, **155**, 143 ; 1945, **157**, 751.

(c) ω-oxidation.* It was observed that on administration of the triglycerides of some fatty acids, dicarboxylic acids with the same number of carbon atoms could be isolated from the urine, *i.e.* the terminal methyl group of the fatty acid had been oxidised to a carboxyl group. The biggest yield of such products was obtained with the triglyceride of capric acid, $CH_3(CH_2)_8COOH$, which gave rise in the urine to sebacic acid, $HOOC(CH_2)_8COOH$, with smaller quantities of the corresponding dicarboxyl acids with six and eight carbon atoms, *i.e.* suberic acid, $HOOC(CH_2)_6COOH$, and adipic acid, $HOOC(CH_2)_4COOH$.

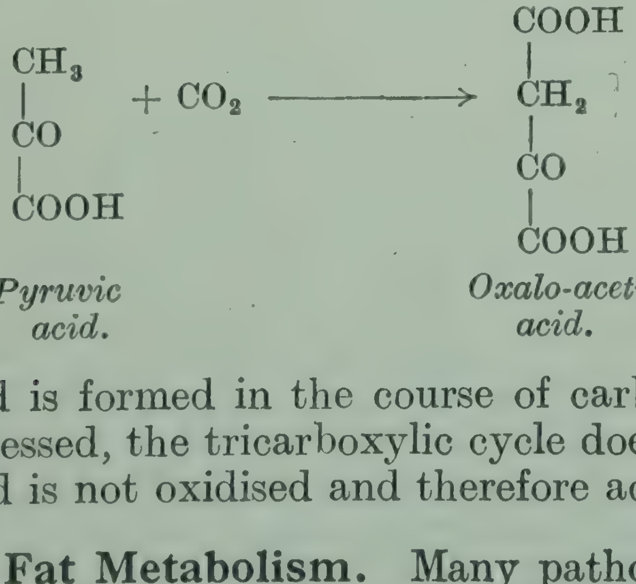
The fate of the ketone bodies which are formed in the course of fat metabolism varies. Some tissues, *e.g.* muscle and kidney, can oxidise them at reasonable rates, but if large amounts are produced their disposal becomes difficult, especially if carbohydrate is lacking (a condition which entails an accelerated production of ketones).

The Anti-ketogenic Action of Carbohydrate. The ketone bodies do not appear in the blood and urine when adequate carbohydrate or other glucose-yielding (anti-ketogenic) substance is being burnt at the same time, and this is the basis of the expression that fat is burnt in a " fire of carbohydrate."

This anti-ketogenic action of carbohydrate has been investigated by dietary studies in which mild ketonuria has been induced by a restricted diet. Such studies † show that when the molecular ratio of ketogenic to anti-ketogenic substances in the food exceeds two, acetone bodies appear in the urine. The anti-ketogenic substances will, of course, include not only dietary carbohydrate, but sugar which may be derived from glycerol, or from the straight-chain amino acids such as alanine ; whilst the ketogenic fraction will include, not only the fatty acids, but also those amino-acids, such as tyrosine, which give rise in their metabolism to aceto-acetic acid. These results are clearly of importance from the point of view of diabetic feeding, and simply expressed they mean that fat oxidation begins to be incomplete when the amount of " fat " in the diet is more than twice that of the carbohydrate actual and potential.

Ketosis is produced or augmented by the injections of certain extracts of the anterior pituitary body. Similar claims regarding the suprarenal cortex have also been made (Ch. L.).

There have been various suggestions for explaining why concurrent oxidation of carbohydrate is essential for preventing ketosis. An attractive one can be understood by reference to the tricarboxylic acid cycle (p. 143). As a result of its operation, acetic acid can be oxidised to CO_2 and water, instead of being condensed to form aceto-acetic acid, and any aceto-acetic acid formed in other ways can also be oxidised. But an essential step in the cycle is oxalo-acetic acid, and this is produced from pyruvic acid and CO_2 under the influence of β-carboxylase :—



$$\begin{array}{l} CH_3 \\ | \\ CO \\ | \\ COOH \end{array} + CO_2 \longrightarrow \begin{array}{l} COOH \\ | \\ CH_2 \\ | \\ CO \\ | \\ COOH \end{array}$$

Pyruvic acid. *Oxalo-acetic acid.*

The pyruvic acid is formed in the course of carbohydrate oxidation, and hence, if this is depressed, the tricarboxylic cycle does not function efficiently, and aceto-acetic acid is not oxidised and therefore accumulates.

The Liver and Fat Metabolism. Many pathological and experimental findings indicate that the liver plays a special part in fat metabolism. The most striking fact in this connection is that fat is transported to the liver in many conditions. Normally the liver contains some 3 per cent. of lecithin and 1 per cent. of glyceride. In the variety of conditions which may be classed together as fatty livers, large amounts of glyceride may appear, increases up to 70 times the normal amount having been observed. These fatty livers appear in the early stages of starvation, in poisoning by phlorrhizin, chloroform, alcohol, phosphorus and a variety of other chemical agents ; they occur after pancreatectomy, in clinical and experimental diabetes, in pernicious anæmia and a number of other pathological states. They may be induced also by diets high in fat or containing cholesterol. Although transportation of fat to such tissues as the heart and kidney also occurs, its frequency is very much less, as is also the actual degree of fat infiltration.

---

* Verkade and Lee. *Biochem. J.*, 1934, **28**, 31.

† Schaffer. *J. Biol. Chem.*, 1921, **47**, 433, 449 ; 1921, **49**, 143 ; 1922, **54**, 399.

Investigations to determine the source of this fat, by experiments in which animals have been starved to remove the depôt fat, then fattened on a "labelled" fat, *e.g.* on fat containing deuterium instead of some of its hydrogen atoms,* and finally poisoned with carbon tetrachloride, or starved, to cause deposition of fat in the liver, indicate that the mobilised liver fat has come from the depôts. But if "labelled" fat containing deuterium is given until the depôts contain that fat, and the animal is then given a diet low in protein but rich in carbohydrate, the liver fat contains no deuterium and so has probably been formed from carbohydrate. Hence it appears that new-formed fat appears directly in the liver, but mobilised fat is transported thither, so that the problem resolves itself into a consideration of why depôt fat appears in the liver. It is to be recalled that the fatty acids present in the liver fats have a higher iodine value than have those of depôt fat, but not much more than half that of the acids present in the liver as phosphatide. This and other findings led Leathes † to suggest that depôt fatty acids are mobilised and transferred to the liver, where they undergo a process of desaturation and conversion to phosphatides. They are then carried to the tissues for oxidation in this now more unstable form or else are, at least partially, oxidised in the liver itself. The proofs that ketone bodies are formed in the liver, including the fact that after removal of the liver the ketosis following pancreatectomy or injection of the pituitary ketogenic fraction is reduced or abolished, supports the view that the initial stages of the oxidation of fats takes place in the liver. There is a close relationship between the rate at which fat is transported to the liver and the extent of ketosis. Thus, adrenalectomy reduces both ketosis and the fat of the liver induced by injection of anterior pituitary extracts. If we accept the view that the oxidation of fats proceeds in the liver up to the stage at which 4-carbon ketone bodies are produced, then it would seem probable that these substances, set free into the blood stream, are finally oxidised, together with glucose—also released by the liver—in the tissues.‡ That certain tissues, *e.g.* heart muscle, can utilise β-hydroxybutyric acid has been demonstrated beyond question.§

Although the evidence in favour of this particular type of desaturation has lost much of its force, this must not be regarded as disposing of desaturation as a biological process, and recent work seems to suggest that desaturation does in fact occur.‖ Incubation and other experiments with livers, both normal and fatty, suggest that the liver can desaturate fatty acids, and it is tentatively suggested that this desaturation, which may be carried out by other tissues also occurs in the α–β positions. We must therefore conclude that desaturation probably occurs, although the original evidence and the particular type o desaturation which was originally put forward is largely disproved.

The common C_{18} acids in nature are oleic, linoleic and linolenic acids. These products presumably built up in the plant from carbohydrate, have their double bonds in the 9 : 10

9 : 10. 12 : 13 ; 9 : 10. 12 : 13. 15 : 16 ; positions respectively. The occurrence of these double bonds symmetrically disposed, three carbon atoms from each other, might suggest that they have been evolved by a synthesis from a three-carbon unit, which has been produced from sugar by some such means as has been indicated in an earlier paragraph. Animals on a fat-free diet build up much oleic acid with traces of higher unsaturated acids (arachidonic acid), although the ability to synthesise linoleic acid is absent, while linolenic acid does not occur. Linoleic acid is a dietary essential for normal growth.*

After prolonged fat-starvation, the per cent. of fat in the dry tissues is as high as in normal animals, showing that formation of saturated fats and olein have proceeded as usual. It remains for future research to show why oleic acid with one double bond can be apparently synthesised with ease, whereas linoleic acid with two double bonds cannot.

Lipotropic Action. Investigation of the fatty liver problem received considerable impetus by the discovery by Best and his colleagues of the control of liver fat—the so-called *lipotropic action*, exerted by choline,† which is now recognised as an essential dietary constituent. On diets which are free from choline, large amounts of fat appear in the liver, whereas if choline be present in the diet, as normally it always is, there is no accumulation of liver fat. Furthermore, in experiments in which fatty livers have been produced it is possible to cause the disappearance of the fat by the administration of choline, whereas in the absence of choline the liver fat remains at its abnormally high level. The kidneys also undergo fatty changes, with extensive destruction of tubules and glomeruli. This action of choline in liver fat control is clearly of great importance, because it enables us by dietary means to produce fatty livers ; furthermore, it allows the amount of liver fat to be controlled at will by the inclusion of suitable amounts of choline in the diet ; it has also provided a new method whereby the *rôle* of the liver in fat metabolism may be further investigated. The amounts of choline which are effective may be quite small, for in the rat 5 milligrammes per day has been found to prevent a rise of some 12 per cent. of fat, expressed as the wet liver weight.

The mechanism of this choline action is probably that it provides the base choline for phosphatide synthesis, and so links up with the hypothesis of lecithin as a carrier of fatty acids.

Proteins also exert a lipotropic action,‡ which appears to be due to their content of methionine.

The effect of choline in preventing the fatty liver was discovered through the observation that depancreatised dogs developed fatty livers. Extracts of pancreas contain a specific substance, *lipocaic*. This may be an enzyme liberating methionine (from protein), which then is used for trans-methylative formation (p. 29) of choline.§

Fatty Degeneration. In certain pathological conditions various organs of the body such as the liver, undergo what has been described as *fatty degeneration* and this was interpreted as a conversion of the proteins of the cells into fat. We have seen already that such a conversion does not occur in the normal animal, and so-called fatty degeneration is due to a mixture of two contributing factors. The first of these is *fatty infiltration, i.e.,* mobilisation from the depôts occurs, as has already been discussed. Secondly, the protoplasm of cells contains " fat " in such a condition that its presence cannot be detected by histological means, probably because it is in some form of adsorption complex with the proteins. Hence the presence or absence of visible fatty globules affords very little clue to the quantities of fat in the cells. In various diseases and toxic conditions this fat is unmasked, due to the effect of various agents in breaking down the intimate cell structure and this is the second factor involved in fatty degeneration. The expression " *unmasked fat* " used in histology and pathology refers to such protoplasmic fat.

The Rôle of Phospholipides in the Tissues. On the grounds of its chemical structure (70 per cent fatty acid) and of the peculiar physical property of forming almost true solutions in water, lecithin obviously suggests itself as one of the means whereby fatty acids could be transported in the body. This brings us to consider whether phospholipides are integral parts of cell structure, metabolically inert from the point of view of fatty acid metabolism, or whether they are actively concerned in the latter process, or both.

---

‡ Channon *et al.* *Bioch. J.*, 1938, **32**, 976 ; 1943, **37**, 483.

§ Chaikoff *et al.* *J. Biol. Chem.* 1945, **160**, 489.

There is considerable evidence that formation of phospholipides may occur in the intestine, from fatty acids; when labelled fatty acids were given they were traceable in the phospholipides of the intestinal mucosa after a short interval,* and it has been suggested that fatty acids may thus be transported in part into the portal blood and not, like neutral fat, into the lymph.

The total ether-soluble material present in such tissues as the normal liver, heart, kidney, etc., consists largely, not of glycerides, but of a mixture of phosphatides. If these two groups of constituents be separated from one another and the fatty acids prepared from them by hydrolysis, the phosphatide acids are always found to be more unsaturated than the glyceride acids, and these in turn are usually more unsaturated than those of the depôt fat. Some illustrative figures are as follows:

	Iodine values of:		
	Total fatty acids.	**Fatty acids of phosphatide.**	**Fatty acids of glyceride.**
Liver	113	134	76
Heart	107	128	67
Kidney	92	117	84
Spleen	90	98	75
Lung	66	77	60

The total amount of ether-soluble material in such tissues as those given in the table varies between some 2 and 4 per cent. and, depending on dietary conditions to some extent, one-half to two-thirds or more may consist of phosphatide with the remainder as glyceride, cholesterol and cholesteryl esters.

The problem then is to decide why phospholipides occur in all tissues and why they are more unsaturated than are the glycerides. Much work has been done to attempt to determine whether lecithin is actively involved in fat metabolism as such. As we have seen when dealing with absorption, there is *primâ facie* evidence that formation of lecithin in the intestine, at any rate, may play an active part either in the absorption of fat or in the processes immediately following it. Further, in certain conditions, the amount of liver phosphatide appears to be changed after a fatty meal, and its fatty acids modified by the fat of the diet; thus iodised fats appear both in the liver and blood corpuscle phosphatides after administration.† Further, the effect of choline ‡ in controlling the level of liver fat also suggests an active *rôle* for lecithin.

On the other hand, the phosphatide of most tissues shows very little change in extreme dietary variations, and such tissue as brain, which contains much phosphatide, apparently does not utilise fats. Moreover, it is particularly the unsaturated fatty acids which are built up into phosphatides in the intestine, and which are retained with tenacity in the tissues. We may conclude then by saying that, although the chemical and physical properties of lecithin make it suitable from the point of view of fat transport and oxidation, the clear evidence so far adduced in favour of its active participation is relatively slight, save perhaps in the case of the liver and intestinal mucosa.

This brings us then to the consideration of the structural functions of phospholipides. These are essential cell constituents, forming an integral part of the cell membrane, and it might be anticipated, therefore, that even though these substances contain 70 per cent. of a fatty acid in their molecule and therefore have a high calorific value, they could not be called upon as reserve material without the destruction of the cells in which they are present. That this is so is indicated by much work carried out by Maeyer and Terroine.* The French School of workers make use of the expression the "*constant element*," by which they mean the fatty acids present in one form or another which cannot be called upon in time of need. That this constant element exists has been shown by studying the lipoids of animals which have died from inanition ; the larger part of the fatty acids of these are present as phosphatides and are constant both in amount and composition. This would imply that the phosphatide fatty acids of a given tissue are characteristic of that tissue and cannot be varied by diet. Whilst the constancy of amount seems to have been confirmed by further work, it has been shown that the nature of the fatty acids, particularly of intestinal mucosa and liver, may be substantially modified by diet. It is, however, interesting to note that the degree of unsaturation of phosphatide fatty acids does seem to be more or less characteristic of the tissue in that the iodine value of the acids in the different tissues seems to run in the same order.

† ARTOM. *Arch. inter. Physiol.*, 1933, **36**, 101; ARTOM and PERETTI. *Arch. inter. Physiol.*, 1933, **36**, 351.

‡ BEST and HUNTSMAN. *J. Physiol.*, 1935, **83**, 255.

As to the part taken by this essential fat of the working cells, in the life of the cell, our knowledge is still very scanty. Fatty acids enter into the constitution of the phospholipides and glycolipides which form important constituents of the protoplasm, Golgi apparatus and limiting membrane of every cell. As constituents of the membrane itself, fatty substances therefore have a protective action and also regulate the passage of substances into the cell across the membrane. The presence of the phospholipides as integral constituents of all protoplasm suggests that they may play a part in the normal transformations which occur within the cell, and may represent, so to speak, the currency into which fat is transformed in order to participate in the vital processes, and to be transported and utilised for the needs of the cell. Much work also indicates that there is a physiological antagonism between cholesterol and lecithin, which presumably is related to their physical properties.

Changes during Absorption. As we have seen earlier, the fatty acids absorbed in the small intestine are partly resynthesised in their passage through the intestinal epithelium, some to neutral fat and some to phospholipide. The fat resulting from this resynthesis may, for several reasons, be of a different character from that of the food. In the first place, the ease of absorption of fatty acids varies with their physical properties. Unsaturated liquid acids are very readily absorbed, especially to form phospholipide, whilst saturated acids are less well absorbed with increasing length of the carbon chain, so that the higher saturated acids are poorly absorbed unless unsaturated acids are being absorbed at the same time. Hence, in some conditions, higher fatty acids may not be absorbed, but passed into the fæces. Further, bile and other secretions contain small amounts of fatty acids and these too may be absorbed with the food fat and cause some modification in its condition.

The original food fatty acids appear in the chyle, and eventually in the blood, as a mixture of phosphatide, glyceride and cholesteryl esters, glyceride usually being in a vastly greater proportion.

This brings us to consider whether the various lipides of the blood show any changes after a meal. Here the evidence is not conclusive. There is, of course, an increase in the neutral fat in the blood, and lipæmia may develop. With this there is also an increase in phosphatide and cholesteryl ester at different times after absorption, and the extent of these changes is different in corpuscles and plasma. Attempts have been made to interpret the findings as meaning that the phosphatides or cholesteryl esters play an active part in the transport of fatty acids † ; another possible view is that with the arrival of food fatty acids into the blood, considerations of physico-chemical equilibrium may require readjustment of the proportions of the phosphatide and cholesteryl ester present. Since cholesterol has a melting point of 150° C., while its unsaturated esters are liquid at body temperature, it may be that these unsaturated esters occur on this account ; but at this stage the somewhat conflicting evidence would make conclusions premature.

† BLOOR. *J. Biol. Chem.*, 1915, **23,** 317 ; 1916, **24,** 447.

Post-absorptive blood fat in the case of some animals consists of phosphatide and cholesteryl esters, with very little glyceride, and in this case it is found that the fatty acids of the cholesteryl esters have a higher iodine value than do those of the phosphatide.* The significance of this has yet to be established.

Sterol Metabolism. The metabolic fate of cholesterol and the other sterols is poorly understood at the present time. Cholesterol can be synthesised in the body † and is a constituent of all cells. It is absorbed from the intestine, provided there is sufficient fat in the diet, and the absorption depends also, of course, on the presence of bile. Plant and some other sterols are absorbed poorly, if at all, from the alimentary tract. Bile always contains cholesterol, and the excretion of sterol in the fæces is largely in the form of coprosterol. Just as fatty acids are converted to neutral fat during absorption, so cholesterol is also in part esterified with fatty acids. The ability of the animal to destroy cholesterol appears to be limited, because if 1 per cent. of cholesterol is present in the diet of rats or rabbits, large quantities are deposited in the different organs, mainly in ester form, and intense fatty livers in which enormous quantities of glyceride also occur may be produced by such means. Further investigation of this problem may have clinical significance. Deposition of cholesterol in the tissues seems to be general, although brain is an exception. In such experiments as these part of the cholesterol is, however, oxidised to unknown compounds. Various bile acids which are being continuously formed are almost certainly derived from cholesterol, as are the sex hormones.

4. CARBOHYDRATE METABOLISM

The Blood Sugar

The carbohydrates present in the body consist of the sugar in the blood and tissue fluids, and the glycogen stored in the tissues. All the carbohydrates in an ordinary diet are ultimately transformed in the alimentary tract into glucose, fructose and galactose. These three, together with mannose, are utilisable from the blood, and conversion into glucose takes place in the body. Glucose is certainly present in the blood ‡ (60–150 mg./100 ml. in man), but whether it is the only simple carbohydrate there is not definitely settled ; no others have so far been isolated from ordinary blood. In the fœtus, however, fructose may be present and account for one-third of the sugar (sheep).

Accurate determination of sugar in the blood is difficult ; blood contains reducing substances other than sugars which may be equivalent to no less than 27 mg./100 ml. of glucose,* but when the same method is used the error due to "non-sugar" substances is constant for a given species, and when it is deducted from the total "apparent glucose," the "true glucose" is obtained. In clinical work, results are often given in terms of apparent glucose, and are 4–30 mg. too high, according to the method of estimation used. The non-sugar reducing substances (mainly glutathione and thioneine) are principally contained in the corpuscles, 100 ml. of which contain 47 mg. (expressed as glucose), while plasma only contains 10 mg./100 ml.† In consequence of this, the corpuscles in normal blood have often been stated to have a glucose concentration 1·1 times that of serum, whereas in fact the ratio is only 0·77.

* BLOOR. *J. Biol. Chem.*, 1924, **59**, 543 ; CHANNON and COLLINSON. *Biochem. J.*, 1929, **23**, 1212.

† CHANNON. *Biochem. J.*, 1925, **19**, 424.

‡ WINTER. *Biochem. J.*, 1930, **24**, 851.

The glucose of the blood plasma is in equilibrium with that in the tissue fluids. Although the body only has, say, 2·5 l. of blood plasma, which would contain about 2·5 g. of glucose, the tissue fluid amounts to about 15 l., and so represents a considerable store of glucose—at least 15 g. Consequently if glucose is suddenly added to the circulating blood, as by intravenous injection, the blood sugar is not raised so much as might be expected, since, after a few minutes, glucose has diffused out into the tissue fluid until equilibrium is reached. If, for instance, 50 g. of glucose were given intravenously, the blood sugar would not rise to 1 per cent., but only to about 0·35 per cent. Conversely the withdrawal by the tissues of 2 g. of glucose would not cause the blood sugar to disappear, but would scarcely lower it appreciably.

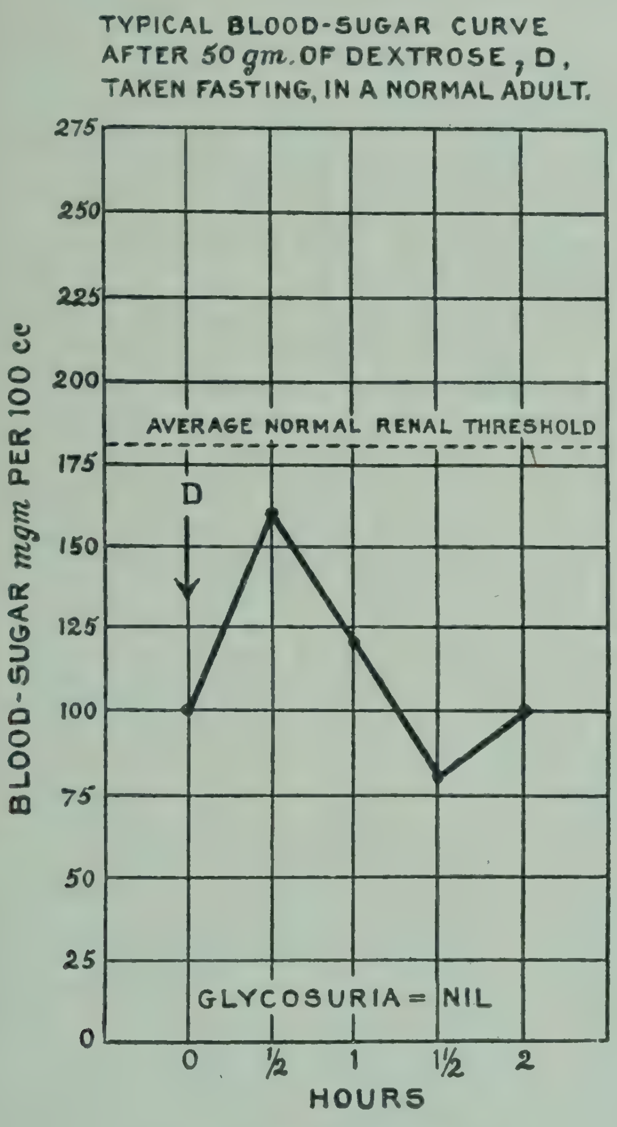

Fig. 589. (Harrison.)

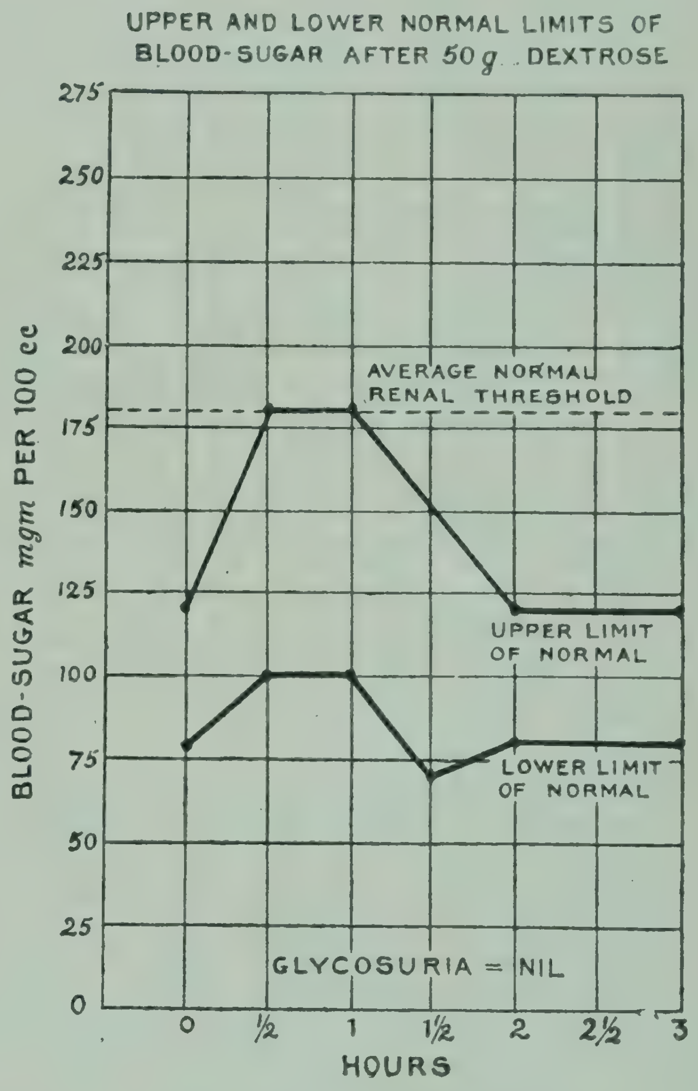

Fig. 590. (Harrison.)

The sugar-values in Figs. 589 and 590 are for total reducing substances, as usually determined for clinical purposes. True glucose figures are 20–30 mg. lower.

During the absorption of a large carbohydrate meal, considerable quantities of monosaccharides enter the blood, and the amount of sugar in the blood is increased. When the absorption is rapid, as, for example, after giving 50 g. of glucose to a fasting person, the systemic blood sugar is, in fact, raised for a while to about double the fasting level; the portal blood sugar is higher still, and runs closely parallel with the systemic blood sugar. This procedure of giving glucose and estimating the blood sugar at half-hourly intervals for the next two or three hours is called the *glucose tolerance test.**

---

* Somogyi. *J. Biol. Chem.*, 1927, **75**, 33; Herbert and Bourne. *B.M.J.*, 1931, i., 94.

† Somogyi. *J. Biol. Chem.*, 1928, **78**, 117.

For this purpose the fasting level of the blood sugar is determined ; it is usually from 60 to 90 mg./100 ml. (true sugar). Then 50 g. of glucose dissolved in water is taken by the mouth. Samples of blood are drawn each half hour for three hours, and their sugar content determined. Within thirty minutes after taking the glucose the true sugar will be found to have risen to a level not usually exceeding 150 mg./100 ml. (Figs. 589, 590) ; in one hour the amount has begun to fall, and at the end of one and a half to two hours the blood sugar has returned to normal again, or it may be even a little below (Fig. 589). The " blood sugar curves " so obtained do not vary greatly in normal persons, and are of considerable value clinically in investigating disorders of carbohydrate metabolism, such as diabetes. It is usual to test the urine for glucose at intervals after taking the glucose ; none should be present. If an ordinary meal containing insoluble carbohydrates capable of digestion, such as starch, be taken instead of glucose, the rise is of slightly longer duration, owing to the relatively slow formation and absorption of the products of digestion (Fig. 591).

It is important to note that although such alterations of the blood sugar occur, these are normally never very great. There is a normal range for each species. In ruminant animals the level is low and the range narrow, *e.g.* for sheep, 30–60 mg./100 ml. ; for most other mammals about 70–150 mg./100 ml. This is because there is a well-controlled means for regulation of the blood sugar concentration, *i.e.* of the sugar available to the tissues. Even during prolonged starvation glucose does not disappear from the blood, nor even fall notably below the amount present after a fast of only a few hours. Conversely, even after the heaviest carbohydrate meal, the systemic true blood sugar in normal subjects does not rise above about 150 mg./100 ml.

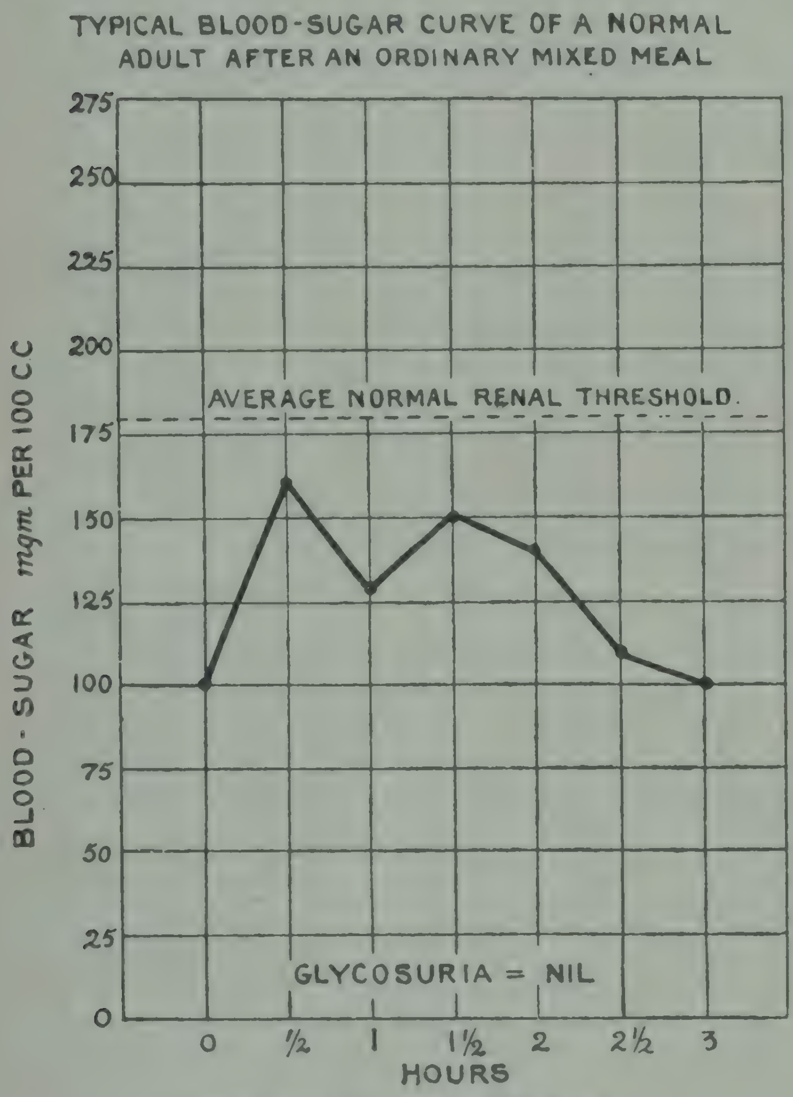

FIG. 591. (HARRISON.)

This relatively steady content of the blood sugar depends on an adjustment of the rates at which sugar enters and leaves the blood stream. If the blood sugar remains constant, it is because, like the water level in a tank, the rates of inflow and outflow are equal. If one is greater than the other, the level must rise or fall *continually* until they again become equal. Under normal conditions the regulating mechanism is " set " to a true glucose level of about 70 mg./100 ml., but under abnormal conditions it may be set at higher or lower levels ; when this is the case we cannot infer that the rates of entry or exit of glucose have undergone any prolonged change—all we can say is that the regulation is set at a higher or lower level.

The following scheme summarises briefly the sources of gain and loss of sugar to the blood :—

---

* *v.* HARRISON. "Chemical Methods in Clinical Medicine." (Churchill.) 1947, p. 133.

Gain.	*Loss.*
From absorbed sugar.	Removed by diffusion into tissue fluid.
From liver glycogen.	Destroyed in blood (glycolysis).
Added by diffusion from tissue fluid.	Removed by liver and other tissues.
	Removed by excretion.

The blood sugar can arise directly from two sources only, viz., from absorbed carbohydrate or from liver glycogen. In the fasting animal the only direct source of blood sugar is the glycogen of the liver.

One method by which glucose may be removed from the blood and tissues is by *glycolysis.* This is due to the action of enzymes by which the glucose is converted into lactic acid. The enzymes are present in the leucocytes, and also in various tissues. The red cells contain diphosphoglycerates and adenosine triphosphate, both of which can yield phosphate ions.

A first stage in glycolysis is brought about by the enzyme *hexokinase,* which catalyses the reaction :—

Glucose + adenosine triphosphate ⟶ glucose (6) phosphate
+ adenosine diphosphate

the subsequent stages being as in the formation of lactic acid from hexose phosphate derived from glycogen (*v.* p. 142). Glycolysis occurs in the circulating blood, particularly in its transit through the lungs,* and accounts for the constant presence of lactic acid in the blood. The glycolysis in shed blood may be prevented by the addition of small amounts of sodium fluoride.†

Sugar is constantly being removed from the circulating blood for use by the cells of the tissues. Hence we find that the venous blood from most parts contains less glucose than is present in the arterial blood, the difference being usually 4–5 mg./100 ml.‡ Since the sugar concentration of the arterial blood is approximately constant, it follows that, even in starvation, glucose must be regularly added to the blood at about the same rate as that at which it is removed. When glucose is being absorbed from the alimentary canal, much of it is rapidly removed from the blood, some of it being burned and some deposited in the form of glycogen in the tissues. Nevertheless, it is not usually removed quite as rapidly as it enters, so that the systemic blood sugar does show a slight rise ; this tends to bring about a still faster rate of removal, so that by the time the blood sugar content has reached 150 mg./100 ml. deposition and combustion keep pace with absorption. In this way many normal persons can dispose of 200 or 300 g. of carbohydrate at a meal. Should the rate of removal be unable, however, to keep pace with the rate of absorption into the blood, or, should glucose be *rapidly injected* into the blood stream, then the excess of glucose is removed from the blood stream by excretion by the kidneys, and appears in the urine, a condition called *glycosuria.* When sugar is excreted in the urine its concentration therein is always much greater than that in the blood ; if the sugar in the blood amounts to, say, 400 mg./100 ml., the urine may contain 5 or 6 per cent. of glucose.

Glucose taken up from the blood by the tissue cells may suffer one of three fates : combustion, conversion to glycogen, or conversion to fat. The last-named process, when carbohydrate metabolism is normal, perhaps plays a larger part in disposing of glucose than has been supposed. By the use of isotopes it has been shown § that in a particular instance, in rats, of ingested glucose, only 3 per cent. is converted to glucose, while 30 per cent. goes to production of fatty acids, most of which are then oxidised. Conversions to glycogen and oxidation are considered below.

† Lovatt Evans. *J. Physiol.,* 1922, **56,** 146.

‡ Somogyi. *J. Biol. Chem.,* 1948, **174,** 189.

§ Stetten. *J. Amer. Med. Assoc.,* 1946, **132,** 373

Although the body only stores about one day's supply of carbohydrate, lowering of the blood sugar beyond a certain level cannot be effected by complete deprivation of food, however prolonged. This means that the starving animal is able to produce blood sugar from some source within the body. The most readily available source is the glycogen store, especially that in the liver, and this is first called upon in starvation. Yet, even after prolonged starvation, the liver is found to be not quite free from glycogen, though the amount present in it may be only 0·20 per cent. or less ; the muscle glycogen likewise never disappears.

If for any exceptional reason the true sugar content of the blood be brought much below 50 mg. per 100 ml., severe symptoms result, and ultimately, if the fall continues, death occurs. This condition of *hypoglycæmia* may be brought about by the action of insulin. In the rabbit an injection of insulin sufficient to cause reduction of the blood sugar to about 5 mg./100 ml. causes severe convulsive seizures, followed by coma, fall of temperature and death from respiratory failure. In man, subjective symptoms are induced when the blood sugar falls to 55 mg./100 ml. These symptoms are hunger, a sense of fatigue and anxiety, vasomotor phenomena, such as pallor or flushing, and general sweating. As the blood sugar falls still further, mental disturbances, delirium and finally profound coma supervene. By that time the true blood sugar may be down to 5 mg./100 ml. (total reducing power = 30 mg. glucose/100 ml.). These serious consequences show that a certain minimal quantity of glucose must always be present in the blood and tissues for the maintenance of the normal functions of the central nervous system.

STORAGE AND WITHDRAWAL OF GLYCOGEN

Liver Glycogen. It was discovered by Claude Bernard * that the blood of the hepatic veins nearly always, but particularly in fasting animals, contains more sugar than is present in the blood taken simultaneously from the portal vein, *i.e.* the liver adds sugar to the blood which passes through it. That the liver can produce glucose he showed by a simple experiment :—

The liver removed from an animal and kept warm for some time was found to contain considerable amounts of glucose. He next performed the classical experiment with the "washed liver" † ; a liver was removed from an animal immediately after death and its vessels washed out with ice-cold water or salt solution ; the tissue was then cut up and thrown into boiling water, in which it was thoroughly ground up. The extract, after separation of the coagulable proteins, contained practically no sugar—hence glucose as such was not stored in the liver. The aqueous extract, however, contained a substance precipitable by alcohol, to which he gave the name of *glycogen*, *i.e.* sugar-former. The large amount of sugar found in the liver which had been kept warm after removal was due to conversion of the glycogen into glucose by the action of enzymes present in the liver. That it is an enzyme action is proved by the fact that fresh liver may be dehydrated with alcohol, dried and powdered, and kept for months in this condition without any alteration occurring in its glycogen. If, however, the dried powdered liver be moistened and allowed to remain at the temperature of the body for some hours, its glycogen disappears and the equivalent quantity of glucose takes its place ; this change does not occur if the liver is first boiled.

In the conversion of glycogen to glucose three enzymes are concerned (*v.* pp. 95, 97), viz. *phosphorylase*, *phosphoglucomutase* and *hexokinase*, which catalyse reactions as shown on next page :—

---

* BERNARD. *Mém. Soc. Biol.*, 1849, 121 ; *Compt. Rend.*, 1850, **21**, 571.
† BERNARD. *Compt. Rend.*, 1855, **41**, 461.

(1) $\text{glycogen} + \text{phosphate} \xrightleftharpoons{(\textit{phosphorylase})} \text{glucose-1-phosphate}$

(2) $\text{glucose-1-phosphate} \xrightleftharpoons{(\textit{phosphoglucomutase})} \text{glucose-6-phosphate}$

(3) $\text{glucose-6-phosphate} + \text{A.D.P.} \xrightleftharpoons{(\textit{hexokinase})} \text{glucose} + \text{A.T.P.}$*

By reversal of the first reaction, glycogen can be produced from glucose-1-phosphate.†

Glycogen (*v.* p. 38) is a white, tasteless and odourless polysaccharide of the empirical formula $C_6H_{10}O_5$. Like starch, it resists the action of boiling potash,‡ but is hydrolysed by acids, or by amylase, into dextrins, maltose and finally glucose. There is no evidence, however, that tissue glycogen is broken down in that way. Its aqueous solution with iodine gives a brownish-red colour, and it is precipitated by 55 per cent. alcohol, strong acetic acid, and various other precipitants which abstract water.

Glycogen may be estimated by Pflüger's method § ; the principle of the method is that weighed samples of the tissue are dropped into their own volume of 60 per cent. boiling potash solution and then heated on a water-bath for one to four hours. This dissolves practically everything in the tissue ; alcohol is then added in amount to make up to 70 per cent. ; the precipitated glycogen is dissolved in water, reprecipitated by alcohol, and finally hydrolysed for three hours in 2·2 per cent. HCl. The glucose thus formed is then estimated, and the results usually expressed in terms of glucose.

Liver Glycogen Formation. If an animal is fed for twelve to twenty-four hours previously on a diet rich in carbohydrates, glycogen may be present in amount up to 12 per cent. or more of the weight of the fresh liver. Glycogen can also be formed on a diet of proteins and the liver can continue to supply sugar to the blood on a diet which includes only proteins and fats. It is doubtful whether a normal existence is possible in man in the total absence of carbohydrates from the food, though in the Eskimos the amount of carbohydrate consumed is small in comparison with the fats and proteins. It does not seem to be possible for the liver to *store* glycogen out of fats. In experiments on feeding with fats it is found that, if fats be administered after the liver has been nearly freed from glycogen, although the liver may store up fats, it does not store up any glycogen. This may be because fat is only slowly converted, so that all the glucose formed from it would be required for use forthwith instead of being stored as glycogen.

The glycogen of the liver represents a reserve material, and is the first to be called upon to meet the increased needs of the tissues during functional activity, such as muscular work or greater heat production. If an animal be starved, the glycogen quickly diminishes in the liver, although, even at the end of ten or twelve days' complete deprivation of food, small traces of glycogen may still be found in this organ. If starvation be combined with hard work, strychnine convulsions, or exposure to cold, the liver glycogen is lowered more quickly. On account of the importance of glycogen as a reserve material, it is stored up in almost all growing tissues, *e.g.* in the placenta during a certain period, in fœtal muscles, in yeast, in oysters, and in the muscles of the body generally. In fœtal muscles it may amount to as much as 40 per cent. of the total dried solids.

It is principally to Claude Bernard that we owe the conception of the *glycogenic function of the liver* which is still current. According to this, the liver cells continually form glycogen, which they can manufacture from a variety of materials. The glycogen so formed may either remain and accumulate in the liver cells, or it may be converted into glucose, and pass out into the blood. Both processes, manufacture of glycogen and conversion of glycogen to glucose, are usually in operation together; if glycogen formation predominates over breakdown, the glycogen store in the liver increases, if the formation of glucose predominates, the store is depleted and formation of glucose ultimately slows down. The balance between the formation and breakdown of glycogen in the liver is determined, on the one hand by the supply of carbohydrate available, whether derived from ingested carbohydrate or by new formation, and on the other hand by the demand for carbohydrate by the tissues of the body.

§ PFLÜGER. Art. "Glycogène" in *Richet's Dictionnaire de Physiol.*, 1907, Vol. 7, [G]228.

In fasting, the blood will have a lowered content of glucose. The liver now, by the activity of its enzymes, rapidly converts its glycogen into glucose—a process called *glycogenolysis*—and this glucose is carried away in the blood of the hepatic veins which now contains much more glucose than that in the portal vein or general circulation. At the same time, new formation (*glyconeogenesis*) of glycogen from protein and fat is accelerated so as to supply the constant demand for blood sugar. In this way, the liver acts as a storehouse, in which carbohydrate, much or all of which it has made, can be temporarily stored and brought out as required.

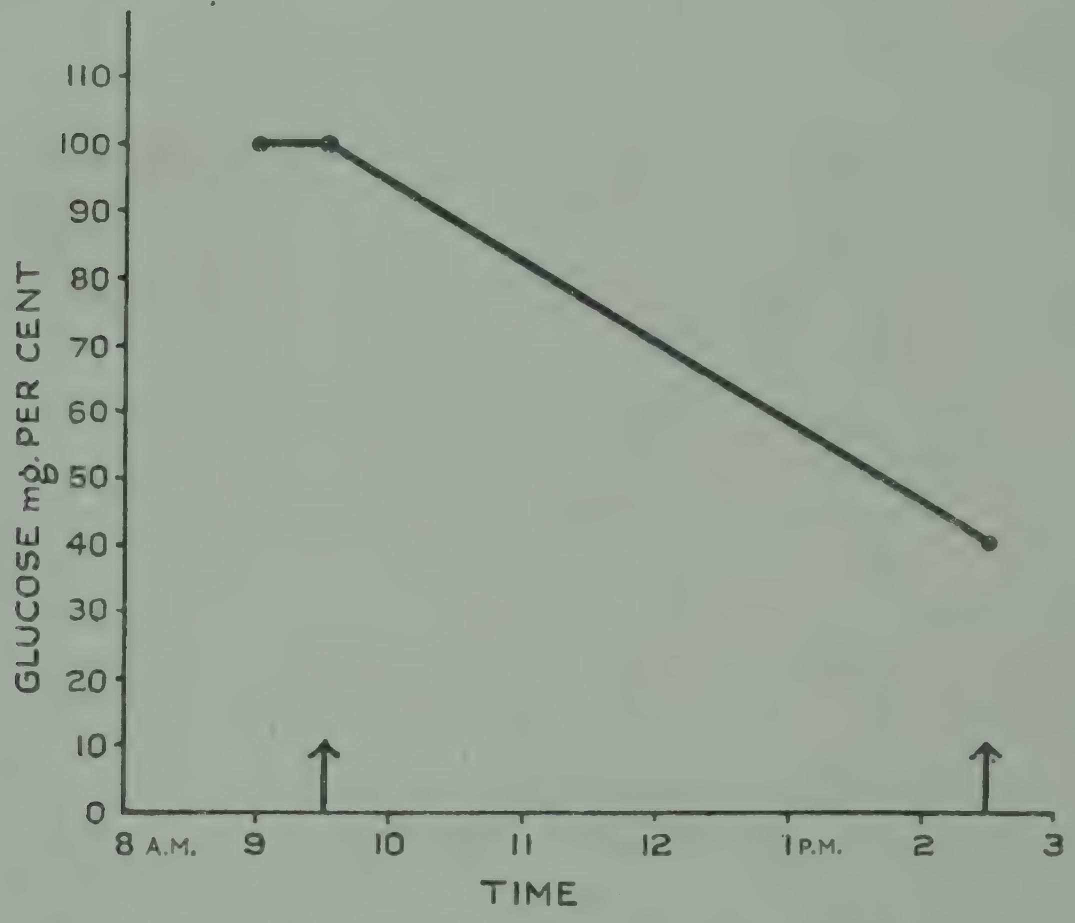

Fig. 592. Blood glucose concentrations in hepatectomised dogs (average of 12 expts.) Liver removed at first arrow; animal moribund, with hypoglycæmic sugar level at second arrow, five hours later. (MANN and MAGATH, 1923.)

The liver is giving out glucose to the blood most of the time, though not always at the same rate. In the fasting animal the liver is the sole source of blood sugar. After removal of the liver the blood sugar rapidly falls (Fig. 592), and soon the animal passes into hypoglycæmic convulsions, but this may be prevented by constant infusion of glucose at a proper rate; when the liver is present the glucose of the blood is kept up during fasting by conversion of liver glycogen to glucose at the same rate. When a carbohydrate meal is given, absorbed glucose enters the portal blood; the liver does not now add so much glucose to the blood, and if absorption is rapid enough it may add none at all. In fact, if the blood sugar is greatly raised, as by intravenous injection of glucose, the liver may actually take up sugar from the blood (Fig. 593), though this does not easily occur. The liver responds to altered blood sugar level in such a way as to tend to restore this to normal, and acts like a regulator "set" to maintain a constant blood sugar concentration: by this homoiostatic response the blood sugar is virtually self-regulating. At blood sugar levels of about 90–100 mg./100 ml., production and liberation of glucose are about equal, provided that the liver is "set," by endocrine factors, to regulate to that level. It is probable that this regulating function of the liver is dependent upon the law of mass action.

After heavy carbohydrate feeding, glycogen accumulates rapidly in the liver, and this led to the belief that the absorbed carbohydrate has been directly stored in the liver as glycogen. This is strengthened by the demonstration that, *in vitro*, glucose-1-phosphate can be converted to glycogen by phosphorylase of liver. But this simple explanation does not always suffice, because the hepatic vein blood usually contains more sugar than the portal blood, though the excess is much smaller during the absorption of a carbohydrate meal.* What happens under these circumstances is simply that more of the glycogen produced by glyconeogenesis remains in the liver, and less of it is converted into blood sugar. At higher blood sugar levels, all the glycogenetic glycogen is stored, and at still higher levels blood sugar is taken up by the liver and stored as glycogen. One substance, viz. lactic acid, is, however, regularly removed from the blood as it passes through the liver, and is converted by the liver into glycogen.

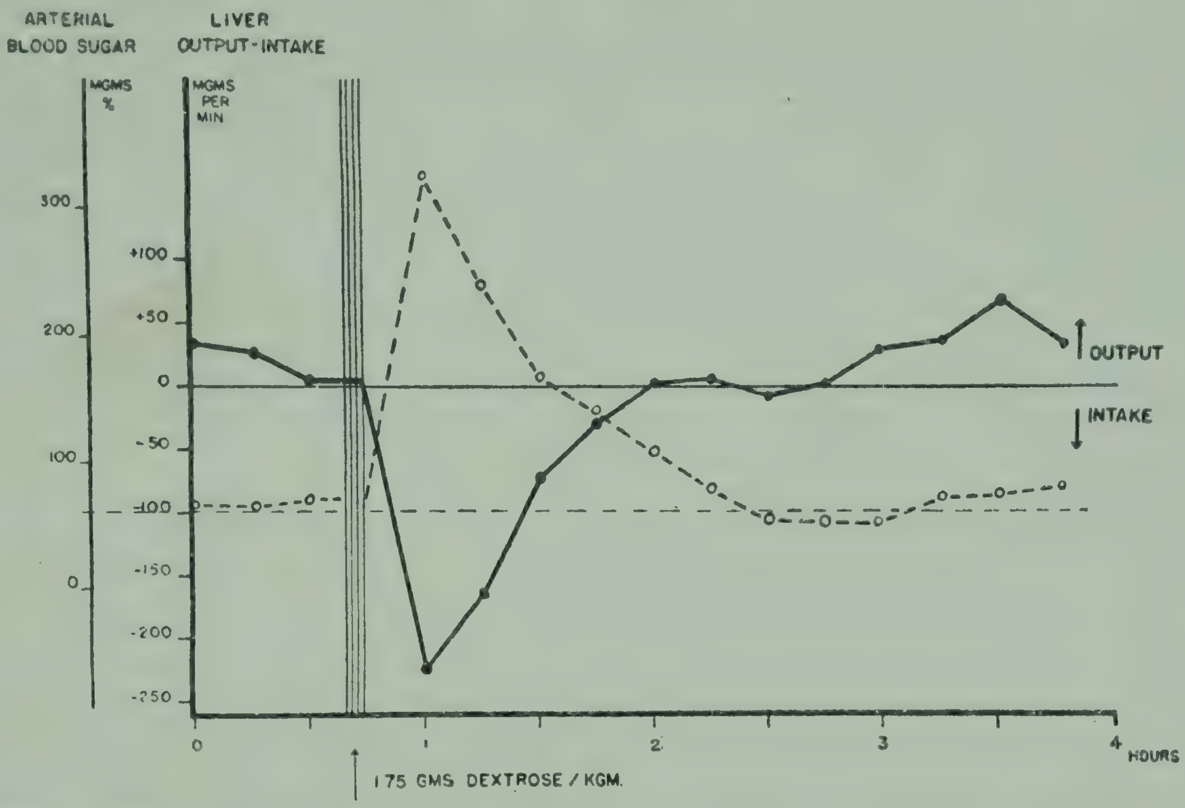

FIG. 593. Arterial blood sugar concentration (disçontinuous line), and liver output or intake of sugar (continuous line) before and after intravenous injection of glucose. Except when arterial sugar is high, the liver is giving out sugar. (SOSKIN *et al.*, 1939.)

When a liver is perfused with blood containing glucose, no glycogen is deposited, but if lactic acid, or fructose, is added instead of glucose, then this is taken up and glycogen is formed.† Probably, therefore, glucose must first be converted to something else before the liver can form glycogen from it. The liver, however, can, and does, convert pyruvic acid, glycerol, dihydroxyacetone, methyl glyoxal, and some amino-acids into glycogen. Hence the liver glycogen may not only be formed after carbohydrate ingestion, but it may also arise from protein and perhaps from fat, by synthetic processes which occur in the liver.

The glycogen content of the liver, therefore, represents the balance between glycogen formation from these various sources, and glycogen breakdown to glucose, and both these processes are continually in operation. The rate at which glycogen is formed in the liver depends mainly on the concentration of sugar in the blood ; the higher the blood sugar the less need there is for the liver to supply it, and the greater the amount of glycogen retained in the liver. When glucose is given and the liver glycogen is increased, it does not necessarily follow that this represents storage as glycogen of the absorbed glucose. Some of the accumulated liver glycogen arises by processes of glyconeogenesis and is retained by the liver, while the absorbed glucose is used by the tissues, instead of these drawing upon liver glycogen.

---

* TSAI and YI. *Chinese J. Physiol.*, 1936, **10**, 105.

† LUNDSGAARD, NIELSEN and ORSKOV. *Skand. arch. Physiol.*, 1936, **13**, 296.

There is some evidence, from experiments with C. isotopes, that carbon dioxide can be incorporated in the glycogen molecule in the liver, but not in muscle, when glucose is converted to glycogen ; such a synthesis would involve a partial oxidation of the glucose, and subsequent assembly of fragments, together with CO_2, to build up glycogen*.

There are various ways by which the process of glycogen storage in the liver may be studied. One of the simplest and most direct of these is the method introduced by Cori and Cori.† They showed that the livers of different white rats of a standard, inbred strain, contain equal amounts of glycogen when the animals are all treated identically. If the animals fast for twenty-four hours the liver glycogen is reduced to about 0·2 to 0·5 per cent. When a sugar solution, *e.g.* glucose, is given in sufficient amount, it is quickly absorbed, and at a constant rate which, as we have already learnt, is characteristic of the particular sugar. Thus, three batches of fasted rats may be taken ; to the first is given by stomach tube some water, to the second the same amount of water containing glucose, and to the third water and a similar weight of fructose. Then animals in each batch are killed each hour and the glycogen in the livers determined. It was found that when 1 to 2 g. of sugar was given per 100 g. of body weight, the maximum amount of liver glycogen was formed after four hours. After glucose the liver contained 5·3 per cent., and after fructose 5·7 per cent. glycogen. Different sugars, however, are absorbed at different rates, *e.g.* in the four hours 1·06 g. of the glucose and 0·540 g. of the fructose was absorbed per 100 g. of rat, and when the glycogen formation is recalculated, taking this into account, it was found that in four hours the amounts of glycogen deposited represented 18 per cent. of the absorbed glucose and 38 per cent. of the absorbed fructose.

Glycogen Storage in Muscle. Skeletal muscle contains from 0·05 to 1·0 per cent. of glycogen, which is formed from the blood sugar, *viâ* glucose-6-phosphate and glucose-1-phosphate by reversal of the reactions given on p. 957. The deposition of glycogen is probably always going on to replace the glycogen continually being used up by the muscle. Hence the venous blood going away from a muscle contains less glucose than the arterial blood. Though normally muscle can take up blood sugar and convert it into glycogen, even *in vitro*, this process happens much more rapidly when insulin is present in excess in the circulating blood. Although, as we have already seen, the muscles *can* transform *d*-lactic acid into glycogen, the process is a roundabout one (*v.* p. 142), and they appear able to do this much less rapidly than the liver, so that if lactic acid is set free into the circulation from the muscles during muscular exercise, it is probably mostly converted into glycogen by the liver ; the muscles then restore their glycogen from the blood sugar, which is replenished either by absorbed glucose from the alimentary canal or by breakdown of liver glycogen.

Though the muscles contain a smaller percentage of glycogen than is present in the liver, the total amount of muscle in the body is so great that the whole musculature usually stores much more glycogen than the liver. Thus, in a well-fed man of average weight the liver can perhaps hold 200 g. of glycogen, while the muscles might hold 350 g. of glycogen ; in the fasting individual the muscle glycogen would not be very greatly reduced, whereas the total liver glycogen might be as low as 10 or 20 g. It is evident, therefore, that the liver glycogen is much more mobile than the muscle glycogen, and even if the latter is considerably reduced during exercise it is soon replenished, largely at the expense of the liver glycogen.

Withdrawal of Glycogen from Liver and Muscles. It is a curious fact that glycogen is removed from liver and muscles in different forms ; it leaves the liver in the form of glucose, and the muscles in the form of lactic acid, and these may enter the blood stream. The explanation is that different enzyme systems are concerned in the two cases. In the liver, as we have seen, three enzymes between them hydrolyse the glycogen to glucose. In muscle, on the other hand, we have to deal with the complex system of enzymes capable of converting glycogen first into pyruvic acid and then into lactic acid (p. 142).

---

* Solomon *et al.* *J. Biol. Chem.*, 1941, **140,** 171.

† Cori and Cori. *J. Biol. Chem.*, 1926, **70,** 577.

The liver, then, can convert lactic acid and other substances, including glucose, into glycogen, and glycogen then into glucose ; muscle can convert glucose (or lactic acid) into glycogen, and the glycogen into lactic acid. These specialised conversions render possible an interesting cycle of changes, by means of which muscle and liver glycogen become virtually interchangeable in the body. This is seen most clearly in the action of adrenaline in certain animals, such as the rat. If rats fasted for twenty-four hours be given a subcutaneous injection of 0·2 mg. adrenaline per 100 g. of body weight, they may excrete much more glucose than could have been derived from all the liver glycogen. Yet it is found that the liver glycogen, which at first fell, at the end of three hours has *risen* from an average of 6 mg. per 100 g. of body weight to 42 mg. per 100 g. body weight, but the muscle glycogen has *fallen* from 128 mg. to 71 mg. per 100 g. body weight.* What happens under these conditions is that the adrenaline for some reason causes conversion of muscle glycogen to lactic acid, the concentration of which in the blood is at first considerably increased ; the lactic acid is then taken up by the liver and converted into liver glycogen (Fig. 594). This, "the Cori cycle," is represented thus :—

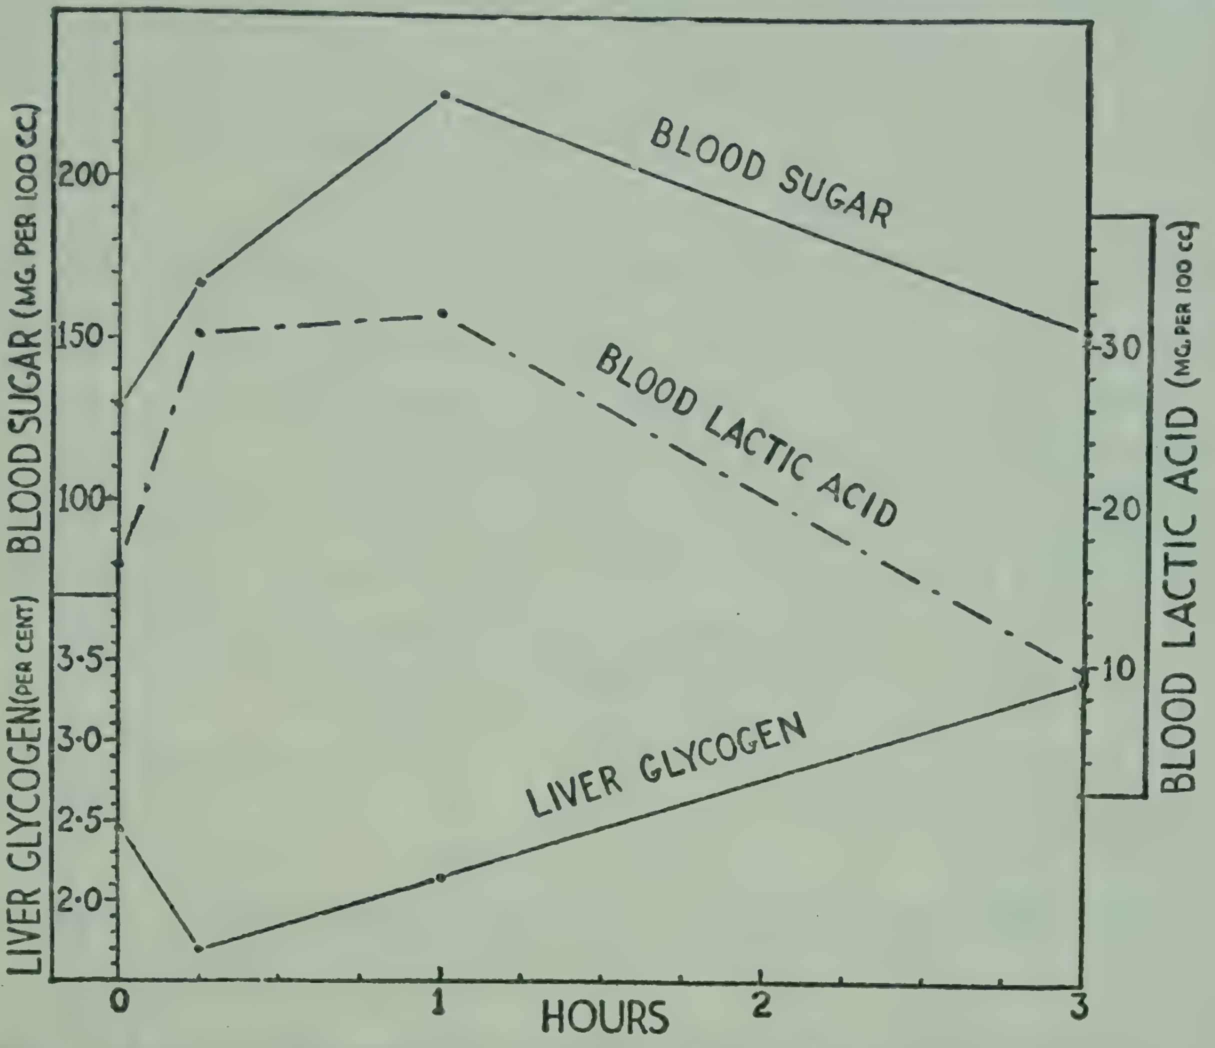

FIG. 594. Effect of subcutaneous injection of adrenaline on blood sugar, blood lactate and liver glycogen of the rat. Adrenaline 0·2 mg./100 grammes given at 0. (THORPE'S *Biochemistry*, from data by CORI and CORI, *J. Biol. Chem.*, 1930, **86**, 375.)

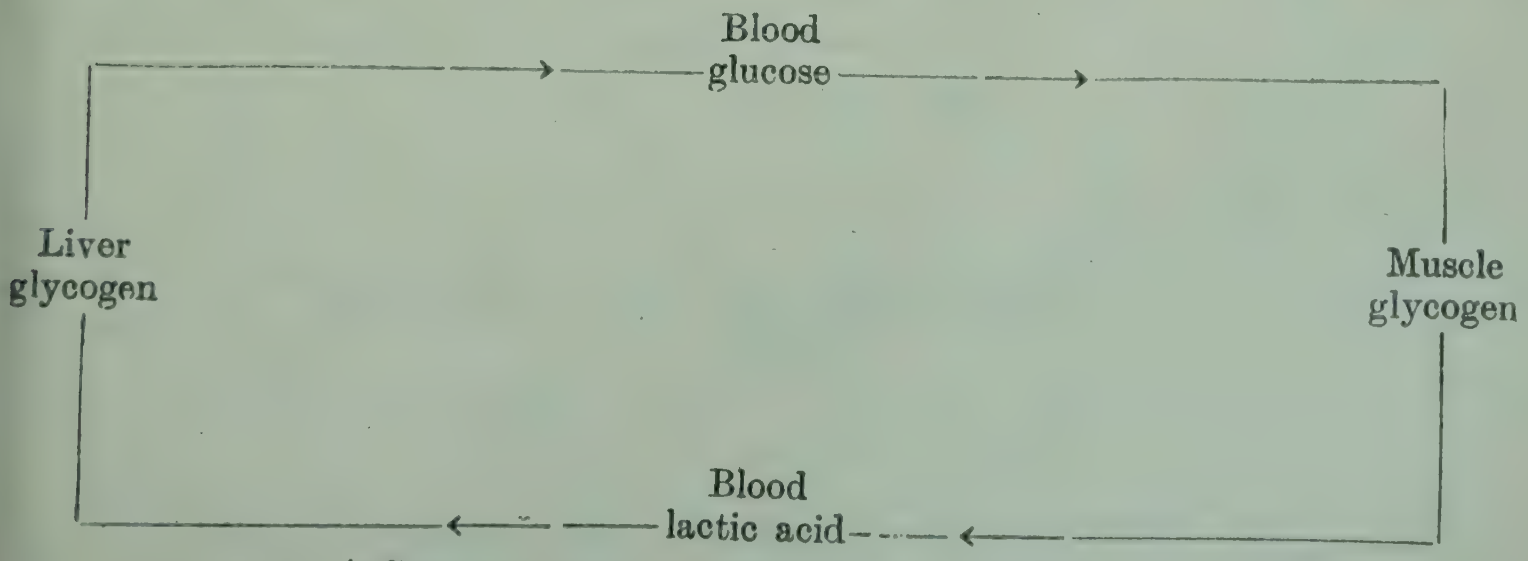

---

* CORI and CORI. *J. Biol. Chem.*, 1928, **79**, 309.

After sixteen hours the increased liver glycogen has disappeared again.

The principal conditions under which glycogen is withdrawn from muscle (either by complete oxidation, or as lactic acid) are under the action of severe exercise or of adrenaline.

The liver converts its glycogen into glucose under a great variety of conditions, most of which can be brought together as being due to the action upon the liver, either of nervous influences, or of adrenaline circulating in the blood. The breakdown of liver glycogen by the action of adrenaline or by nerve stimulation may be inhibited by the action of insulin. This does not imply, however, that insulin by itself might be able to lead to formation of liver glycogen.

INTERMEDIARY METABOLISM OF CARBOHYDRATE

We have already studied the inter-relations of carbohydrates, such as glucose and glycogen, in the body (pp. 38, 97), and the chemical relationships of substances closely connected with carbohydrates (pp. 31, 34). We have also considered the biochemical changes concerned in the utilisation and ultimate oxidation of carbohydrates in muscle (pp. 142, 143), and the nature of oxidising enzymes (pp. 98, 99), and tissue oxidations in general (p. 745).

It will only be necessary at this stage to bring all these data together by way of recapitulation. The following diagram does this in outline.

FIG. 595. Summary of the metabolic fate of glucose and glycogen. (YOUNG. *Sci. Prog.*, 1948, **141**, 13.)

The diagram shows by what chemical stages glucose and glycogen ar interconvertible, how glucose can be converted into pyruvic acid, and how th latter substance is either oxidised to CO_2 and water in the tricarboxylic cycle (p. 143) or alternatively reduced to lactic acid. The cytochrome cycle on the right is here represented as a means by which hydrogen derived from dehydrogenase actions is ultimately oxidised by oxygen, as described on p. 747.

The importance of pyruvic acid as a substance in common in the intermediary metabolism of carbohydrate, protein and fat has already been mentioned. It should also be noted that it can be converted into either oxaloacetic acid or α-ketoglutaric acid, which enter into the tricarboxylic cycle.

HYPERGLYCÆMIA AND GLYCOSURIA

Normal urine contains a small proportion of reducing substance, but at least half of this is not glucose. The term *glycosuria* is not employed unless glucose appears in quantities large enough to give a reaction with Fehling's solution. Such a condition may easily be brought about by the injection of glucose, subcutaneously or intravenously. This causes a high blood sugar, or *hyperglycæmia*. Cane sugar or lactose, introduced in the circulation, is quantitatively excreted in the urine. Glucose, fructose, mannose or galactose, if introduced slowly enough into the circulation, are used up, and glycogen appears in the liver. If, however, the sugar in the blood rises above about 0·18 per cent. (the *renal sugar threshold*), glucose appears in the urine.

The occurrence of glycosuria depends upon two things: (1) the sugar content of the blood; (2) the renal sugar threshold. When glycosuria occurs it means that the blood sugar has risen to a value higher than the renal threshold (normally 180 mg./100 c.c.); consequently, glycosurias may be due to one of two classes of cause: first, to an abnormally high blood sugar; second, to an abnormally low kidney sugar threshold. The latter type, occurring naturally, is called *renal glycosuria*, and has no further interest for us here, apart from the importance of distinguishing between it and other glycosurias which are more serious.

(1) **Alimentary Glycosuria.** Hyperglycæmia may be induced by the administration of large quantities of glucose by the mouth. Glycosuria from this cause in normal people, however, is largely a figment of the imagination, since the body can dispose of the excess of glucose as fast as it is absorbed; even when 500 grammes of glucose is taken no sugar may be passed.* In certain individuals the power of utilising glucose may be deficient, so that prolonged hyperglycæmia and copious glycosuria may be caused by any over-indulgence in carbohydrate food. This condition is revealed by a glucose tolerance test.

(2) **Influence of the Nervous System.** The liver is richly supplied with sympathetic nerves, division of which does not seem to affect the glycogenic function.† Stimulation of them, however (after removal of the suprarenals), produces rapid reduction of the glycogen content of the liver, hyperglycæmia and glycosuria.

(3) **Adrenaline.** The injection of small amounts of adrenaline into the circulation has a similar effect to that of stimulation of the splanchnic nerves.

Asphyxia, the administration of anæsthetics, infective processes, pain, emotion, all cause depletion of liver glycogen, usually with a rise of blood sugar, and often with glycosuria. Most of these factors act by causing a discharge of impulses along the sympathetic nervous system, which include among their effects a liberation of adrenaline into the circulating blood. If the suprarenals are previously removed, these conditions cause a smaller rise of blood sugar and smaller loss of liver glycogen. If the liver is removed no rise of blood sugar is caused in these conditions.

---

* TAYLOR and HULTON. *J. Biol. Chem.*, 1916, **25**, 173; BENNETT and DODDS. *J. Physiol.*, 1925, **59**, Proc. lxiii.

† DONALD. *Amer. J. Physiol.*, 1931, **98**, 605.

Prolonged administration of adrenaline, as by subcutaneous administration, may give different results. This is because the Cori cycle becomes increasingly important, with the result that muscle glycogen is converted first into lactic acid and then into liver glycogen, which at the end may be raised.

(4) **Piqûre Glycosuria.** It was shown by Claude Bernard,* using rabbits, that puncture at a certain spot on the floor of the fourth ventricle was immediately followed by glycosuria. This "piqûre" glycosuria may last for twenty-four hours or more, and is accompanied by hyperglycæmia, which is more evident if the animal has previously been well fed.

It is due to the stimulation of a group of nerve cells from which impulses pass out by way of the splanchnic nerves to the suprarenals and liver. Hence if both splanchnic nerves have previously been divided the hyperglycæmia and glycosuria are much reduced or altogether lacking. The "centre" can be reflexly affected by stimulation of various afferent nerves, such as the vagus, sensory nerves, etc.

Effects somewhat similar are seen when the central nervous system is transected at the level of the superior corpora quadrigemina.† The same condition is seen on removal of the cerebral cortex,‡ or section of the hypothalamus,§ after which operations there is a sustained excitation of the whole sympathetic nervous system.

Piqûre or decerebration causes a large outpouring of sugar into the blood, even in fasting animals, and in these the amount of sugar released may be greater than can be accounted for from the observed reduction of glycogen in liver and muscles.‖ Indeed, in fasting animals, piqûre or decerebration may even produce an increase of liver glycogen, in spite of the large amount of sugar which is excreted. It would seem probable, therefore, that the consequences of piqûre may be three-fold : first, in the well-fed animal a discharge of liver glycogen in the form of excreted glucose ; second, transfer (often only transitorily) of muscle glycogen to the liver, by way of the Cori cycle ; third, in the fasting animal, in addition to the discharge of glycogen from the liver, processes of glyconeogenesis are accelerated in the liver.

(5) **Phlorrhizin Glycosuria.** Phlorrhizin is a glucoside of phloretin from the root cortex of the apple tree. When given suspended in olive oil or propylene glycol, by subcutaneous injection in doses of 1 g. per 10 kg. per day, it gives rise to intense polyuria and glycosuria. The glycosuria is not due to hyperglycæmia. The blood sugar is, in fact, diminished. Phlorrhizin glycosuria is due to an action on the kidney ; the condition resembles renal glycosuria, but the renal threshold is here quite abolished. If cannulæ be placed in the two ureters so as to collect the urine from each kidney separately, and a small dose of phlorrhizin be then injected into the left renal artery, the urine flowing from the left ureter will in two minutes be found to contain sugar, while the urine from the right kidney will not contain any sugar for another five or ten minutes. In the normal kidney, the glucose passing into the glomerular filtrate is all reabsorbed into the blood, in the proximal convoluted tubule, and so does not reach the urine (*v.* Chapter XLVII). In phlorrhizin poisoning the reabsorption fails, and so the glucose, together with considerable water reaches the urine. The action of phlorrhizin is due to its inhibiting the phosphorylation of glucose, which is an essential step in its absorption by the kidney tubules.

Phlorrhizin thus continually drains off sugar from the blood, and the various effects which it produces are consequences of this. As some of the effects closely resemble the phenomena of diabetes mellitus, it was once thought that the fundamental causes were similar, but this is not so.

Because of the lowered glucose content of the blood, the liver produces fresh sugar to take the place of that lost. At first the liver will convert most of its stored-up glycogen, but if a second dose of phlorrhizin be given when the liver may be regarded as nearly free from glycogen, glycosuria is produced as before, and the excretion of sugar can be continued indefinitely by repeated administration of the drug.

So long as sufficient carbohydrate food is given, the loss of sugar does not entail any increase in the destruction of the tissues ; but otherwise the waste of sugar has to be made good at the expense of material other than carbohydrate. The readiest source of the sugar excreted by a starved phlorrhizinised animal is protein, hence there is a connection, though no constant ratio, between the amounts of nitrogen and of sugar excreted. In different experiments this mean G : N ratio varies from 1·0 : 1 to 3·6 : 1.

Glucose administered to a phlorrhizinised dog is practically all recoverable from the urine.[*] The sugar excreted in starvation must be derived largely from the amino-acids of tissue protein. It was shown by Lusk, Embden, and Dakin that the amino-acids now called anti-ketogenic (p. 928) yield glucose when administered to a phlorrhizinised animal. On the other hand, the ketogenic amino-acids give no increase in the output of sugar, but are converted into aceto-acetic acid. The administration of fats to a phlorrhizinised dog is also without effect on the sugar excretion.

Another effect of continued administration of phlorrhizin is fat infiltration of the liver, a result of the carbohydrate starvation. The liver seems to be able to act as a storehouse either of fat or of carbohydrate, so that there is an inverse ratio between the amount of glycogen and the amount of fat stored up in the liver at any given time.

Ketosis. We have seen (p. 947) that, when carbohydrate oxidation is suppressed, the last stages in the oxidation of fats make default, so that the acetone bodies are formed in the liver, accumulate in large quantities in the blood (*ketonœmia*), and are excreted in the urine (*ketonuria*). The appearance of these keto-acids and acetone is spoken of as *ketosis*, and sugar is said to be *antiketogenic*. There is a relationship between the amounts of carbohydrate and fats which are necessary to prevent ketosis. It has been shown that no ketosis occurs when one molecule of sugar is oxidised in the body for each molecule of aceto-acetic acid which may be formed from the fats (or a portion of the proteins) of the food. When the proportion is only 1 to 2, there is always some ketosis, and when the proportion of potential aceto-acetic acid to glucose exceeds 2, the whole excess is excreted as ketone bodies. This relationship is of practical importance in the dieting of diabetics.

Not only does the excretion of ketone bodies involve a loss of energy to the body, but these organic acids require bases for their neutralisation. Their excretion therefore robs the body of available base (acidosis). When the supply of these fails the acids are excreted in combination with ammonia. If the condition of carbohydrate starvation be continued, this mechanism of neutralisation is insufficient, and dyspnœa and coma ensue as the death of the animal approaches. The coma is accompanied by failure of the brain to utilise oxygen.[†]

(6) **Pancreatic Diabetes.** Von Mering and Minkovski[‡] found that pancreatectomy (excision of the pancreas) gives rise to a rapidly fatal diabetes, similar to the severest cases of diabetes in man. The operation is followed almost at once by hyperglycæmia, which may exceed 1,000 mg./100 c.c., and by the appearance of a large amount of sugar, 5 to 10 per cent., in the urine. The glycosuria persists ; if glucose is given it is all excreted ; there is polyuria and thirst, the urinary nitrogen is raised, but there is not,[§] as formerly supposed, a constant G/N ratio during fasting. The respiratory quotient is low (about 0·7) ; acetone bodies are excreted ; liver glycogen almost disappears, and muscle glycogen is much reduced, but the glycogen in the heart is increased ; the glucose uptake of some of the tissues is reduced, as is shown by the slight difference in glucose content between arterial and venous bloods ; the animal rapidly wastes, and finally dies in diabetic coma at the end of a week or so. The condition of diabetes observed under these circumstances has nothing to do with the absence of the pancreatic juice from the intestines, since ligature of the ducts of the pancreas, or grafting the pancreas beneath the skin, does not give rise to diabetes, although these procedures are followed by atrophy of the secretory part of the gland.[||]

We thus see that the pancreas has a two-fold function: the secretion of the pancreatic juice, and an influence, the absence of which is followed by diabetes. Corresponding with this two-fold function, two kinds of structures are present in the gland, the secreting acini and the islets of Langerhans. These latter, though arising in connection with the ducts, are solid masses of cells and have no communication with the ducts. The stainable islet cells may be divided into two varieties,[*][†] which have been given the name of α and β cells, according as their granules are fixed respectively by alcoholic or watery solutions. These cells undergo no alterations when the gland is excited to secrete [‡] pancreatic juice (Fig. 596). On the other hand, if four-fifths of the pancreas be removed, the remaining part may gradually become inadequate to prevent diabetes; and when under these circumstances diabetes supervenes, the granules disappear from the β cells; also, the insulin content of the remnant falls to a very low level.[§] Changes have also been alleged in the islets of Langerhans in fatal cases of diabetes in man.

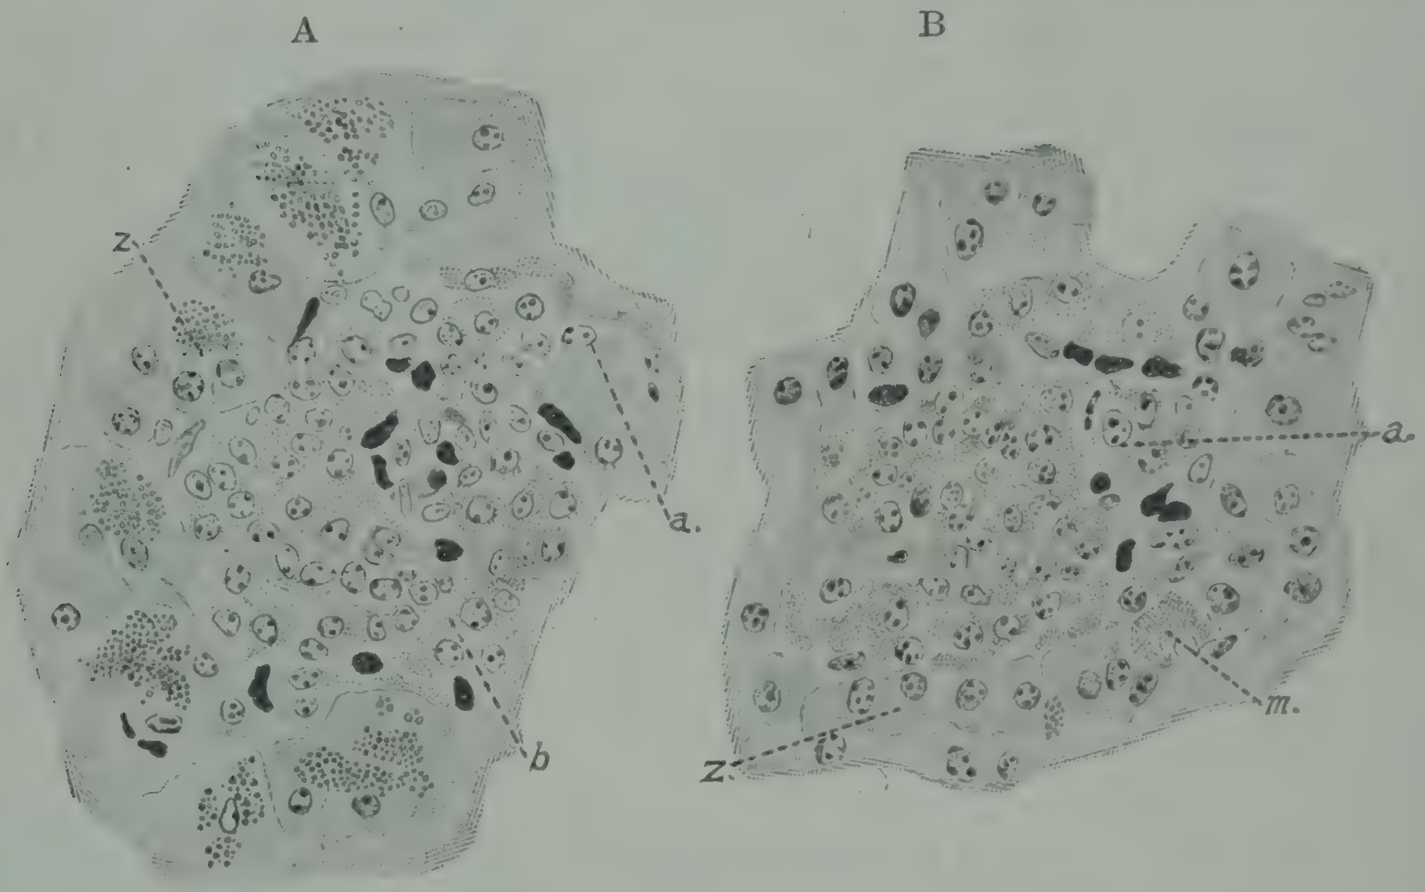

FIG. 596. (A) and (B) show an Islet with the surrounding Tissue in a resting Gland (A) and after Exhaustion with Secretin (B).

In (A) the secreting acini (z) are charged with zymogen granules. In (B) these have entirely disappeared. On the other hand no change is noticeable in the cells of the islet. In the latter the granular cells (m) are the β cells, and the clear hyaline cells are the α cells. (HOMANS.)

If large doses of alloxan (200 mg./kg.) are injected into the circulation there is at first a rise in blood sugar, then a fall, and finally, after eighteen to twenty-four hours, a permanent hyperglycæmia, and the animal becomes very ill. The initial rise of blood sugar is a sympathetic response, the succeeding fall, at six to twelve hours, is due to liberation of pre-formed insulin from the β-cells.[||] These are damaged within a few minutes of the injection, and do not recover; hence the permanent hyperglycæmia; it is found that the β-cells in the islets of Langerhans have degenerated, and a state of diabetes, equivalent to a partial pancreatectomy, results.[¶]

There are two classical theories of the nature of the diabetic state; these attribute the condition respectively to non- (or under-) utilisation of glucose by the tissues or to over-production of glucose by the liver. Many of the facts fit in with either theory. The earlier view of under-utilisation, which has since lost ground, would suppose that the supply of sugar to the body by the liver remains unaltered, but the demand by the tissues is reduced or abolished, with consequent hyperglycæmia and glycosuria. Increased protein and fat metabolism is necessitated to provide the energy, but also leads to increased sugar formation. The opposing view considers that the liver regulating mechanism is "set" to a high blood-sugar level, and accordingly the liberation and formation of sugar by the liver is accelerated; hence the increased protein, and fat, metabolism; the tissues do not demand, and cannot use, the increased amount of sugar, and the excess is excreted.

Uncontrovertible evidence that diabetic tissues can still utilise glucose was provided by the observation that after removal of the liver, the blood glucose fell at an even more rapid rate in diabetic (depancreatised) than in non-diabetic dogs, and ultimately both sorts of animal ended in hypoglycæmic convulsions.* Further, it has been shown that in order to maintain the blood sugar in the liverless dog, glucose must be infused into the blood stream at the rate of about 0·25 g./kg./hr., and a similar rate is needed to keep up the sugar level in the *diabetic* liverless ("eviscerated") dog.

Whichever theory is invoked, there seems to be little doubt that much of the sugar excreted by fasting diabetics arises from proteins. At one time it was generally supposed that the G/N ratio was constant, and that this pointed to protein as the sole source of the neogenetic glucose, but it now seems clear that the observations were strained to fit this hypothesis, and that quantitative data are both inadequate and of equivocal significance.

Since it must be conceded that diabetic tissues do utilise glucose, it is doubtful whether protein alone could provide all the sugar that is excreted, and this means that gluconeogenesis from fat is likely. Against this has been urged that feeding on fat does not raise the sugar excretion. But calculations based on sugar utilisation and excretion in depancreatised and/or hepatectomised dogs gave strong indications that in the fasting diabetic the production of sugar from fat proceeds at the maximal rate,† so that giving fat in the diet could not augment it.

Some direct experiments give support to this view, since liver perfusions and liver tissue-slice experiments showed a conversion of fat, or fatty acids, into glucose.‡

The low R.Q. in diabetes and the absence of a rise if carbohydrate is ingested, have in the past been taken to mean that carbohydrate oxidation is greatly lowered, and that combustion of fat has taken its place. But, in fact, its meaning is doubtful, since all metabolic processes are deranged, and the R.Q. is of such a composite nature as to preclude any firm conclusions.

Although the diabetic tissues continue to utilise, and probably to oxidise, glucose, they do not seem to do so as easily as normal tissues can. Glycogen formation in muscle is sluggish and the rate at which glucose is converted into fatty acids is lowered. The rate of glucose uptake by the tissues varies with the glucose concentration of the blood, and in the diabetic this level is greatly raised. At this raised level the rate of utilisation of glucose by the diabetic is about the same as that of the normal tissues with normal blood sugar level. The fundamental change in the diabetic state therefore seems to be that both the liver and the remaining tissues are "set" to a high sugar threshold; the liver continues to produce sugar even when the blood sugar is already high; the tissues utilise sugar, even at this high level, no more readily than normal tissues would do at normal levels; but at these high levels the kidney threshold is passed and sugar is excreted. Hence liver glycogen is very low, muscle glycogen is low, glyconeogenesis is accelerated, and fat metabolism increased; fat accumulates in the liver, and there is abundant fat in the plasma (lipæmia). Administration of glucose to the animal causes an almost corresponding increase in the amount of glucose excreted in the urine; this is probably due to the fact that sugar is already being formed by gluconeogenesis at a rate too fast for the tissues to utilise it, together with the failure of the liver and muscles to store glycogen. With increased production and diminished storage of carbohydrate, the blood is flooded with sugar, which escapes by the kidneys, while the accelerated breakdown of fat leads to the formation of ketone bodies in large amounts. These ketones can probably be used, up to a point, by the tissues, *in lieu* of glucose. But beyond a certain point (about 2·5 g. of fat per kg. per day at rest), the ketones cannot be so utilised, and are excreted in the urine.

INSULIN

Many facts led physiologists to believe that the pancreas produced, in the islets of Langerhans, a hormone necessary for the normal metabolism of carbohydrates, but it was not till 1922 that Banting and Best[*] succeeded in extracting the hormone from normal pancreas, and in showing that, by its injection, it was possible to obviate the effects of removal of the pancreas in dogs, and by regular dosage to effect a restoration to health in cases of diabetes in man.

In order to prepare insulin, the fresh pancreas is finely minced and extracted with several changes of alcohol which, diluted by the water contained in the gland, is evaporated to a small bulk and poured into absolute alcohol. A white precipitate is produced which represents the crude insulin. The yield of insulin is increased by extracting in the first instance with alcohol containing sodium bicarbonate. Insulin forms an insoluble compound with picric acid, which is decomposed by weak hydrochloric acid with the formation of an hydrochloride. These properties are made use of to effect a further concentration of the active principle.[†]

The insulin so prepared is a white powder, obtainable in crystalline form,[‡] easily soluble in water and in dilute alcohol. As usually prepared, crystalline insulin contains zinc.[§] It does not dialyse, will withstand boiling for a short time, is stable in acid solutions, and undergoes slow oxidation in alkaline solution. It is a protein of molecular weight 35,000, contains sulphur, and is destroyed by pepsin and trypsin, so that it is ineffective if given by mouth. 0·2 mg. injected into a normal rabbit causes a rapid diminution of the blood sugar, and finally the symptoms of hypoglycæmia.

In has long been known that with some preparations of insulin a transitory rise of blood sugar precedes the fall. This is due to the presence of an insulin-like component which accelerates gylcogenolysis in the liver. The distribution of the substance, and its persistence in the pancreas of rabbits deprived of β-cells by alloxan suggests that it is present in the α-cells.[||]

The strength of insulin preparations must be carefully controlled by biological standardisation. The method is based on the reduction of the blood-sugar level of animals by the sample. Up to a certain dose, of about 1 unit/kg., the *rate of fall* of blood sugar increases with the dose, and the per cent. fall of sugar is proportional to log. dose. Larger doses than 1 unit per kg. produce longer lasting falls of blood sugar. When the true sugar reaches a particular low level, probably near to zero, convulsions occur. A dose of about 2 units per kg. will in four hours lower the blood sugar level of a fasting rabbit to

the convulsive level. The present method is to determine the fall of blood sugar brought about in five hours in a fasting rabbit by subcutaneous injection of known amounts of the solution to be tested, as compared with that induced by the international standard preparation, of which 1 mg. contains 22 units. The purest crystalline insulin has a potency of about 23 units per mg.

Human pancreas contains about 1·7 units of insulin per g., and most mammalian pancreas gives similar figures. In the islet tissue it has been calculated that there is about 150 units per g. Presumably it is liberated at an appropriate rate into the blood, though it has not been demonstrated there, and then is taken up by the tissues.

If insulin be injected into a pancreatectomised animal the excretion both of sugar and of ketone bodies ceases, arterio-venous glucose difference rises, showing that the animal is utilising sugar; and on the administration of carbohydrates glycogen accumulates in the muscles and liver. The animal increases at the same time in weight and strength, and can be maintained alive for its normal span. It is necessary, however, to inject insulin subcutaneously two or three times a day, since it is gradually used up in the body.

One of the first questions concerning the action of insulin is the fate of the blood sugar which so rapidly disappears when insulin is given. In the normal animal the tissue carbohydrate and blood sugar may be regarded as derived either directly from ingested carbohydrate, or indirectly from glycogen formed from blood sugar, or from the breakdown of protein, and to some extent also from fat. Whether carbohydrate is ingested or not, its presence and continual metabolism in the tissues are essential to life.

In the diabetic subject, it seems quite clear that the effect of administering suitable amounts of insulin is to restore the carbohydrate metabolism, and hence metabolism in general, to normal; in other words, to accelerate the uptake of carbohydrate, to check glyconeogenesis, and to allow the liver and muscles to carry a store of glycogen; hence, to lower the blood sugar; because the carbohydrate metabolism is restored, and because new formation of carbohydrate is reduced, ketone bodies speedily disappear from the blood, and therefore from the urine and breath. It also accelerates the rate of conversion of glucose to fatty acids, lowers the blood amino-acids, the inorganic PO_4''' of plasma, and blood potassium. It is evident that, in the diabetic, insulin produces all these effects by supplementing the inadequate action of the pancreas.

How insulin acts is not exactly known. In the normal animal or man, there is already an efficiently functioning pancreas, so that by administering insulin to them we shall get abnormal effects due to the presence of an excess of that substance. We shall consider its actions later.

ENDOCRINE INFLUENCES

In addition to the effects of insulin, carbohydrate metabolism is affected by internal secretions set free into the blood by the adrenal medulla (adrenaline), the adrenal cortex, the thyroid and the anterior pituitary. The effects of adrenaline have already been considered.

Influence of Anterior Pituitary Hormone (see also Chap. L.). In diseases associated with enlargement of the anterior lobe of the pituitary body (*e.g.* acromegaly and pituitary basophilism) there is in 20 or 30 per cent. of cases, hyperglycæmia and glycosuria.

The work of Houssay and of Young has shown that the anterior pituitary body produces hormones which have fundamental importance in the regulation of carbohydrate metabolism.

Hypophysectomy. After hypophysectomy (removal of the pituitary body), no serious effects are seen if the animals are well fed. Their nitrogen excretion is much below normal, which means that glyconeogenesis is slowed down, the total metabolism is low and there is a low blood sugar. Carbohydrate oxidation is augmented.

On fasting, or on any treatment that lowers the glycogen stores of the body, the blood sugar falls to a low level, and hypoglycæmic seizures ensue. The animals when fasting are demonstrably much (often 30 times) more sensitive to the action of insulin than are normal animals,* and less responsive to adrenaline.

One of the results of hypophysectomy is a reduced activity of other endocrine organs, *e.g.* thyroid and adrenals, and some of its effects may be secondary to such alterations.

Combined Pancreatectomy and Hypophysectomy. The results of removal of both pancreas and pituitary are most striking †: the state of diabetes, which usually follows the extirpation of the pancreas, is held in abeyance. Animals subject to the double extirpation are often called " Houssay " animals : if fed moderately, they show practically normal blood sugars, little if any glucose excretion, no ketosis, normal glucose tolerance, and normal glycogen

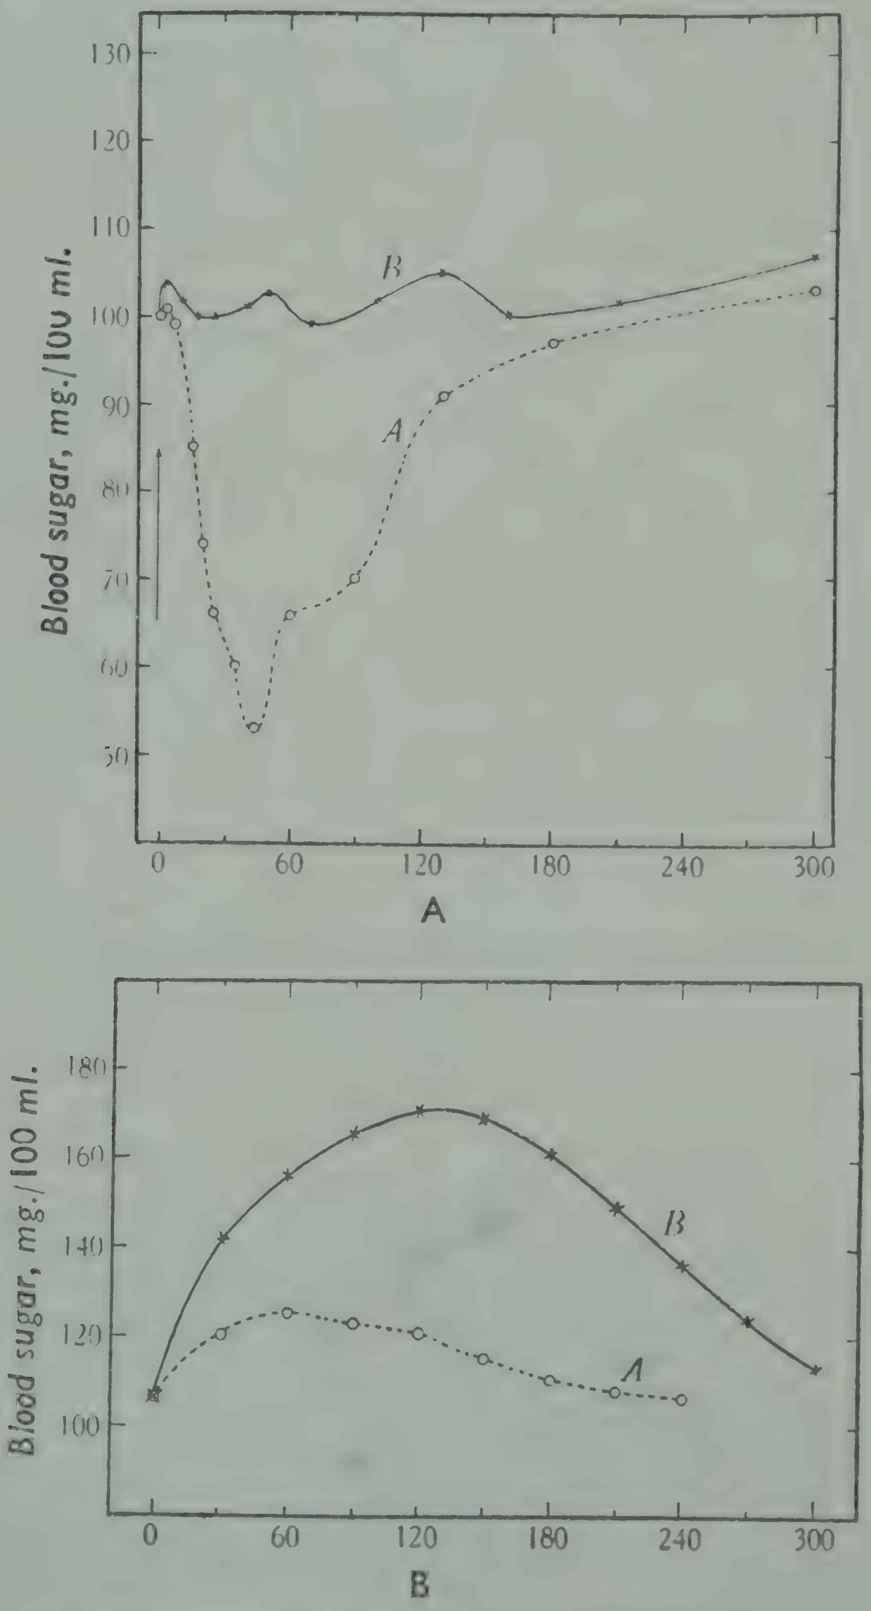

FIG. 597. Effect of anterior pituitary extract on the sensitivity of rabbits to insulin (Graph A) and adrenaline (Graph B).

stores in liver and muscles. Their nitrogen excretion is about normal, and they survive for weeks or months, but are subject to hypoglycæmic crises if subjected to fasting. It seems evident that their carbohydrate metabolism is unstable and is easily tipped in the direction of the hypoglycæmic state.

Injection of Pituitary Extracts. The number of hormones now claimed to be formed by the pituitary anterior lobe is considerable, and there is some doubt about the individual existence of some of them. But by the injection of extracts of the anterior pituitary, prepared in various ways, a diabetogenic effect is produced. This effect comprises an accelerated rate of gluconeogenesis in the liver, an opposition of the action of insulin, hyperglycæmia, etc.

The Diabetogenic Hormone. By repeated intraperitoneal injections of such extracts of the anterior pituitary into dogs, symptoms resembling those of diabetes develop after a few days : these symptoms comprise reduction of the insulin content of the pancreas, depletion of liver glycogen, hyperglycæmia, glycosuria, ketonuria, high nitrogen output, etc. Extirpation of the liver prevents these results. Given to "Houssay" animals, the injections cause a revealing of all the latent diabetic symptoms.

Usually the symptoms resulting from a few injections subside soon after discontinuance of the dosage. But after repeated dosage there results a permanent condition of diabetes (metahypophyseal diabetes).* In animals thus rendered permanently glycosuric, the islets of Langerhans were found to have undergone degenerative changes.† These are presumably due to overwork of the β-cells, which, during the injections, secrete insulin at ten to twenty times the normal rate ; if enough insulin is given with the pituitary extract, these changes are obviated.‡

The most usual explanation of the facts is that the hormones of the pituitary exert an influence in favouring glyconeogenesis, in opposition to insulin, which appears to check it. Also, they counteract the peripheral action of insulin on the tissues, and hence reduce the uptake of sugar from the blood. After hypophysectomy, the nitrogen output is reduced, while administration of pituitary extracts raises it. We may thus suppose that under ordinary conditions, in which the pituitary hormones are present, a good deal of glyconeogenesis is going on, so that, even in starvation, glucose is still being added to the blood by the liver. The administration of insulin to the fasting animal may somewhat tax this supply of carbohydrate, but after hypophysectomy the endogenous supply of carbohydrate is much diminished, while demands by the tissues are not reduced, so that the animals become very much more sensitive to the hypoglycæmic action of insulin. With the action of adrenaline it is the reverse of this—carbohydrate is most available when liver glycogen is high, and labile, so that hypophysectomy reduces the response to adrenaline, and the administration of pituitary extracts enhances it. When both pancreas and pituitary are removed the animal's carbohydrate metabolism somewhat resembles that of the normal state, provided it is well fed, and thus given a supply of ready-made carbohydrate to draw upon. Then, although glyconeogenesis is reduced by loss of the pituitary, there is at the same time less tendency to hypoglycæmia because the pancreas is also lacking, and hence there is sufficient carbohydrate to meet most ordinary needs.

The amount of carbohydrate consumed in the normal body is subject to wide variations, dependent on the supply of carbohydrate in the diet. When the supply is restricted, it is endogenously produced from protein and probably also from fat, so that the irreducible minimum of blood sugar is available as long as life lasts. Determination of the glucose-tolerance curves shows that on low carbohydrate diets the tolerance is reduced and on carbohydrate-rich diets it is augmented, *i.e.* the more carbohydrate in the diet the more readily can administered glucose be disposed of * (Fig. 598). Hypophysectomy abolishes this effect of diet. Low carbohydrate diet also reduces the response to insulin. All these facts taken together suggest that the pituitary hormones are secreted in greater amount when the diet is poor in carbohydrate and *vice versâ*.† After prolonged total fasting the capacity to utilise ingested sugar is much impaired, so that when sugar is given it may at first be excreted unchanged (hunger diabetes). The lost ability to use glucose is not due to inability to store glycogen in the liver ‡ ; it is possibly due to the fact that glyconeogenesis has been going on intensively, the new-formed glycogen being at once converted into glucose, the usage of which is reduced. When glucose is given this floods the organism until such time as the excessive gluconeogenesis can be checked and the rate of usage restored.

Influence of Adrenal Cortex. The adrenal body exerts an effect on carbohydrate metabolism not only through its medulla, which liberates adrenaline into the blood, but also through the cortex. It is well recognised that after removal of the suprarenals the absorption of monosaccharides from the intestine is retarded, and the glycogen stores of the body somewhat reduced even if full diet is maintained ; in fasting the glycogen stores are rapidly depleted, while the blood sugar is lowered and the blood lactate raised.

Further study shows that the effects of removal of the adrenals somewhat resemble those of hypophysectomy. Thus there is the same tendency to hypoglycæmia on fasting, the lowered glycogen reserves, especially on fasting, the sensitivity towards insulin, the raised oxidation of carbohydrate, with raised R.Q., the depressed glyconeogenesis, and, what is even more important, the same amelioration of diabetic symptoms in the pancreatectomised animal. The diabetogenic action of pituitary extracts, moreover, is reduced by adrenalectomy. This is especially well seen in the partially depancreatised rat, which is very sensitive to anterior pituitary hormones (Fig. 599).

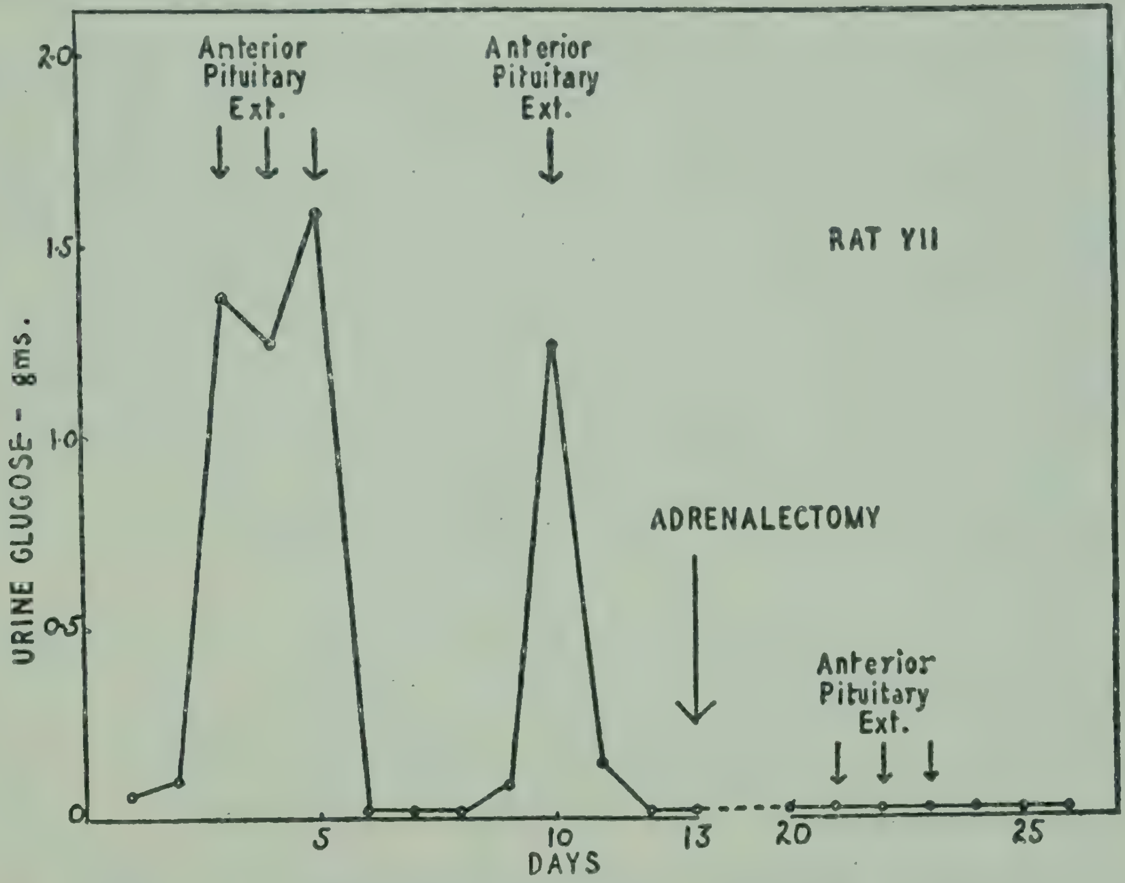

FIG. 599. Effect of adrenalectomy on the glycosuric response to anterior pituitary extract in the partially depancreatised rat. (LONG. *Harvey Lectures*, 1937.)

When extracts of the adrenal cortex, or the cortical hormones (the ones with O or OH at position 11) are injected into adrenalectomised animals, the effects of the adrenalectomy are reversed. If the adrenal cortical extract is given to fasting hypophysectomised rats there is a rise in the blood sugar and in the store of glycogen, as the following summary shows :—

MEAN CARBOHYDRATE LEVELS OF FASTED RATS INJECTED WITH CORTICAL HORMONE *

Treatment	Muscle Glycogen. m.g./100g.	Liver Glycogen. m.g./100g.	Blood Glucose. m.g./100g.
Normals, untreated	521	188	84
Hypophysectomised, untreated .	320	94	52
Hypophysectomised, given 0·03 mg. Kendall's Adrenal Comp. B every hour for 24 hours .	450	1,520	107

It may reasonably be concluded that the adrenal corticosteroids mainly influence carbohydrate metabolism through their action on glycogen storage, particularly and primarily in the liver. This action is due to reduced oxidation of carbohydrate, reduced influence of insulin, and increased glyconeogenesis.

It is probable that some of the effects connected with the pituitary body are actually effected through a stimulating effect which this has, through one of its hormones, on the adrenal. After hypophysectomy, the adrenal lacks this stimulus to produce or liberate its cortical hormones, and the reduction of glyconeogenesis is partly due to this. Not all of the effects are likely to be due to this, however, since anterior pituitary extracts are still diabetogenic, though less so, after adrenalectomy. It is probably expedient, therefore, to assume that the pituitary hormones affect carbohydrate metabolism in two ways; first by their stimulating effect on the adrenal, and secondly by a direct effect in stimulating glyconeogenesis in the liver.

Influence of the Thyroid. The thyroid hormone (Ch. L.) has a powerful effect in increasing general metabolism, and so it is not surprising that increase or diminution of the hormone respectively stimulates or depresses carbohydrate metabolism. Most of the effects are probably a reflection of this action and do not represent a primary and specific action of the thyroid on carbohydrate metabolism.

Adrenal Cortex, Anterior Pituituary and Insulin. Fresh light has been thrown on the mode of action of insulin by study of its relation to hexokinase action. This enzyme catalyses the reaction by which glucose is converted into glucose-6-phosphate, which, as we have seen, is the first step in the formation of glycogen from glucose and in the oxidation or glycolysis of glucose. Hexokinase action has been shown * to be inhibited *in vitro* by anterior pituitary extracts, and the inhibition is accentuated if adrenal cortical extracts are also added. If insulin is added to such an inhibited enzyme system, the inhibition is removed and the activity restored. Insulin also enhances the hexokinase activity of diabetic muscle, and of muscle of rats previously injected with anterior pituitary extracts, but does *not* increase the hexokinase activity of normal muscle.

Although some discrepancies have still to be cleared up, this demonstration of such a fundamental action of insulin may well prove to be the key to all its physiological properties, since, by overcoming the inhibitory action of the pituitary-adrenal hormones it would virtually accelerate the formation of glycogen in liver and muscles, and thus " set " their regulating mechanisms to function at lowered blood-sugar levels. Reduced glyconeogenesis, increased conversion of glucose to fatty acids, and reduction of ketosis would probably be secondary consequences.

Nature of Insulin Action. We have seen that the blood-sugar level is to a large extent self-regulating, owing to its effect on the liver, which, when " set " to a particular level, will liberate or absorb glucose in such a way as to maintain that level. The setting of the level is dependent on the influence of various hormones, pituitary and adrenocortical hormones tending to " set " the liver to maintain a high blood sugar, and hence encouraging both glyconeogenesis and glycogenolysis, insulin tending to " set " the regulator to a low blood sugar, and hence checking both glyconeogenesis and glycogenolysis in the liver. Insulin, as Soskin has expressed it, " plays the part of a catalyst or activator in a process which can proceed at a slower rate in its absence. More specifically, it permits rates of carbohydrate utilisation at low blood-sugar levels which in its absence would require abnormally high blood-sugar levels."

The insulin liberated from the pancreas is mainly retained in the liver, and the influence of insulin on the whole animal is chiefly on the liver. This is shown by a calculation by Bouckaert and de Duve of glucose retentions by liver and extrahepatic tissues in the dog. The calculation expresses the glucose uptake, when blood sugar is kept at normal levels, in g./kg. body weight in eighty minutes (negative figures mean *release* of glucose into blood):

	Hepatic Retention.	Peripheral Tissue Retention.
(1) With normal amount of insulin .	− 0·21	+ 0·21
(2) With no insulin	− 0·69	+ 0·09
Difference = retention due to insulin.	+ 0·48	+ 0·12

---

* Colowick, Cori and Slein. *J. Biol. Chem.*, 1947, **168**, 583.

Whether carbohydrate oxidation is accelerated by insulin has been contested, but the balance of evidence indicates that it is. The total calorie production shows a slight rise, but the rise of R.Q. after giving insulin and glucose is not to be accepted without reserve, because conversion of glucose to fatty acid would also give a rise. If insulin is given to a normal individual, we get the effects of excess of it, and if at the same time the blood sugar is allowed to fall, as it normally would owing to increased uptake by the tissues, we find that liver glycogen is rapidly *reduced*. This is because glycogenolysis is increased owing to liberation of adrenaline, and at the same time glyconeogenesis is checked. But in normal endocrine balance insulin leads to glycogen deposition in both liver and muscle.

Best, Hoet and Marks * showed that when the blood sugar of the eviscerated spinal cat was kept at a high level for two to five hours by intravenous injection of glucose, there was no demonstrable change in the glycogen content of the skeletal muscles. When insulin was also given, there was an accelerated rate of sugar disappearance, and an *increase* in the glycogen content of the muscles, irrespective of whether actual hypoglycæmia resulted or not, and this deposition of the glycogen was enough to account for from 40 to 50 per cent. of the sugar which had been lost from the blood. It may be concluded, then, that under the conditions of these experiments, much of the lost sugar was recoverable as glycogen.

The Normal Regulation of Blood Sugar. Large amounts of carbohydrate can be dealt with by the normal individual without any appreciable loss of sugar by way of the urine ; on the other hand, owing to glyconeogenesis, abstinence from carbohydrates for quite long periods does not lead to hypoglycæmia. Now in the treatment of diabetes it is necessary to secure a proper balance between the amounts of insulin administered and carbohydrate ingested, as otherwise there will be either an excretion of glucose in the urine, or else the unpleasant effects of hypoglycæmia. In the normal state, since neither of these effects ensue, there must therefore be some means by which the rate of uptake of carbohydrate by the tissues corresponds with the amount of carbohydrate to be dealt with.

Up to a point this regulation is automatic, the liver adjusting its output or uptake of glucose, and the other tissues altering their rate of uptake according to the sugar concentration in the blood plasma. But there is evidence that the rate of manufacture, and of release, of insulin, is also controlled by the blood sugar level, *i.e.*, according to the need for it : fasting, feeding with fat, or administration of insulin for instance, all lead to a fall in the insulin content of the pancreas,† presumably because the rate of its formation is slowed down.

Apparently, when carbohydrate is taken by the mouth, there is an accompanying liberation of insulin to deal with it ; it is often seen that in a blood-sugar curve the blood sugar falls very rapidly after its initial rise, and reaches a level slightly below that of the blood in the fasting state (Fig. 589). The rapid fall is not because absorption of glucose from the alimentary canal is at an end ; in the diabetic subject the rapid fall is not seen. The fall in the normal subject without doubt occurs because by that time the insulin liberation has been raised sufficiently to reduce the blood sugar in spite of the continuing sugar absorption. So if a second 50 g. of glucose is given to a normal subject as soon as the blood sugar has reached its low level, there is little or no further rise in the blood sugar. It has even been shown that a transfusion into a diabetic subject of blood taken from a normal individual during the absorption of glucose will lead to a fall in the blood sugar of the patient, just as though insulin had been given.

It is uncertain how this regulation of insulin output by the pancreas is effected. Since it appears to be unaffected by denervation of the pancreas, it would seem to be independent of any nervous control, and to depend upon a direct effect of the blood-sugar level on the pancreas. This is well seen in experiments in which the pancreas has been transplanted, and therefore denervated. When glucose solution is injected into the artery supplying such a pancreas, there is a definite fall in the sugar in the circulating blood (Fig. 600). But Macleod and collaborators and G. A. Clark * have given some evidence that the liberation of insulin can also be controlled by influences reaching the pancreas by way of the vagus.

---

* Best, Hoet and Marks. *Proc. Roy. Soc.*, 1926, **100B**, 33.

† Best and Haist. *J. Phyiol.*, 1941, **100**, 142.

Nervous control does come into the picture when hypoglycæmia is present. Just as the hyperglycæmia produced by adrenaline, or in any way, can be counteracted by insulin so the hypoglycæmia brought about by an overdose of insulin can be relieved by administration of adrenaline if sufficient glycogen is present in the liver. Cannon, McIver and Bliss † showed that when insulin is given, as soon as the blood sugar falls to a certain level (about 50 mg./100 c.c.) there is excitation of the sympathetic system and a discharge of adrenaline from the suprarenals. This produces accelerated glycogenolysis in the liver, and so checks the further fall of blood sugar. We thus see that the regulation of the blood sugar involves a balance of several competing factors. Apart from the entry of carbohydrate into the body during absorption from the intestine, glycogen is constantly being produced in the liver, certainly from protein, probably also from fat, by processes of glyconeogenesis. According to the extent to which the carbohydrate requirements of the body are being met by absorption from the intestine, this glycogen is converted into glucose and liberated, rapidly in fasting, slowly during the well-fed state, into the blood passing the liver. The process of glyconeogenesis is accelerated by the diabetogenic hormone of the pituitary, partly through its action on the suprarenal, and is checked by insulin. Conversion of glycogen in the liver into glucose is accelerated by adrenaline. When the blood sugar tends to rise, more insulin is set free from the islets of the pancreas, and this not only checks glyconeogenesis

in the liver, but also accelerates glycogen storage in the muscles and oxidation of glucose in the tissues. When the blood sugar tends to fall, adrenaline is liberated into the blood stream, and conversion of glycogen to glucose in the liver and of glycogen into lactic acid in the muscles is speeded up, until the blood sugar level is set right again.

Removal of the pancreas not only depresses the oxidation of glucose in the tissues, but also leaves the process of glyconeogenesis in the liver unchecked. Removal of the liver, or of the pituitary, or, to a lesser extent, the suprarenal, leaves the glucose-removing functions of the pancreas in charge of the situation. Proper regulation of the blood sugar is only got by appropriate collaboration between all these various factors.

Diabetes in Man.* There is good reason to suppose that diabetes in man may be due either to excessive secretion of the pituitary "diabetogenic" hormone, or to inadequate secretion of insulin by the pancreas. The latter form seems much the more common. It has been shown by Himsworth † that there are two types of diabetic, one sensitive to insulin and one less, or more slowly, responsive. The sensitive type, if given glucose and insulin, show an almost normal response to the latter ; the insensitive type, on the other hand, shows the great rise of blood sugar in response to the glucose, as though no insulin had been given (Fig. 601). It is suggested that the insulin-sensitive types, which are usually the more severe, are due to lack of insulin in the body, while the insensitive types are due to impairment of the action of insulin on the tissues, as happens in normal individuals on low carbohydrate diets, presumably because of over-production of pituitary hormones. In its severer forms, the diabetes of man resembles very closely that produced in the dog by total extirpation of the pancreas. The output of urine is largely increased, and the urine, though light in colour, is of a high specific gravity, 1,030 to 1,035, and

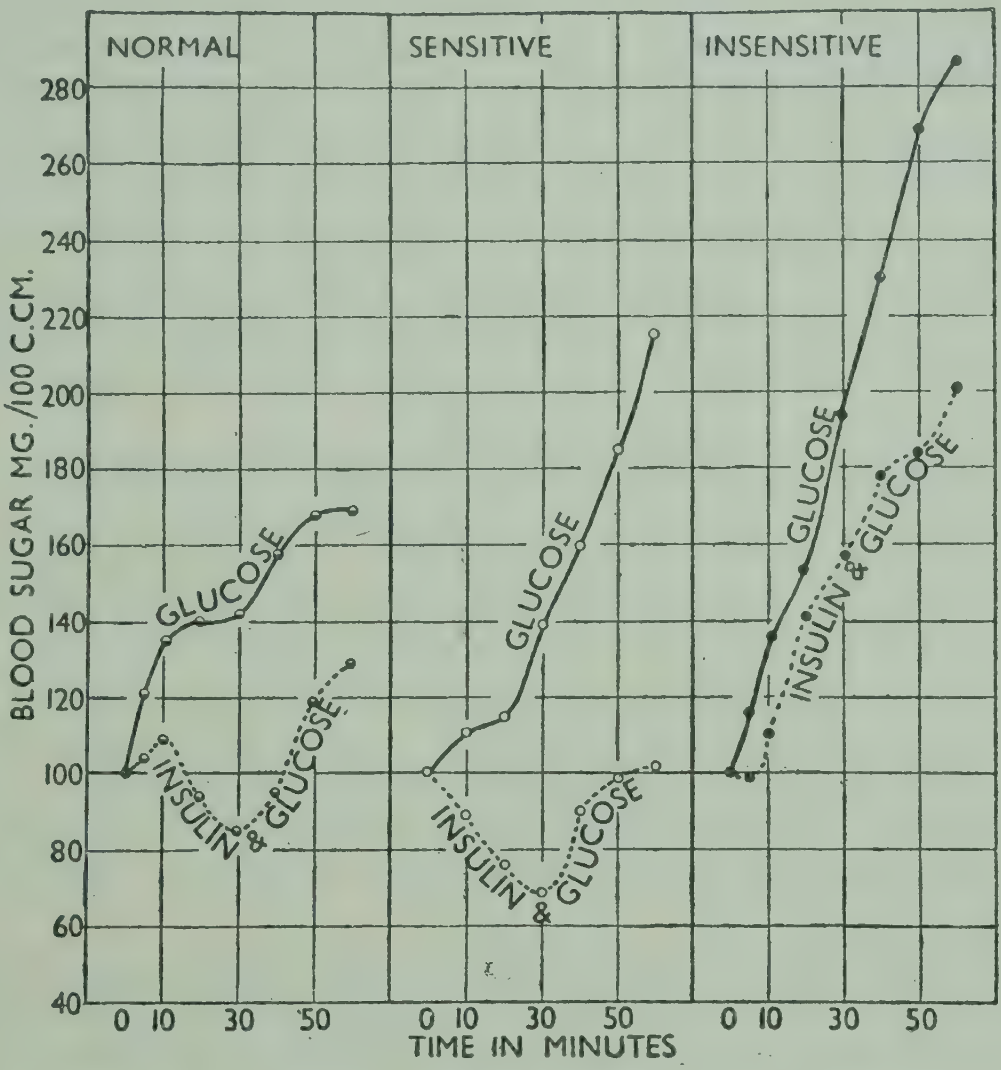

FIG. 601. Glucose tolerance and insulin-glucose curves from a normal subject, from an insulin-sensitive diabetic and from an insulin-insensitive diabetic, all on same diets. (HIMSWORTH and KERR, *Clin. Sci.*, 1939, **4**, 119.)

† HIMSWORTH, *B.M.J.*, 1940, i, 719.

may contain from 5 to 10 per cent. of sugar. The appetite is largely increased, yet the body wastes. The patient after some months or years may die in a condition of diabetic coma. Warning of the onset of this condition is given by the rise of ammonia in the urine, and by the appearance of β-hydroxybutyric and aceto-acetic acids. The breath may smell of acetone, and this substance may also be present in the urine. The diabetic state is attended by diminished resistance of the tissues to infection. In a few cases the pancreas is found to be atrophied or diseased, but in the large majority no marked pathological change is to be observed with the naked eye in this organ. Where it has been possible to apply refined methods of microscopical examination, some change has often been found in the islets of Langerhans. We may find all grades between such cases and those in which there is still a considerable power of glucose assimilation. In order to determine the grade of the disorder, it is usual to give a glucose test meal, and to examine the urine for sugar and make a blood-sugar curve. In many cases the sugar will disappear from the urine on the administration of a diet consisting entirely of proteins and fats. When this has been effected, carbohydrates may be added in small proportions to the diet up to the limit of the assimilatory powers of the patient. Some think that administration of carbohydrate in excess of this limit is of disadvantage to the patient and hastens the progress of his disorder. When the power of assimilating carbohydrates is entirely abolished, death is inevitable unless insulin be given. This point may be determined in two ways. In the first place, a patient with no power of carbohydrate assimilation will continue to excrete sugar in the urine on a pure protein-fat diet. A very low respiratory quotient is a sign of severity of the disorder.

As in the diabetes produced by extirpation of the pancreas, the patient may often be restored to health, and kept in that condition, by the repeated administration of hypodermic doses of insulin. Increasing the carbohydrate in the diabetic diet does not necessitate a corresponding increase in the amount of insulin required, because, as with normal individuals, the carbohydrate tolerance and the insulin sensitivity are raised when the carbohydrate in the diet is increased. Care must be taken not to give too large a dose of insulin, as the hypoglycæmia thereby produced is more immediately dangerous than the hyperglycæmia. This state of hypoglycæmia, if accidentally induced by an overdose, can be removed by administration of glucose, either orally or by intravenous injection.

A drawback in insulin treatment is that, unless very frequent small injections be given, the dosage is rather sudden and irregular. Many attempts have been made to find some means of spreading out the action of a given dose of insulin so as more closely to imitate the steady production by the pancreas. The most useful of these are by the use of zinc insulinate and protamine zinc insulinate, both of which are more slowly absorbed and so produce more smooth effects. If the administration of insulin be intermitted, the patient returns at once to the diabetic condition.

BOOK VII

THE REMOVAL OF WASTE MATERIAL AND TEMPERATURE CONSERVATION

EXCRETION AND TEMPERATURE REGULATION

HISTORICAL NOTE

Kidneys and Urine. Knowledge of the functions of the kidneys is inseparable from that of their structure, and of the chemical constituents of the urine. Galen, about A.D. 200, knew, and perhaps discovered, that the urine is formed by the kidneys, but it was centuries before knowledge progressed much further than that. Early in the 17th. century an attempt was made by Van Helmont to discover the nature and origin of the urinary constituents, and in 1669 the alchemist Brand isolated elementary phosphorus from urine, and was doubtless astonished by its properties; but proper appreciation of the nature of the urinary constituents had to await the development of organic chemistry, and, indeed, played a part in that development, during the 19th century. There is thus little reason for surprise at the failure of Boerhaave's attempt, early in the 18th century, to make an analysis of the urine. The first rough quantitative analysis was, in fact, made by Berzelius in 1809.

The first step towards realisation of the chemical nature of the urine was the discovery in it of hitherto unknown substances. Of these, urea, recognised by Rouelle in 1773, but fully discovered in 1797 by Cruickshank, was of critical importance. By 1822, Prévost and Dumas had shown that after nephrectomy the blood contained large amounts of urea, and this gave grounds for believing that the kidneys merely removed from the blood substances already there. Urea was of further historical importance as the first organic substance to be prepared synthetically (Wöhler, 1828): it was shown by Liebig in 1842 to arise from ingested protein, and by Meissner, about 1868, to be formed in the liver.

The excretion of hippuric acid after ingestion of benzoic acid was observed by Wöhler in 1824, and was the first discovered case of a synthesis in the animal body. But when Schmiedeberg, in 1876, showed that the synthesis was effected in the kidney, somewhat of a check was suffered by the opinion that the kidney was solely an excretory organ.

Uric acid had been isolated by Scheele and Bergmann (1776), and its mode of origin studied by Kossel (1885) and by Horbaczewski (1890). Thereafter the story may be left as recent history.

Knowledge of the details of kidney structure accumulated side by side with that of the chemistry of the urine. The uriniferous tubules, seen by Bellini in 1662, the glomeruli injected by Malpighi in 1665, and the terminal capsules observed by J. Müller in 1830 were all brought into proper relationship in 1842 by Bowman, who promulgated the first plausible theory of urine formation. This was the filtration-secretion theory, which is referred to more fully in the text of the next chapter. Two years later, however, the great mechanist Ludwig enunciated an opposing theory, the filtration-reabsorption theory. Although Goll's work, in 1854, lent colour to this theory by showing that the urine flow was closely related to the arterial pressure, many facts were left unexplained, both as regards the vascular effects, and as regards the relative concentrations of the urinary substances in blood and urine; and when Ustimowitsch, in 1869, showed that the injection of urea would re-start urine secretion previously checked by low arterial pressure, Ludwig was prepared to admit that the composition, as well as the pressure, of the blood was an important factor.

Ludwig's customary antagonist, Heidenhain, supported Bowman, and by his classical experiments with indigo-carmine (1875) considered that he had finally vindicated the tubular secretion theory, for which further evidence was provided by Nussbaum's well-known experiments on the frog kidney in 1878.

In this state of conflicting indecision the matter remained until the third decade of the present century. In the intervening period a good deal of work was done, such as that on the relation between blood pressure, kidney volume (with the oncometer devised by Roy for the purpose in 1881), blood flow, and urine flow, but none of it decisive as between the two contending theories. Cushny, in 1917, showed that, by the hypothesis of threshold substances, the filtration-reabsorption theory could be made to fit most of the facts, but it was thought by many that this exposition did not amount to demonstration.

About 1925, however, the phase of micro-experimentation was ushered in by RICHARDS' work on the frog kidney ; it became possible directly to collect and analyse the glomerular filtrate and the urine from other parts of the tubule. Work on various clearances, which began with that of urea by VAN SLYKE in 1928 and was extended to that of other substances by REHBERG (1926), SMITH, SHANNON and others, also threw much light on the whole subject. The study of the aglomerular kidneys of fishes by MARSHALL and others from 1928 also gave a new viewpoint by bringing positive proofs of normal tubular excretion. The present position is that the filtration-reabsorption theory is the one chiefly upheld for the mammalian kidney, but that in specific instances tubular secretion also occurs.

Acquaintance with the movements of the urine, and the mechanism of micturition mainly developed during the great growth of experimental physiology in the late 19th century. HALLER, in 1778, recognised that urine was retained by a reflexly maintained tone. The active period began with KOHLRAUSCH's work on micturition in 1854 and ENGELMANN's work on the movements of the ureters (1869). The innervation was mainly settled by the studies of BUDGE (1872), ZEISSL (1893), and LANGLEY and ANDERSON (1896) : the reality of the internal sphincter was confirmed by REHFISCH in 1897.

Skin and Heat Regulation. The structure of the skin was described by MALPIGHI (1687), who noted the sweat glands, more accurately described by PURKINJE in 1834, and enumerated in different areas of the body by KRAUSE in 1844.

The insensible perspiration was first studied by SANCTORIUS (1614), and afterwards by DODART, 1725, LAVOISIER and SEGUIN, 1790, and others, right up to modern times. Sweat was collected by ANSELMINO in 1844, and first analysed by SCHOTTIN in 1851. The secretion of sweat by stimulation of a mixed nerve was first noted by GOLTZ in 1875 ; it was OSTROUMOW and LUCHSINGER who showed, in 1876, that the nerve supply was of sympathetic origin, the exact path for which was mapped out by LANGLEY in 1891.

That animals were separable into those with constant and those with variable temperatures, rather than into warm and cold-blooded divisions, was pointed out by JOHN HUNTER in 1837, and again by DONDERS in 1845 : the names homoiothermic and poikilothermic respectively were introduced by BERGMANN in 1847.

The invention of the thermometer by GALILEO in 1595 soon led to its application, by SANCTORIUS, to the study of fevers. They used air thermometers, and a fanciful form of clinical air-thermometer was invented by the Grand Duke Ferdinand of Tuscany in 1654. Galileo used the first liquid (alcohol) thermometer in 1612, and in 1701 NEWTON proposed that body temperature be taken as a fixed thermometric point. A mercury maximum clinical thermometer was introduced by EHRLE in 1869. Thermo-electric couples for temperature measurements were used by ROSENTHAL in 1876, and the radiation of heat from the skin was first studied by the use of the thermopile by CHRISTIANI and KRONECKER in 1878.

A survey of body temperatures and of the topography of skin temperatures was made by J. DAVY in 1845, and it was from his studies that the mean temperature in the mouth was accepted as 98·4° F.

A series of calorimeters has been used for the study of animal heat ; the ice calorimeter of LAVOISIER and LAPLACE (1780) was followed by a water calorimeter by CRAWFORD in 1788, which was further improved by DULONG in 1842. An air calorimeter, the forerunner of many later types, was tried out by SCHARLING in 1849, and D'ARSONVAL in 1886 invented a differential air calorimeter. The modern highly accurate types are mostly of the ATWATER and BENEDICT pattern, and date from about 1905 : they are elaborations of the water-calorimeter.

It was LAVOISIER who showed, in 1780, that the heat generated in the body could be accounted for by the combustion processes which terminated in the production of CO_2 and water ; many others, notably RUBNER (1894) fully confirmed this, and showed that the heat produced was the same as that formed by combustion of the ingested food materials. The chemical regulation of heat production was first postulated by VOIT in 1878.

The ancients could in no way explain the warmth of animals, and considered it to be an innate " vital " phenomenon ; ARISTOTLE (350 B.C.) believed it to emanate from the heart, and that breathing cooled the body. There was not much advance in opinion until late in the 18th century. Thus, VAN HELMONT (1648) still attributed it to the " vital spirits " of the blood, DESCARTES and WILLIS (1670) to a fermentation, BOERHAAVE (1708) and STEPHEN HALES (1733) to friction of the blood, and HALLER (1760) held some similar opinion.

JOHN MAYOW, certainly, got rather near the modern idea in 1674, with his view that the heat was due to the combination of the " nitro-aerial spirit " (= oxygen) with combustible " particles ". But it was LAVOISIER's demonstration of the real nature of combustion, in 1777, that brought the subject into the ambit of modern views. He was wrong, however, in supposing that the lungs were the seat of the oxidative processes, and it was not until it was shown that the blood of the right side of the heart is warmer than that of the left (MALGAIGNE, 1832, BERGER, 1833, and many since) that this error was brought home. The demonstration that in deep-seated organs the venous blood is warmer than the arterial (LIEBIG, 1853, CL. BERNARD, 1876, etc.), together with the work of PFLÜGER and others showing that the tissues were the seat of the oxidative processes, fully confirmed this viewpoint. The notion that, nevertheless, the lungs were capable, when the tissues had failed, of completing oxidative processes, was again put forward in 1897 by Bohr and Henriques, but was speedily repudiated.

Boerhaave thought that lung-breathing animals could not survive in surroundings at temperatures above their own : this was opposed by Haller, on the evidence of tropical explorers, and Ellis, in 1758, made the significant observation that the human skin had a temperature of only 97° F. when the environmental temperature was 105° F. Franklin explained this as due to the evaporation of the sweat. The relative effects of dry and moist air were shown by Delaroche and Berger in 1806, and in 1875 Blagdon and others performed the crucial experiment of supporting unscathed a temperature of 127° C. in dry air for several minutes.

That the body temperature was influenced by the central nervous system became evident from the experiments of Benjamin Brodie in 1811, and was confirmed by the subsequent work of Williams (1835), Claude Bernard (1876), and many others. Damage to the spinal cord or other parts of the C.N.S. often caused a fall, but sometimes a rise, of body temperature : hyperthermia was especially noted by Tscheschicin, in 1866 (damage to pons), and by Aronsohn and Sachs (1885) and Hale White (1890), who first showed that puncture in the region of the corpus striatum produced a prolonged rise of body temperature.

CHAPTER XLVII

RENAL EXCRETION

1. THE COMPOSITION AND CHARACTERS OF THE URINE

WATER is got rid of by the lungs, skin, and kidneys. The residues of the bile and digestive secretions are eliminated with the fæces. With these exceptions, practically all the waste products, except CO_2, resulting from metabolism are excreted in the urine. We have thus in this fluid the last chapter in the metabolic history of a large number of the constituents of the diet. Since, moreover, the kidneys may excrete almost any substance which circulates through their blood vessels, many of the intermediate metabolites may be found in minute quantities in the urine. Under pathological conditions, these metabolites may appear in the urine in larger amounts and serve then as an index to some interference with metabolism.

The composition of the urine must, therefore, vary according to the activity of the body, the quantity and nature of the food taken, and the relative amount of water escaping by other channels.

The urine of man is a clear yellow fluid, which froths when shaken. On standing, a cloud of mucus is deposited, consisting of a very small amount of protein derived from the epithelial lining of the bladder and urinary passages. In concentrated urine a deposit of *urates* occurs on cooling, and dissolves when the urine is warmed. When normal urine is turbid as it is passed, the turbidity generally consists of calcium phosphate and is not cleared up by heating, but dissolves in dilute acid.

The *colour* of the urine varies with its concentration. After severe sweating the urine is of high colour and after copious draughts of liquid may be very pale.

Ordinary urine has an aromatic *odour*, but this varies largely with the character of the food.

The *specific gravity* of the urine is proportional to its concentration. Normally it is 1,016 to 1,020, though it may rise as high as 1,040 or sink as low as 1,002. The specific gravity of the urine when fluid intake is suspended is an important index of the functional condition of the kidney. If fluid intake is stopped for twenty-four hours, the urine secreted during the second half of the period should have a sp. gr. not below 1,026 : in nephritis it may be as low as 1,010.

Its osmotic pressure is usually much above that of the blood plasma, Thus, the Δ of urine normally varies between 0·87 and 2·71° C. (Δ of blood = 0·56°), but after copious draughts of water the Δ may be as small as 0·25° C.

The *reaction* of urine is generally acid. This is due to the fact that neutral constituents of the food may give rise to acid end-products of metabolism. The sulphur of proteins is converted into sulphuric acid and the phosphorus of nucleic acid and lecithin into phosphoric acid. There is thus a predominance of H-ion over OH-ion in ordinary urine. The *p*H of the urine can easily be determined by indicators, is on the average 5·3, and varies from 8·0 to 4·8.* This, however, applies only to man and to carnivora. In the food of herbivora there is a predominance of salts of organic acids. The acids, *e.g.* tartaric, malic, and citric acids, undergo oxidation in the body, so that their corresponding cations have to be excreted ; hence the H-ion concentration of the urine is reduced ; the urine of herbivora therefore is alkaline in reaction, and turbid. If a herbivorous animal be starved, so that it has to live on its own tissues, its urine becomes clear and acid. The urine of man can similarly be made alkaline by the ingestion of large quantities of vegetables, by the administration of alkalies (*e.g.* $NaHCO_3$) by the mouth, or by prolonged forced breathing.* Under such circumstances, the urine, as passed, is turbid from the presence of calcium phosphate.

---

* HENDERSON and PALMER. *J. Biol. Chem.*, 1912, **13**, 394.

In determining the titratable acid of the urine, it is usual to adhere to one indicator, *e.g.* phenolphthalein, and to give the acidity in terms of decinormal acid, naming the indicator used. The total acid set free in the body per day is equal to about 700 c.c. of N/10 acid, but some is neutralised and excreted as ammonium salts (= c̄ 400 c.c. N/10 acid daily). The rest, the urinary titratable acid, amounts to about 300 c.c. $\frac{N}{10}$ acid daily.

Owing to the buffering action of phosphates, the *titratable acidity* of urine is always much greater than the H-ion concentration would suggest. By titrating, first with methyl red and an acid, and then with phenolphthalein and an alkali, we obtain a useful measure of the buffers of the urine. By the first titration we convert the dibasic phosphates to the monobasic salt (NaH_2PO_4), and by the second we convert the monobasic to the dibasic phosphate (Na_2HPO_4). Hence the ratio of the first to the second titration gives us the ratio $\frac{Na_2HPO_4}{NaH_2PO_4}$.† Other buffer systems are also present.

For Reference

BRUNTON (1933). The Acid Output of the Kidney and the So-called Alkaline Tide. *Physiol. Rev.*, **13**, 372.

THE AVERAGE COMPOSITION OF THE URINE. The following may be taken as a fair daily average for an adult man on ordinary mixed diet, in Europe :

Total amount of urine = 1,500 c.c.

This contains about 60 g. of solids, of which 25 g. are inorganic and 35 g. organic. The chief constituents are distributed roughly as follows :

INORGANIC CONSTITUENTS	
Sodium chloride	15·0 g.
Potassium	3·3 ,,
Sulphuric acid	2·5 ,,
Phosphoric acid	2·5 ,,
Ammonia	0·7 ,,
Magnesium	0·1 ,,
Calcium	0·3 ,,
Other substances	0·2 ,,
Iron	0·005 ,,

ORGANIC CONSTITUENTS	
Urea	30·0 g.
Creatinine	1·0 ,,
Uric acid	0·7 ,,
Hippuric acid	0·7 ,,
Indican	0·01 ,,
Acetone bodies	0·04 ,,

The quantity of urine will naturally vary according to the habit of the individual with regard to the intake of fluids and with his occupation. Thus, after copious sweating, the total amount may fall to 400 c.c. in the course of the day. If large draughts of liquid be taken, it may rise to 3,000 c.c. or more. There are also diurnal variations in the amount secreted, probably depending largely on the circulation through the kidneys. The secretion is at a minimum during sleep, and especially between 2 and 4 o'clock in the morning. It is at its maximum during the first hours after rising, and generally increases after each meal. Muscular exercise may also give an initial increase, owing to the greater vigour of the circulation associated with exercise. If the exercise is severe enough to cause sweating, or is carried to fatigue, there may be a consequent diminution in the amount of urine secreted.

THE INORGANIC CONSTITUENTS OF THE URINE

(*a*) **Anions.** The *chlorides* of the urine are derived from the chlorides of the food. The output of chlorides, which normally varies from 6 to 10 g. Cl. per day, will therefore vary with the intake. On Cl.-free diet the chlorides may almost disappear from the urine, although the blood contains practically the normal amount of chlorides, showing that the body retains essential chloride as long as possible. Chlorides may also temporarily disappear from the urine under various pathological conditions, *e.g.* acute pneumonia.

Sulphates. The sulphates of the urine are derived almost entirely from the oxidation of the sulphur of protein. Hence, as the nitrogen of the urine goes up, so the sulphates will increase. On an average diet, the ratio of urinary nitrogen to SO_4 is about 5 : 1 ; though this ratio will alter with the nature of the protein taken as food. The daily output of sulphuric acid varies between 1·5 and 3 g. SO_4. The greater part is present as sulphates of the alkaline metals. A certain proportion, about 10 per cent., occurs in the form of ethereal sulphates, chiefly indoxyl sulphate. It is formed in the liver by the union of phenolic compounds with the sulphate ion.* A small proportion of the sulphur in the urine is as so-called neutral sulphur. This probably includes a number of different bodies, among which thiocyanates, mercaptans and cystine are the best known.

---

* DAVIES, HALDANE and KENNAWAY. *J. Physiol.*, 1921, **54**, 32.

† LEATHES, *B. M. J.*, 1919, p. 165 ; *Lancet*, 1920, ii., 933.

Phosphates. The phosphates of the urine are derived, partly from the phosphates of the food, partly from the oxidation of the organic phosphorus-containing constituents of the food and of the tissues, *e.g.* nuclein, lecithin, etc. If the food contains much calcium and magnesium, the amount of phosphates excreted in the urine diminishes, since they are excreted with the fæces as calcium and magnesium phosphates. According to the diet therefore, phosphoric acid may be excreted either by the intestine or by the kidneys. The amount of phosphates, reckoned as P_2O_5, excreted in the course of the day may vary between 1 and 5 g. In the urine, the phosphates exist as a mixture of the mono- and di-basic phosphates (Na, K, NH_4, etc.), the relative amounts of the di- and mono- being dependent upon the hydrogen ion concentration of the urine. If the urine is neutral or alkaline there is often a deposit of earthy phosphates. Whether this deposit is present or not, depends on the reaction of the urine. Thus the mono-magnesium phosphate $MgH_4(PO_4)_2$ and the mono-calcium phosphate $CaH_4(PO_4)_2$ are both fairly soluble in water, and would be present in acid urine. With lowered acidity of the urine, the proportion of the two bases present in these forms is diminished. The di-magnesium and di-calcium phosphates are only slightly soluble in water, and would be deposited. One may indeed, in slightly acid urine, find the di-calcium phosphate occasionally present as a crystalline deposit (" stellar phosphate "). On heating the urine, the di-calcium phosphate breaks up into a mono-calcium phosphate and a tri-calcium phosphate, while the acidity of the urine is increased by the solution of the mono-calcium phosphate. Alkaline urine will always present a precipitate of tri-calcium phosphate, $Ca_3(PO_4)_2$. When normal urine is allowed to putrefy, the urea is converted into ammonia, and the urine becomes alkaline. Under such conditions we may often find a crystalline precipitate of ammonium magnesium phosphate, NH_4MgPO_4, the so-called " triple phosphate."

(*b*) **Cations.** The principal ones are potassium, sodium, ammonium, magnesium and calcium.

The amount of *potassium* excreted per day varies between 2 and 3 g., according to the food. With a large meat diet, and in fasting, the output is increased.

The amount of *sodium* excreted in the twenty-four hours is on the average about 5 g., but fluctuates largely with the diet.

Calcium and *magnesium* are invariably present in urine, but in much smaller quantities than the alkaline metals. The average amount of these two bases in the twenty-four hours varies in each case between 0·1 and 0·2 g.

Normal human urine always contains a small amount of *ammonia*, on an average between 0·6 and 0·8 g. in the twenty-four hours. As we have already seen, in dealing with the origin of urea, the quantity of ammonia in the urine is an index to the excess of acids over bases which have to be excreted. Nash and Benedict † showed that the ammonia of the urine is almost entirely formed in the kidney itself, and does not represent an excretion from the blood. It appears to be formed mainly from glutamine, the amide of glutamic acid, which is present in small amount in the blood (except that of the renal vein).*

---

* HELE. *Bioch. J.*, 1931, **25,** 1736.

† NASH and BENEDICT. *J. Biol. Chem.*, 1921, **48,** 463 ; BENEDICT and NASH, *Ibid.*, 1929, **82,** 673.

Traces of *iron* may be excreted by the urine, as a rule less than 5 mg. per day.

ORGANIC CONSTITUENTS OF THE URINE

Of the innumerable organic constituents, many contain nitrogen ; in man on an ordinary mixed diet, most of this is distributed as follows :

Urea	85–90 per cent.
Ammonia	2–4 ,,
Creatinine	3 ,,
Uric acid	1–3 ,,

About 6 per cent. of the urinary nitrogen is in the form of other substances, such as hippuric acid, pigments, etc. All the organic constituents of the urine (except hippuric acid) are obtained direct from the blood ; hence they represent real excretory products. Their origin in the body has already been discussed in Chapter XLVI.

Urea, $CO\!<\!\begin{smallmatrix}NH_2\\NH_2\end{smallmatrix}$. From 20 to 35 g. per day are usually excreted. Urea may easily be prepared from urine by evaporating to dryness with animal charcoal and extracting the dry residue with acetone. On evaporation of the filtered extract, urea crystallises out.

Urea is hydrolysed by certain micro-organisms, *e.g.* the *micrococcus ureæ*, which is responsible for the ammoniacal change which occurs in urine when exposed to the air : $CON_2H_4 + H_2O = CO_2 + 2NH_3$.

This action is due to an enzyme, *urease*, which is also present in certain plant tissues, *e.g.* the seeds of the soya bean. When urea, in slightly acid solution, is incubated with ground soya bean, the urea is all converted into ammonium salts. This forms the basis of a method for the estimation of urea.†

Urea is the most important index to the protein metabolism of the body. It may be regarded as partly exogenous, partly endogenous. The greater part is exogenous, and it is formed in the liver (Chapter XLVI.).

Creatinine. Creatinine usually occurs in quantities of 1·0 to 1·5 g. in the twenty-four hours. It can be prepared from urine by precipitation as picrate, and conversion into the zinc chloride compound, which is then decomposed by ammonia.‡

Uric Acid. 2-6-8-trioxypurine. The amount of uric acid per day varies, according to the diet, from 0·1 to 2·0 g. Uric acid can be prepared from urine by precipitation, as ammonium urate, with ammonium chloride and ammonia.

It is only slightly soluble in water, but soluble in concentrated acids and in alkalies. At physiological *p*H values, uric acid acts as a weak monobasic acid so that it exists as an equilibrium mixture of uric acid and monobasic urate. In urine at the usual *p*H, and in the brick-red amorphous precipitate which occurs in concentrated urine on cooling, the greater part of the uric acid consists of such a mixture. The more acid the urine, the greater the proportion of free uric acid.

Small traces (16 to 60 mg. per day) of *purine bases*, xanthine, hypoxanthine and adenine, also occur in urine. When tea and coffee are taken the methyl purines may occur, namely, caffeine, theobromine and their derivatives.

Allantoin is only present in traces in human urine (5 to 15 mg. per day).

Amino-Acids. Amino-acids are always present in traces in the urine, and contribute per day from 0·1 to 1·0 g. of nitrogen.

Hippuric Acid or benzoyl glycine, $C_6H_5CO{\cdot}NH{\cdot}CH_2COOH$, is a frequent, though not a constant, constituent of human urine. It is derived from benzoic acid, or from substances which, on oxidation, give rise to it.

---

* Van Slyke, *et al.* *J. Biol. Chem.*, 1943, **150,** 481.

† Van Slyke and Cullen. *J. Biol. Chem.*, 1914, **19,** 141 ; Youngburg. *J. Biol. Chem.*, 1921, **45,** 391.

‡ Benedict. *J. Biol. Chem.*, 1914, **18,** 182.

In the dog this coupling can be effected in the kidneys, but in most other animals, including man, it is probable that the synthesis occurs mainly in the liver. In fact, in diseases of the liver, administration of benzoic acid is followed by a slower excretion of hippuric acid than is seen in normal subjects, and this has been made the basis of a liver-function test.*

The amount of hippuric acid excreted in the day may vary between 0·1 and 1 g. After a diet rich in fruit or vegetables its amount may rise to 2 g. It is present in considerable quantities in horses' urine. It forms milk-white crystals, which are only slightly soluble in cold water, but easily soluble in alcohol and in ethyl acetate.

Other Aromatic Substances. The chief of these (about 5 to 20 mg. per day) is the so-called "urinary indican" or potassium-indoxyl-sulphate. This is derived from the indol produced in the intestines from tryptophan by putrefaction (p. 930). It is converted into indigo by the action of mild oxidising agents.

The Urinary Pigments. Normal urine gives no definite absorption bands. It owes its colour to the presence of a yellow pigment, *urochrome*. In order to separate urochrome, urine is acidified slightly with acetic acid and extracted with $\frac{1}{10}$ its volume of *n*-butyl alcohol. After washing and concentrating the alcoholic solution, it is again washed with chloroform, benzene and ether; then after further concentration the solid urochrome crystallises out as a brown powder.† The pigment is precipitated by various salts of heavy metals, and is decolourised by reduction with zinc and HCl. About 73 mg. of urochrome is excreted per day by an average adult, the amount varying with the basal metabolism. Urochrome, on treatment with aldehyde, yields a pigment closely similar to urobilin. On the other hand, urobilin, evaporated with wet ether, is converted into urochrome. Urochrome is therefore probably derived from urobilin, possibly by union with a polypeptide.

Urobilin is only present in traces in normal urine, and then chiefly in the form of a chromogen, *urobilinogen*, from which it must be set free by acidification. In certain pathological conditions, especially in cirrhosis of the liver, urobilin may occur in the urine in considerable quantities.

The urobilin of urine, which has now been obtained in pure crystalline form, is closely related to stercobilin, the colouring matter of the fæces.‡ It is formed in the intestines by the reducing action of micro-organisms on bilirubin, and urobilinogen is a result of further reduction.

Urobilin may be detected in the urine by Schlesinger's test. The urine is acidified with acetic acid and extracted with amyl alcohol. The amyl alcohol layer is removed and a few drops of alcoholic zinc chloride added, when a green fluorescence appears.

Urobilinogen is detected by Ehrlich's test—addition of a solution of *p*-dimethyl-aminoazobenzaldehyde in 50 per cent. HCl gives a red colour.

Uroerythrin gives the pink colour to urate sediments. Its chemical nature is not known. It is distinguished by the fact that on addition of caustic soda the pink colour is changed to green. On suspending the red-coloured precipitate of urates in hot water and extracting with amyl alcohol, a pink solution is obtained which shows two absorption bands in the green part of the spectrum.

Porphyrins of series I (coproporphyrin I, and uroporphyrin I) are present only in very small amounts in normal urine, but under certain conditions, especially after poisoning with sulphonal, may occur in such large quantities as to give the urine a deep purple colour. Under these circumstances they are found in the form of alkaline porphyrins and give the characteristic absorption bands of the latter.

Non-Nitrogenous Organic Constituents. Among these is *oxalic acid*, of which about 30 mg. per day is excreted, though more is present if oxalates are taken by mouth; if soluble calcium salts, or milk, are taken by mouth with oxalate, or with foods (*e.g.* rhubarb) containing it, the oxalate is precipitated and not absorbed, so that the oxalate excretion by the urine is not increased.* There is also *lactic acid*, the amount of which, usually 75 to 200 mg. per day, varies with the amount of muscular exercise recently taken. Glucuronides, various derivatives of sex hormones, vitamins, etc., and traces of aceto-acetic and β-hydroxybutyric acids are also present.

ABNORMAL CONSTITUENTS OF THE URINE †

A large number of substances occur in minute traces in the urine. Most of the so-called pathological constituents may be detected in traces in normal urine. It is only when they occur in easily detectable amounts that their presence becomes of significance.

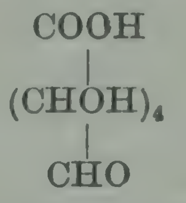
Coagulable Protein. Normal urine contains only minute traces of dissolved protein (av. about 4 mg./100 ml.). When foreign proteins of a molecular weight lower than about 68,000 are present in the blood, these are excreted in the urine; proteins of higher molecular weight, though foreign to the blood stream, are not passed out by the normal kidney.‡ If the kidneys are damaged by disease, by interference with their blood supply or by circulating poisons, the glomerular epithelium permits the passage of a certain amount of the serum albumin and serum globulin of the plasma, and on histological examination the coagulated protein may be seen in Bowman's capsule. The presence of coagulable protein (generally spoken of as albumin) in the urine is associated with Bright's disease. A small trace will often be found in the urine which is passed shortly after taking muscular exercise, but this has no pathognomonic significance.§

Hæmoglobin or its derivatives is present in the urine when hæmolysis occurs in the blood stream or urinary passages (*v.* p. 998).

Sugar. In diabetes, glucose appears in large quantities in the urine. In renal glycosuria glucose appears in the urine, but the blood sugar is rather lower than normal. Lactose may occur in the urine of nursing women.

In rare circumstances, fructose or a pentose may be found in the urine.

Glucuronic Acid. Glucuronic acid is an oxidation product of glucose, having the formula:



$$\begin{array}{c} COOH \\ | \\ (CHOH)_4 \\ | \\ CHO \end{array}$$

It reduces Fehling's solution and is lævorotatory.

About 150 mg. are excreted daily in normal conditions. Most of it is conjugated with other substances to form glucuronides, and this conjugation, effected in the liver, is one means by which poisonous substances when administered or when formed in the body are detoxicated. Camphor, chloral, and to some extent phenol, indol and skatol, and certain steroids related to the sex hormones, *e.g.* pregnandiol, are excreted in the form of glucuronides.

Acetone Bodies. These are *acetoacetic acid*, *β-hydroxybutyric acid* and *acetone*; they are present in traces (20 to 50 mg. per day) in normal urine, and in large amount in untreated severe diabetes, and may also occur in any condition of carbohydrate starvation, relative or absolute (*v.* p. 945).

Cystine. This is found in the urine of certain individuals.‖ The condition represents an inborn error of metabolism, and persists throughout life. In such cases, the cystine may give rise to urinary deposits or even to calculi.

Homogentisic Acid. This is dihydroxyphenyl acetic acid (*v.* p. 929).

It occurs in the urine of individuals affected with *alcaptonuria*.

Bile pigments are present in the urine in jaundice, owing to the presence of bilirubin in greatly increased amount in the blood plasma.

Bile Salts are also often detectable in the urine in obstructive jaundice, *e.g.* in jaundice due to gall-stones.

Urinary Deposits. In addition to formed elements, such as blood corpuscles, bacteria, or pus cells, which may occur in abnormal urine, the following deposits may be found:—

(*a*) *In Acid Urine.* (1) Amorphous urates occur generally as a brick-red amorphous deposit, thrown down as a concentrated urine cools. It is redissolved on warming the urine.

(2) Uric acid. Whetstone, dumb-bell, or sheaf-like aggregations of crystals, generally deeply pigmented so as to resemble cayenne pepper (Fig. 605).

(3) Calcium oxalate (Fig. 604). Colourless, transparent, highly refractive octahedral crystals.

(4) Ammonium magnesium phosphates (in faintly acid or neutral urine). The crystals have been compared to knife-rests or coffin-lids (Figs. 602 and 603).

(5) Calcium hydrogen phosphate, $CaHPO_4$. They form prismatic crystals often arranged in rosettes.

(6) Tyrosine and cystine under very rare circumstances.

(*b*) *In Alkaline Urine.* (1) The commonest precipitate consists of earthy phosphates, amorphous, easily soluble in dilute acetic acid.

(2) Ammonium magnesium phosphate, or triple phosphate (Fig. 603), is common in urine which has undergone ammoniacal fermentation.

2. THE SECRETION OF URINE

With the exception of ammonia, and perhaps hippuric acid, all the constituents of the urine are formed in parts of the body other than the kidneys, which merely excrete them from the blood. Hence extirpation of both kidneys leads to an accumulation of these specific urinary constituents in the blood and tissues. Considered from a broad standpoint, the function of this organ is the preservation of the normal composition of the circulating blood. Whenever the latter contains an abnormal non-colloidal constituent, or normal constituents in abnormal quantities, the kidney excretes the substance in question until the normal composition of the blood is restored. The problem is to determine the conditions which influence the quantity and quality of the urine secreted by the kidneys, and to ascribe to each structural element its proper share in the total work of the kidney.

Structure of the Kidney. Our views as to function are intimately dependent on our knowledge of the structure of the kidney. This organ is a branched tubular gland consisting, in man, of ten to fifteen nearly equal divisions, known as the Malpighian pyramids. In certain animals, such as the rabbit and rat, only one pyramid is present. It is divided into an outer portion, or cortex, an inner portion, the medulla, and between these the " boundary zone," containing the larger branches of the renal blood vessels (Fig. 606). From the outer boundary of the Malpighian pyramids of the medulla, a number of processes, the medullary rays, pass out into the cortex towards the surface of the kidney.

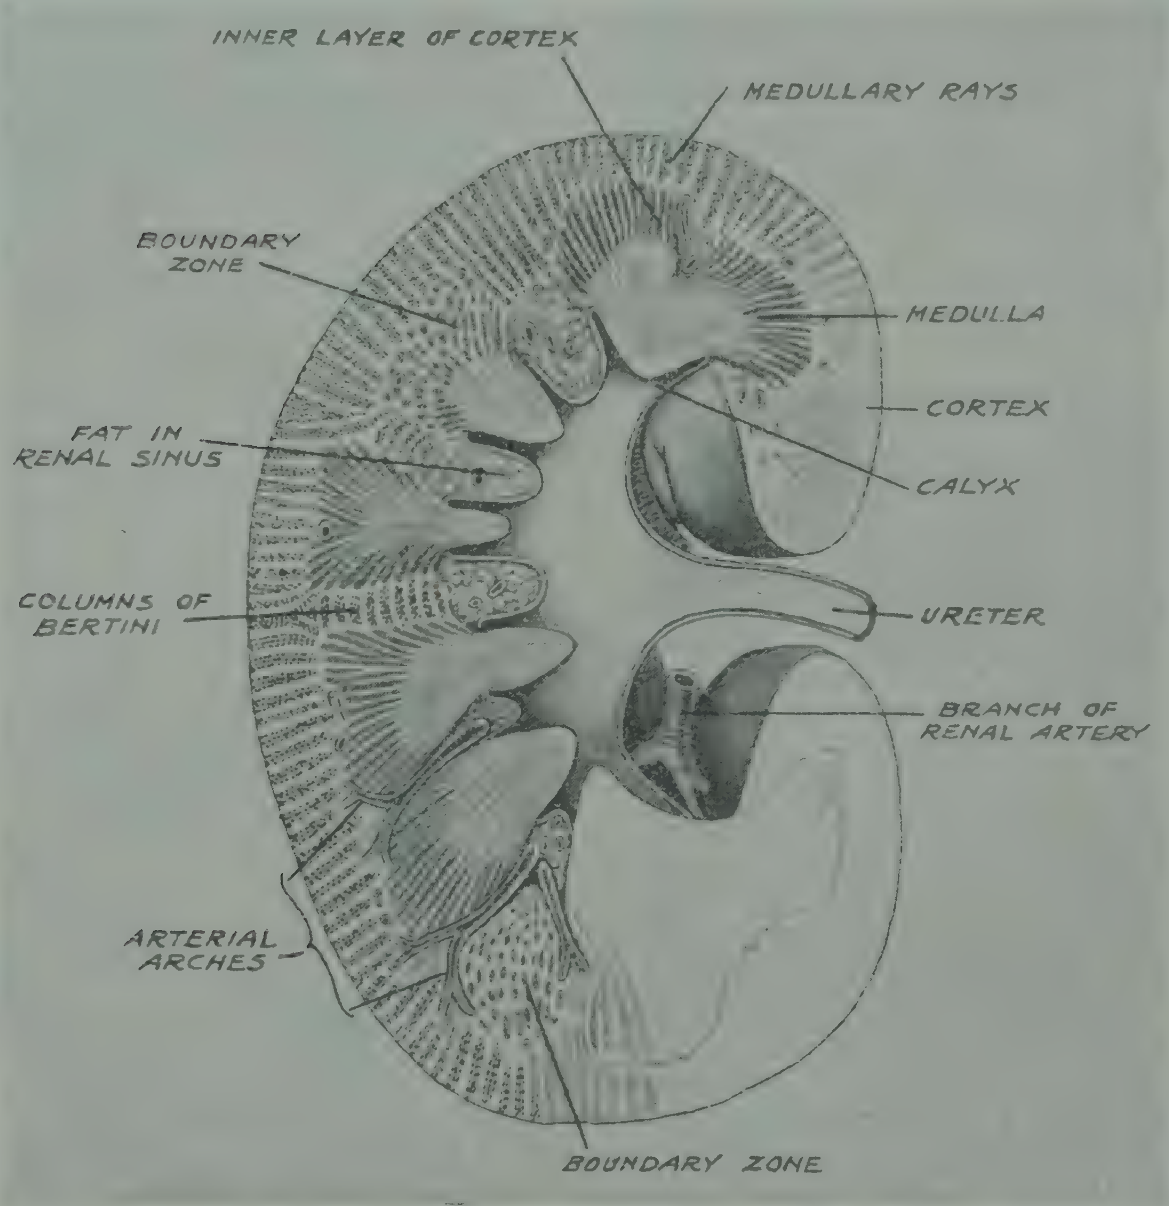

FIG. 606. Longitudinal Section of the Kidney, opening up the Kidney Sinus. The pelvis of the ureter and some of its calyces have been laid open as they lie within the sinus. (RAUBER-KOPSCH.)

The kidney is made up of separate units, or *nephrons*, all of similar structure and function. They are intricate tubules embedded in scanty connective tissue and richly supplied with blood vessels (Fig. 608). Each nephron begins by a blind dilated extremity in the cortex, known as *Bowman's capsule*, which surrounds a bunch of capillary blood vessels, the *glomerulus*, the two together forming the *Malpighian body*. In most mammals there are roughly 2 million glomeruli in the two kidneys for each sq. m. of body surface.* This means that the number is correlated with the general metabolism of the body. In man there is a greater weight of kidney, but fewer glomeruli, per sq. m. of body surface, and the blood flow to each nephron is greater than in rabbit or dog.

---

* KUNKEL. *Bull. Johns Hopk. Hosp.*, 1930, **47,** 285.

From Bowman's capsule a short *neck* (or 1st segment) leads into a *proximal convoluted tubule* (or 2nd segment), and this into a U-shaped portion which passes down into the medulla, and consists of straight *descending* (3rd segment) *and ascending limbs and the loop of Henle* (Fig. 608). The ascending limb passes into a *distal convoluted tubule* (which, together with the ascending limb of Henle, is called the 4th segment), and this by a *junctional tubule* (5th segment) joins with a number of others to form a straight *collecting tubule.* Several of these unite to form the papillary ducts, which open on the surface of the papilla in the calyx. The whole tubule consists of epithelium lying on a basement membrane; the epithelium varies in structure in different parts of the tubule. The glomerular capillaries are covered with a very thin layer of endothelial cells, and a similar layer forms the lining of Bowman's capsule. The convoluted tubules contain cells which are cylindrical in cross-section and have long been distinguished as "rodded epithelium" (Fig. 607) on account of the ease with which a radial disposition of rods or granules is demonstrated in their protoplasm. Moreover, the free margin of the cells, instead of being irregular, consists of a well-marked striated border, formed of a number of very fine processes closely set together and springing from a row of granules in the peripheral part of the cell (Fig. 607). The processes, which make up the striated border, have not been observed to present ciliary movement, and are probably comparable with the similar structures found clothing the free border of the epithelium of the intestinal villus. The descending limb of Henle's loop is narrow, and possesses flattened epithelial cells, while the ascending limb presents an epithelium similar to that of the convoluted tubules, but with less marked striation. The junctional and collecting tubules are lined with cubical or columnar cells with a clear protoplasm.

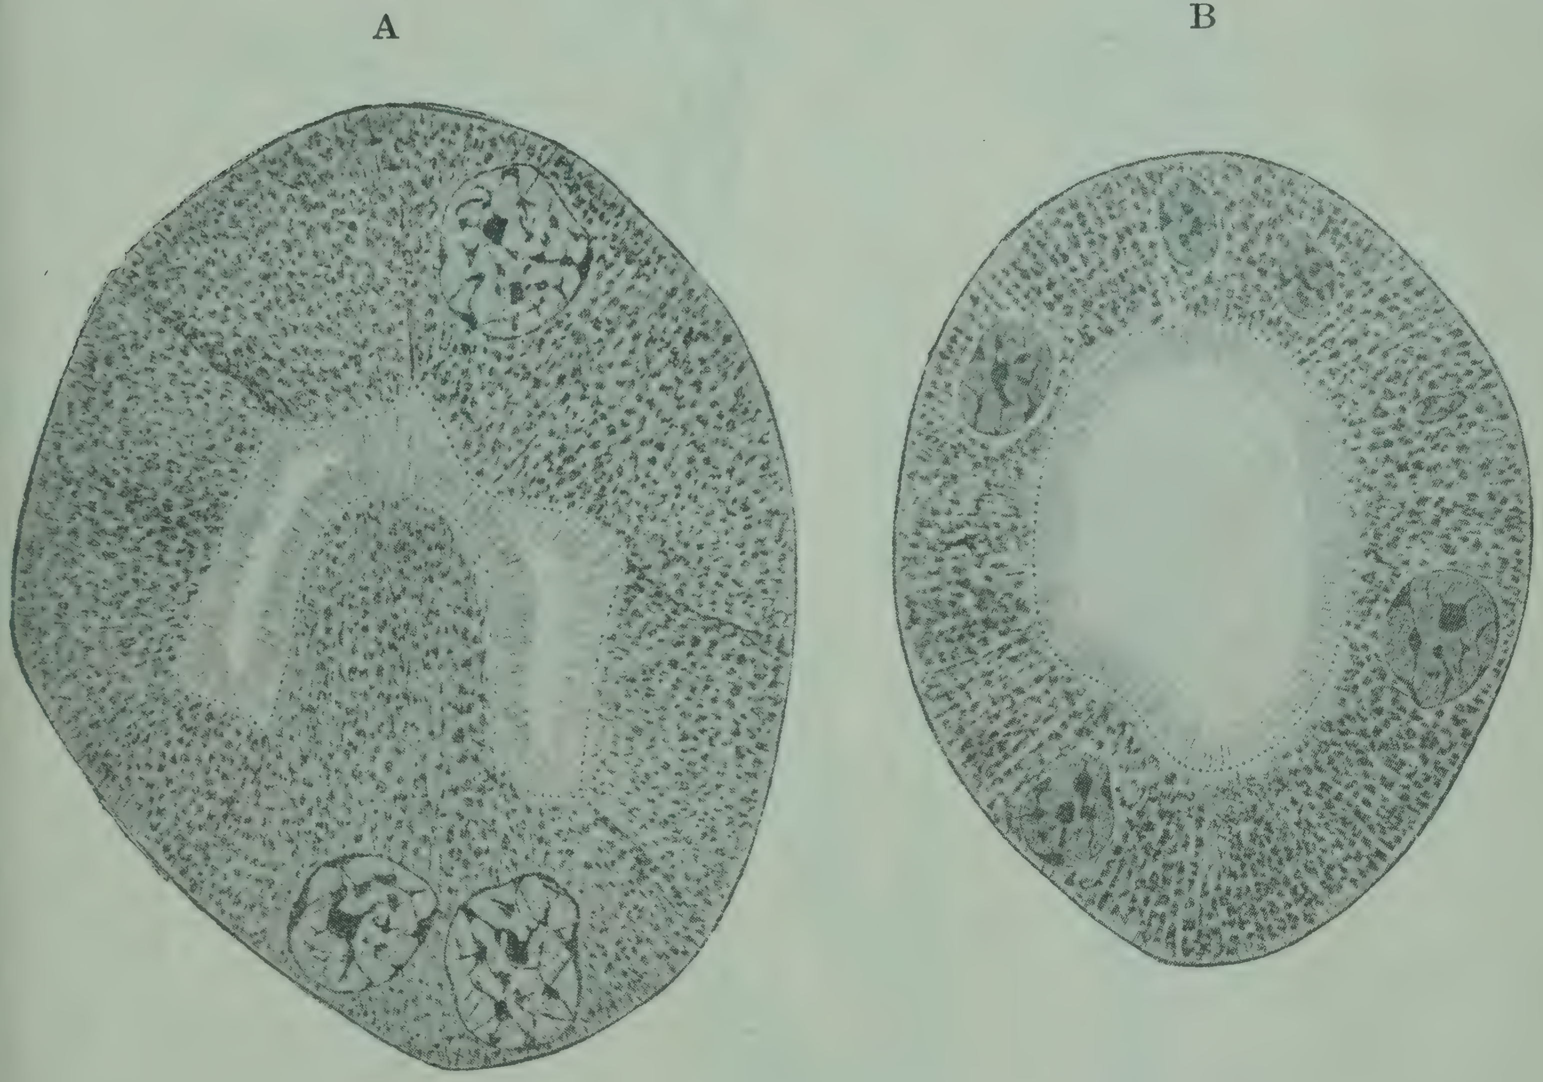

FIG. 607. Cross sections of Convoluted Tubules from Kidney of Rat. (SAUER.)
A. During slight secretion. B. During maximal secretion.

The clear differences between the structure of these various parts point to a differentiation of function. This conclusion is borne out by a study of the blood supply which in the medulla is quite different from that in the cortex. The renal artery divides in the pelvis into five or six branches which pass up to the boundary zone and there give off arteries which run towards the surface and are called the interlobular arteries. Each of these, which is an end-artery presenting no anastomoses with its fellows, gives off on all sides short wide branches, which pass to the glomeruli and constitute the *vasa afferentia* of these bodies. Each vas afferens has a thick muscular wall.

In the vicinity of the afferent arteriole the cells of the distal convoluted tubule are densely packed, and near to the glomerulus the afferent arteriole contains numerous epithelioid cells which are believed to alter in volume, so regulating the blood flow through the glomerulus, perhaps in relation to the contents of the distal tubule; in some conditions of arterial hypertension they become hypertrophied, and are thought by some to be sites of production of renin (p. 659); others believe that renin is produced in the proximal tubules. The glomerulus itself consists of a number of wide capillaries invested by an extremely thin wall. The glomerular capillaries are collected together to form an efferent vessel, the *vas efferens*, which is narrower than the vas afferens and, like the latter, presents a well-marked muscular coat. By alteration in the tone of the afferent and efferent arterioles the blood flow through the cortex and the intraglomerular pressure can be widely varied. The vas efferens breaks up again into a second set of capillaries, which ramify round the tubules of the cortex. From the capillaries of the tubules, the blood is collected again into veins, which leave the kidney partly by the cortex and capsular vessels, chiefly by inter-lobular veins and thence by large trunks which join to form the renal vein at the hilum of the kidney.

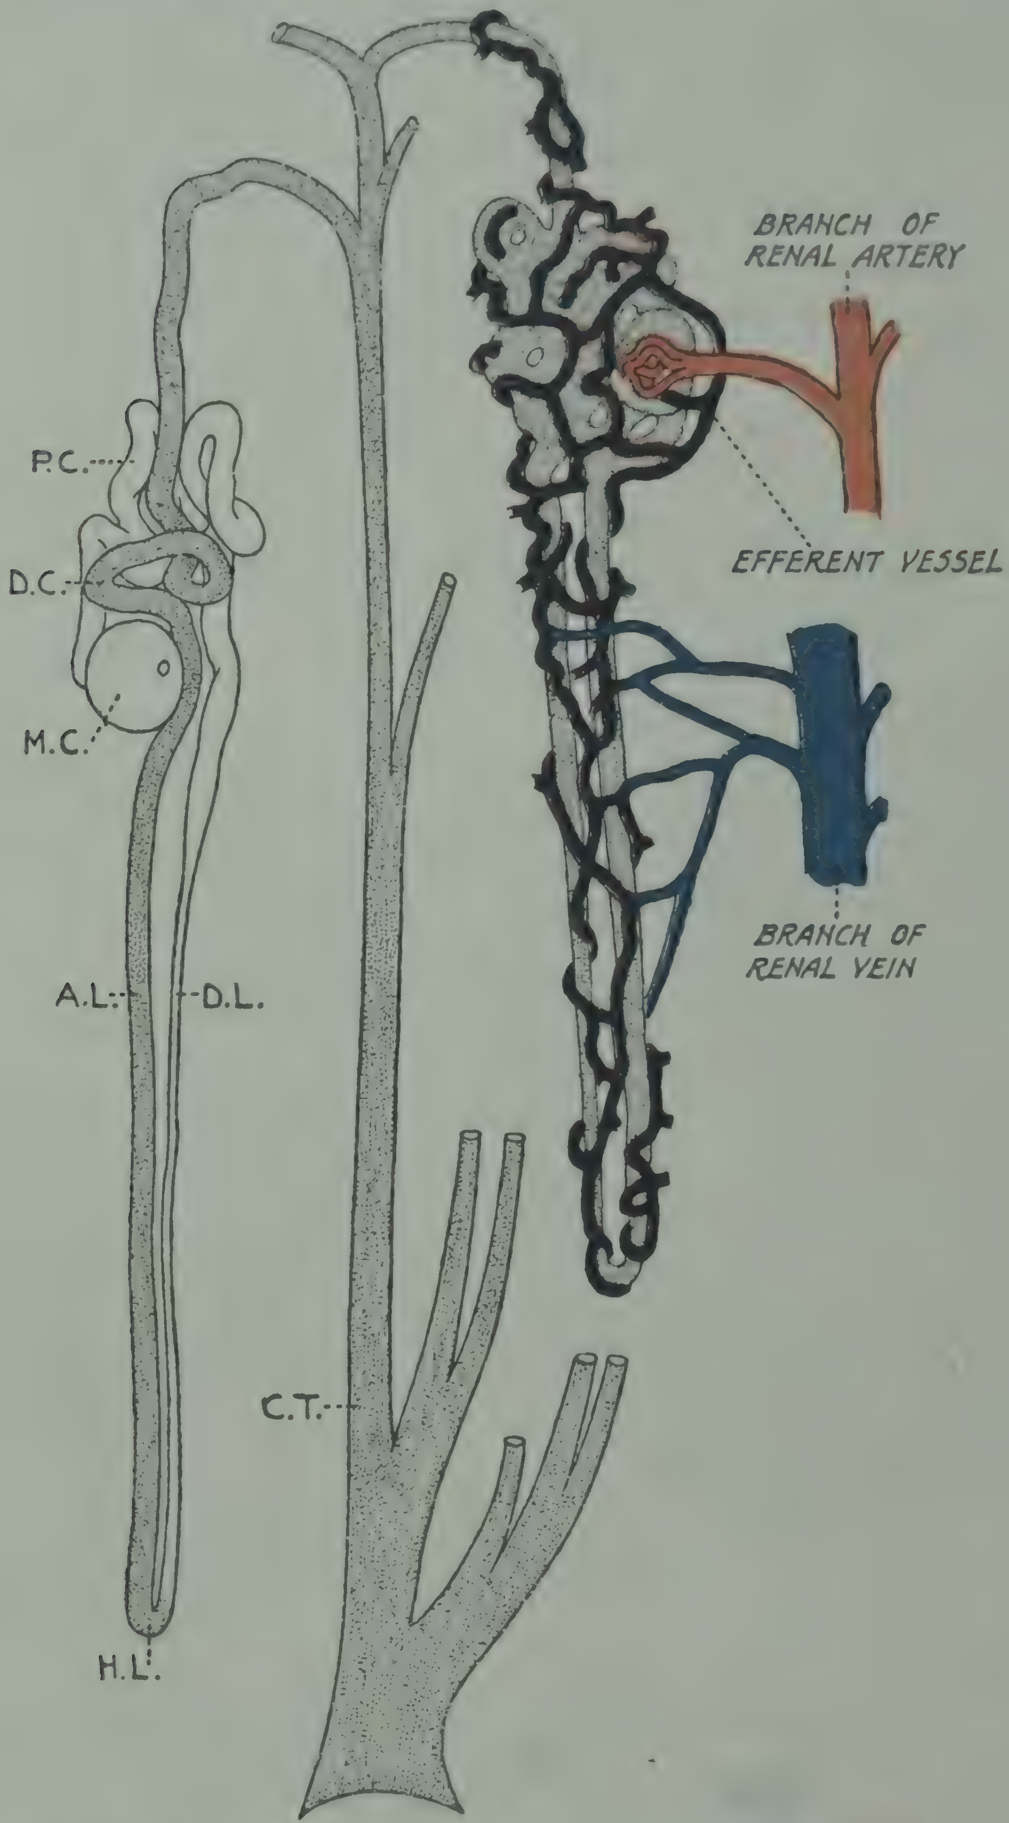

Fig. 608. Diagram of Two Nephrons. On the left, the tubule is outlined from the capsule to the loop of Henle and is shaded from that point to the end of the collecting tubule. On the right, a diagram of the circulation is added. M.C., Malpighian capsule. P.C., Proximal convoluted tubule. D.L., Descending limb. H.L., Loop of Henle. A.L., Ascending limb. The blood supply to the medulla is peculiar, and is derived from the efferent arterioles of the glomeruli nearest to the medulla (juxtamedullary glomeruli); these glomeruli are often simplified in pattern. Their efferent arterioles break up into tufts of long, roughly straight and parallel vessels, which are matched by corresponding veins that open into the inter-lobular veins (Fig. 609). These vessels are called the *vasa recta*, and from the arterioles some capillaries branch off and supply the medullary tubules. But in the main the juxtamedullary arterial vessels loop back directly into the venous ones, at various levels.* This arrangement constitutes an arterio-venous shunt which, when closed, diverts the blood supply to the cortex, and when fully open can divert much of the supply to the medulla and render the cortex ischæmic. Taken together with the vascular control in the cortex itself, this gives a very wide range of separate variability in the blood supply of cortex and medulla.

The kidney is richly supplied with nerves derived mainly from the 6th to 13th dorsal spinal roots,† which are chiefly distributed to the muscular walls of its blood vessels.

FIG. 609. Diagram of blood supply of Cortex and Medulla of the kidney. (Reprinted from "X-ray Studies of the Kidney Circulation" (FRANKLIN, *Science News*, No. 10, 1949), by courtesy of Penguin Books Ltd.)

Some authors have described a fine nerve-plexus surrounding the tubules and sending branches between and into the cells of the convoluted tubules themselves. There is no evidence that the secretion of urine is influenced by the nerves, except through their effects on the blood vessels ‡ : a transplanted kidney functions in agreement with this.§

Relation of Structure to Function. The main points in the structure of the kidney were made out by Bowman * and suggested the two theories of urinary secretion, those of Bowman and of Ludwig (1844),† which have furnished the basis of all subsequent investigation of the subject. Both observers appreciated the great difference between the "membrane" covering the glomerular loop and that of the lining of the tubule, and both drew attention to the difference in the circulation in these two portions of the kidney. The glomerular capillaries, supplied with blood through a short wide artery, and drained by an efferent vessel smaller than the afferent, would represent a region of relatively high capillary blood pressure, whereas the pressure in the capillaries surrounding the tubules must be at least as low as that in most other capillary regions. Bowman therefore suggested that the urine arises from two sources, namely, one part containing the water and salts, produced by a process of filtration through the walls of the glomerular capillaries, and another part containing the specific urinary constituents, urea, uric acid, etc., secreted by the cells of the convoluted tubules and added to the dilute glomerular product as it passed on its course along them.

To Ludwig, on the other hand, it seemed possible, at first, to account for the whole process of formation of urine on the assumption that absorption, and not secretion, was the main function of the tubules. He imagined that the whole of the urinary constituents passed, together with much water, through the walls of the vessels of the glomerulus by filtration from the blood. The glomerular transudate, filtering through what is nowadays called the "glomerular membrane," into the Bowman's capsule, would represent, therefore, an ultrafiltrate of blood plasma, and this view still holds the field as the most likely explanation of the functions of the Malpighian body. Ludwig ascribed the great difference in urea content between the blood and the urine to a concentration taking place in the fluid in its passage along the tubules, in which water and certain of the salts were reabsorbed; a process of reabsorption conditioned by the difference in protein content between the urine within the tubules and the tissue fluid and blood under low pressure on the outside of the tubules.

In its original form, the theory of Ludwig is untenable, because the difference of osmotic pressure between blood plasma and its ultrafiltrate is too small to attract from the filtrate back again into the blood enough water to produce the requisite concentration, even of urea, found in urine.

For the production of urine from the glomerular filtrate, a certain amount of work would have to be done by the cells of the tubules in abstracting the necessary amount of water and returning it to the blood. The minimum work necessary to form a given amount of urine of a given concentration, from blood of average composition, can be found very roughly by comparison of their osmotic pressures, by any of the methods described in Chapter V. For example, we may find their freezing points. A depression of freezing point of 1° C. in an aqueous solution corresponds to an osmotic pressure of 122·7 m. of water and hence, to concentrate a fluid with a freezing-point of −1° C. to one with a freezing-point of −2° C., would require an expenditure of work equivalent to that required to compress 100 c.c. of a gas at a pressure of 122·7 m. of water to half its bulk. In this way it has been calculated that the work necessary to change a fluid of $\Delta = -0{\cdot}56^\circ$ C. (such as plasma) to one of $\Delta = -2{\cdot}3^\circ$ C. (urine), and to yield 1,000 c.c. of the latter would be of the order of 215 kg.m.

More exact calculation would involve the application of thermodynamics, since it would necessitate the separate calculations of the "free energy" changes involved in all the important changes of concentration that occur in converting the glomerular filtrate into the urine. Such calculations have been made,‡ and indicate that for average human urine the kidney does work amounting to about 0·7 gram calories per c.c. of urine formed, or 70 gram cals. per gram of nitrogen excreted. This would amount to about 300 kg.m. per litre of urine, or, taking accepted values for the oxygen usages of the kidneys, say 2–4 c.c./g./hr.,§ an "efficiency" of about 1 per cent. Direct estimation of the constituent of the urine and of the oxygen usages of the kidney also give efficiencies of about 1 per cent for isolated perfused dog's kidneys.‖

§ Fee and Hemingway. *J. Physiol.*, 1928, **65**, 100.

‖ Eggleton, Pappenheimer and Winton. *J. Physiol.*, 1940, **96**, 363.

This amount of work done in order to bring about concentration is not prohibitively high, and in any case is the same, by whatever way the urine is produced. In man, the actual work done is really trivial when compared with that effected by the heart, which, though not weighing much more than the two kidneys, would do at least thirty times as much work in the same time.

However, it is certain that the formation of urine from glomerular filtrate does not occur in any simple fashion. If we compare the composition of blood plasma with that of urine, as in the table given below, we see that the constituents are concentrated to very different extents, so that urine formation, whether by reabsorption or by secretion is a selective process.

RELATIVE COMPOSITIONS OF BLOOD PLASMA AND NORMAL URINE IN MAN.

	Blood plasma, per cent.	Urine, per cent.	Change in concentration in kidney.
Water	90–93	95	—
Proteins, fats and other colloids	7–9	—	—
Glucose	0·1	—	—
Urea	0·03	2	60
Uric acid	0·003	0·05	17
Na	0·32	0·35	1
K	0·02	0·15	7
Ca	0·008	0·015	2
Mg	0·0025	0·006	2
Cl	0·37	0·6	2
PO_4	0·009	0·27	30
SO_4	0·003	0·18	60
Creatinine	0·001	0·10	100

The abandonment of Ludwig's view as to the exact mechanism of the concentration does not, however, place his theory out of court. The questions that will still have to be discussed are whether the chief object of the tubules is the concentration of the fluid produced in the glomeruli, or whether they add to this fluid by a further secretory process, or whether they may not possess both functions, and, in their various parts, alter the fluid flowing through them, either by addition or by withdrawal of water or dissolved constituents. The questions which we have to decide by experiment are :

(1) The nature of the glomerular function, the conditions which determine the amount of fluid formed by the glomeruli, and, especially, whether or not the energy required for the formation of the glomerular fluid is all furnished by the blood pressure within the capillaries.

(2) The function of the tubules, whether they secrete or absorb, and in either case, what substances ; also what parts are played in these processes by the various segments of the tubules, which differ so widely in their histological characters.

FUNCTIONS OF THE GLOMERULI

It is generally agreed that a watery exudation, free from protein, is formed in the glomeruli, and that this becomes concentrated on its way through the tubules, either by the absorption of water and certain salts from it, or by the secretion and addition of urea, uric acid, etc., to it. As to the nature of the glomerular functions, two opinions have been held. According to the Ludwig school, the process is one of simple ultrafiltration, in which, under the pressure of the blood in the glomerular capillaries, some 20 per cent. of the water and crystalloid constituents of the plasma are filtered through the glomerular membrane, leaving the protein constituents behind. This view is now thoroughly vindicated. Heidenhain believed that the process also involved a secretory activity of the glomerular epithelium. If we are to accept the opinion that the only function of the glomeruli is that of filtration, the energy for which is supplied by the blood pressure, certain conditions must be fulfilled. Briefly, they are these :

(1) The fluid passed out from the blood into the Bowman's capsules must be identical with the blood plasma *minus* its colloids.

(2) The blood pressure in the glomerular capillaries must be great enough to form the requisite amount of filtrate, and the amount of filtrate formed must vary with that pressure, and, within certain limits, only with that.

There are other requirements also, which follow in the nature of corollaries to these.

One of the difficulties of experimentation on the kidney is that, according to all reasonable theories, the glomerular filtrate must suffer great modification, in volume, in composition, or in both, as it passes along the tubule. The essential problem then is to attempt to disentangle the functions of the glomerular and the tubular portions, and this has, in part, been solved.

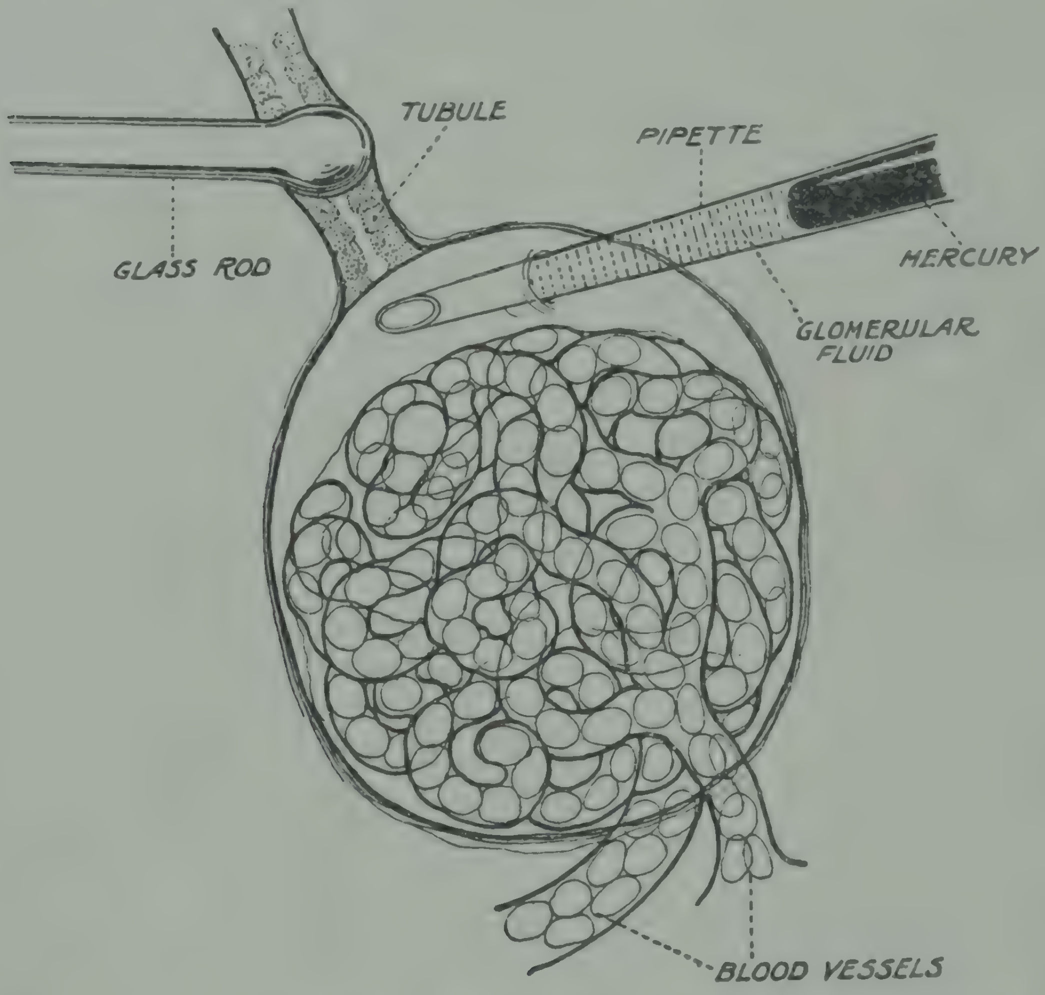

FIG. 610. Diagram to illustrate Richards' method of obtaining samples of glomerular fluid from Bowman's Capsule in the Frog.

The tubule leading from the capsule is closed by pressing on it with a fine glass rod, operated by a micromanipulator (*v.* p. 11). A very fine glass pipette, connected with a reservoir of mercury, is thrust, by a micromanipulator, through the wall of the capsule, and fluid drawn into it by gradually lowering the mercury reservoir. (Winton and Bayliss's "Human Physiology.")

(1) **The Composition of the Glomerular Transudate.** There is abundant evidence that the glomerular transudate has a composition identical with that of the plasma *minus* protein. Thus Richards and his colleagues * inserted capillary pipettes into the Bowman's capsule of the frog's kidney, and so obtained directly a small amount of fluid from the capsule (Fig. 610). By micro-chemical methods they showed that the concentration of chlorides, urea, uric acid, phosphate, glucose or various added substances, such as phenol red, etc., in this fluid, was approximately equal to that in a plasma filtrate from the same blood. The kidney of *Necturus*, which has very large capsules, was similarly examined,† and gave glomerular fluid, which resembled that of the

† WHITE and SCHMITT. *Science*, 1925, **62**, 334 ; WHITE. *Amer. J. Physiol.*, 1928, **85**, 191.

frog. The fluid in both these animals contained glucose, which is absent from the urine. Further, the general identity of the glomerular fluid with a plasma ultra-filtrate was shown, for both frog and *Necturus*, by Bayliss and Walker * ; they showed that the electrical conductivity of the fluid prepared by filtering the blood plasma through cellophane was identical with that of the glomerular fluid drawn by puncture.

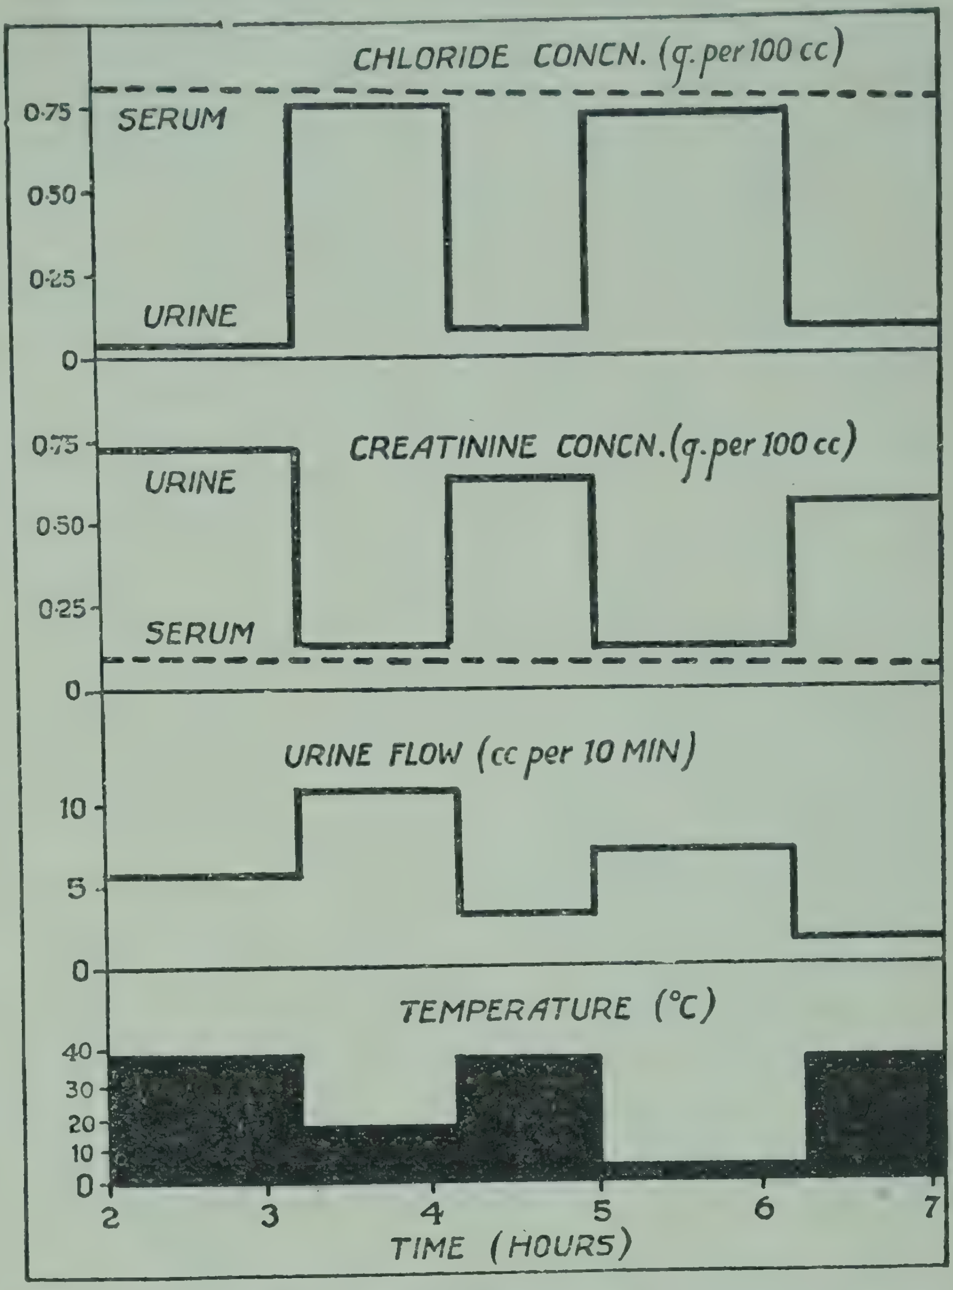

FIG. 611. Effect of Temperature on isolated perfused Dog's Kidney. Cooling put the tubules out of action, so that the urine flow increased, while the chloride content increased and the creatinine content diminished to nearly the same values as in the serum. (BICKFORD and WINTON.)

The collection and analysis of fluid from the glomeruli and other parts of the nephron of mammalian kidneys has also been effected, and with similar results.†

The direct evidence obtained from these experiments is so compelling that there is need for little other.

It has been possible to obtain some indirect evidence on the mammalian kidney. Bainbridge and Evans ‡ connected an excised dog's kidney "in parallel" with the arterial side of a heart-lung circulation, and obtained a secretion of urine. The blood-perfused isolated kidney has since been extensively used by Verney and Starling, and by Winton. A constant circulation of warm oxygenated blood can be maintained, the pressure, velocity and composition of the blood supplied to the kidney being under control. The urine obtained from the perfused kidney contains urea, creatinine, and certain colouring matters in higher percentage than they are present in the circulating blood. The urine is, however, hypotonic and contains only 0·02 to 0·2 per cent. NaCl, as against 0·65 per cent. or more in the plasma of the circulating blood ; creatinine, on the other hand, is present in a concentration several times greater than that in the plasma. It is believed that this is because chloride has been absorbed from the glomerular filtrate as it passes down the tubules, while creatinine has been concentrated by removal of water.

If the fluid produced by the glomeruli is similar in its molecular concentration to the circulating plasma, the alterations on its way down the tubules, however effected, must necessitate the expenditure of energy on the part of the cells lining the tubules. Bickford and Winton § subjected such perfused kidneys to different temperatures and found that when cooled to 25° C. the urine flow was increased, while its composition came very closely to resemble that of an ultra-filtrate of plasma, *i.e.* the chloride increased and the creatinine diminished (Fig. 611). They explained this change as due to the effect of the cold in depressing the activity of the tubule cells and so causing a reduction in the absorption of chloride and of water. A similar effect is produced by poisoning the tubules by adding HCN to the blood: the urinary chloride increases and the urea diminishes.*

Further, the composition of the urine approximates more closely to that of glomerular transudate when the filtration is rapid, because the transudate travels more rapidly along the tubules, so allowing less time for alteration to occur in it, the more rapidly the formation takes place. The following experiment shows that this is the case. The rate of secretion of a kidney in a heart-lung-kidney preparation was altered by altering the arterial blood pressure. Sodium chloride and urea were added to the blood.† It will be observed that as the urine flow accelerated the urine chloride rose and the urea fell, both of which changes approximated it in composition to the blood serum.

2·30	95	43·5	0·99	0·54	0·042	0·112

In accordance with the theory, the total quantity of a solid excreted in a given time should rise with any increase in the urinary flow—for whatever the activity of the tubules, the glomeruli must blindly turn out a constant concentration of solutes. Thus, in the above quoted experiment, the following amounts of urea and chloride were excreted per fifteen minutes:

Urine flow, c.c.	mg. Urea.	mg. NaCl.
14·6	61	51
91·5	81	630
43·5	49	235

Proteins are normally absent from the glomerular filtrate and from the urine, since the glomerular membrane will not allow the normal plasma proteins to pass. It is, however, somewhat permeable, the pores being only just small enough to hold back the plasma proteins, the smallest molecules of which are serum albumin with a molecular weight of 72,000 ‡ and diameter of 38 Å. Hæmoglobin, if present owing to hæmolysis, is passed out and appears in the urine if it exceeds a certain small amount in the plasma; its molecular weight is 67,000. If egg albumin, or Bence-Jones protein, or gelatin (35,000, diam. 18 Å) are added to the blood, they are freely excreted, whereas foreign proteins of high molecular weight, *e.g.* casein (200,000), are not.

Damage to the glomerular membrane by oxygen lack, or by certain diseases, increases the permeability so that the normal serum proteins are excreted, giving rise to the condition of albuminuria. Some persons are at the threshold and pass albumin in the urine when up and about but not when lying in bed (postural proteinuria).

A more likely explanation of postural proteinuria is that the inferior vena cava is compressed against the spine by the liver when the subject is in a lordotic posture, and this causes passive congestion of the kidney and so proteinuria.§

(2) **Factors affecting the Amount of Glomerular Filtrate.** The theory that the fluid formed in Bowman's capsule is an ultra-filtrate of the blood in the glomerular capillaries would lead us to anticipate that the rate at which it is formed in each glomerulus would be determined by factors essentially mechanical in nature. These are the ureter pressure, the venous pressure, the glomerular capillary pressure, the intrarenal pressure (*i.e.* the pressure in the kidney substance) and the extrarenal pressure (*i.e.* the pressure on the outside of the kidney). The resultant of all these is called the *effective filtration pressure.* This would be increased by increase of blood pressure in the glomeruli and opposed by increase of pressure in the Bowman's capsule or ureters.

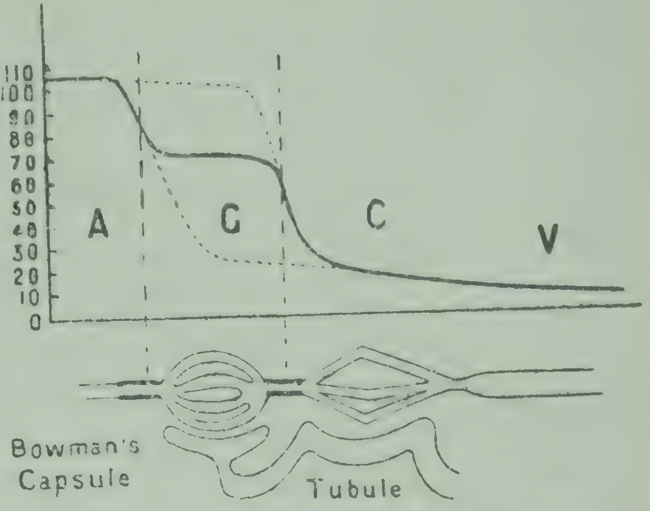

FIG. 612. Diagram (after MORAT) to illustrate the effect of Active Changes in the Vasa Afferentia and Efferentia on the Pressure in the Glomerular Capillaries.

If the vas afferens constricts, the pressure will be represented by the lower dotted line. On the other hand, constriction of the vas efferens would raise the pressure in the glomerulus till it almost equalled that in the renal artery, as is shown by the upper dotted line.

A. Arteries.
C. Tubular capillaries.
G. Glomerular capillaries.
V. Vein.

There are, however, various factors which complicate this apparently simple relationship. One of these is that the number of glomeruli through which blood is circulating is not necessarily constant. It has been shown * that under certain circumstances, glomeruli of the frog's kidney can be seen to constrict so that no blood passes through them. Intermittent closure of the glomeruli is to some extent spontaneous, but the number so closed is greatly increased by stimulation of the kidney nerves, by various reflexes, and by adrenaline. It is thought that closure of the glomeruli in this way is not a frequent phenomenon in the mammalian kidney, and it is now commonly disregarded.

Another complicating factor is possible, should the afferent and efferent glomerular arterioles have different states of tonus, and this condition actually occurs. If a constriction affects the afferent arteriole, the result anticipated would be a reduction of blood flow, a fall in glomerular pressure and a lowered rate of glomerular filtration: on the other hand, with a constriction affecting only the efferent arteriole, the result would be again a reduction of blood flow, but with it a rise of glomerular pressure and of filtration rate (Fig. 612). In the isolated mammalian kidney, adrenaline in very small concentrations causes diuresis with slowing of the blood flow; in larger amounts it lowers the flow of blood still more and then the urine flow is reduced. The smaller doses constrict the efferent arterioles and relax the afferent ones, thus raising the glomerular pressure; larger doses constrict both vessels.† In man, too, adrenaline in small doses acts in a similar manner, reducing blood flow but not filtration rate. In general there is a reciprocal relation between glomerular pressure and blood flow, because in man the renal blood flow is regulated mainly by the efferent arterioles: hence filtration rate tends to remain constant in spite of change in blood flow, if the latter is the result of local regulation.

The pressure in the glomerular capillaries can be raised, not only by an increase of general arterial pressure, but also by a relaxation of the afferent arterioles (if these are constricted), which would diminish the resistance to the blood flow into the kidney. Hence, if, in an anæsthetised animal, in which considerable sympathetic muscular tone exists, the nerves entering the kidney be divided, the arterioles of the organ become dilated and the urine flow is increased.* It should be noted, however, that in the normal, unanæsthetised animal, the renal vessels are apparently not in a state of tonic constriction, since denervation of the kidney is without effect on the rate of urine formation.† In many of the older experiments it was shown that, in general, an increase of the volume of the kidney, due to a rise of arterial pressure, and/or to a relaxation of the renal arterioles, accompanied an increase of urine secretion. Conversely, constriction of the renal arterioles, as by stimulation of the splanchnic or renal nerves, or a fall of blood pressure, led to shrinkage of the kidney and reduction in the urine flow.

* RICHARDS and SCHMIDT. *Amer. J. Physiol.*, 1924, **71**, 178.

† WINTON. *J. Physiol.*, 1931, **73**, 151.

An important practical point arises in this connection. It has been stated that reflex suppression of urine secretion may occur after surgical operations; suppression may also follow on serious dehydration due to vomiting, diarrhœa, etc. The probable explanation is that these conditions all decrease glomerular filtration and low blood pressure may be a cause of this; death from renal failure may thus occur without any renal disease.

The urinary secretion can be stopped by obstruction of the ureter. On applying a ligature, the secretion continues for a time, until the pressure in the ureter rises up to a certain point, when the secretion comes to an end. This usually happens when the difference of pressure between urine in the ureter and blood in arteries is between 40 and 50 mm. Hg.

Experiments on the heart-lung-kidney have shown that the effects of alteration of ureter pressure are somewhat complex, but that when the rate of urine formation is changed by alteration of the ureter pressure, the resulting alterations in the composition of the urine are the same as those produced when the rate of urine formation is changed to the same extent by an alteration in the arterial pressure.‡

It was objected by Heidenhain § that, according to the filtration hypothesis, a rise of pressure in the renal vein should raise the glomerular pressure and so accelerate the rate of urine formation, whereas, in fact, it retards it. It appears that this is because the effect of the rise of renal vein pressure produces its greatest effect in pressing upon the tubules and so by increasing the intrarenal pressure, retarding the flow of urine in the same way as does a rise of ureter pressure.‖ Whether the urine flow is retarded by raising ureter pressure, raising the venous pressure, or lowering the arterial pressure, however, the resulting alterations in the composition of the urine are practically identical.

Magnitude of the Filtration Pressure. Working against the mechanical filtration pressure is the colloid osmotic pressure of the blood plasma. The proteins of plasma exert an osmotic pressure of about 30 mm. Hg. Hence, for ultrafiltration to be possible the pressure in Bowman's capsule, and in the ureter, must be at least 30 mm. Hg lower than that of the blood in the glomeruli.

The anatomical arrangements are such as to bring the glomerular blood pressure up to a high value. The vasa afferentia are short, and the vasa efferentia are only two-thirds of the diameter of the vasa afferentia. Moreover, the sudden increase of bed in the bundle of capillaries must itself diminish the fall of pressure in the latter, or might even cause an actual slight rise, owing to the transformation of the kinetic energy of the moving fluid into potential energy, *i.e.*, pressure on the walls of the capillaries. It has been shown by White, however, that this effect is small. In the frog, Hayman ¶ has directly estimated the pressures in the various vessels to be as follows :—

Aorta	37·3 cm. H_2O	
Afferent arteriole of glomerulus .	31·0 ,, ,,	or 84 per cent. of aortic pressure.
Capillaries of glomerulus . .	20·0 ,, ,,	,, 54 ,, ,, ,,
Renal portal vein . . .	5·2 ,, ,,	,, 14 ,, ,, ,,
Renal vein	2·6 ,, ,,	,, 7·1 ,, ,, ,,

The colloidal osmotic pressure of the frog's plasma was estimated by White to be about 10 cm. H_2O, which would leave a margin of 4 to 10 cm. H_2O for filtration pressure.

An indirect method for estimating the mammalian glomerular capillary pressure * indicates a glomerular pressure about 0·65 of the arterial pressure.

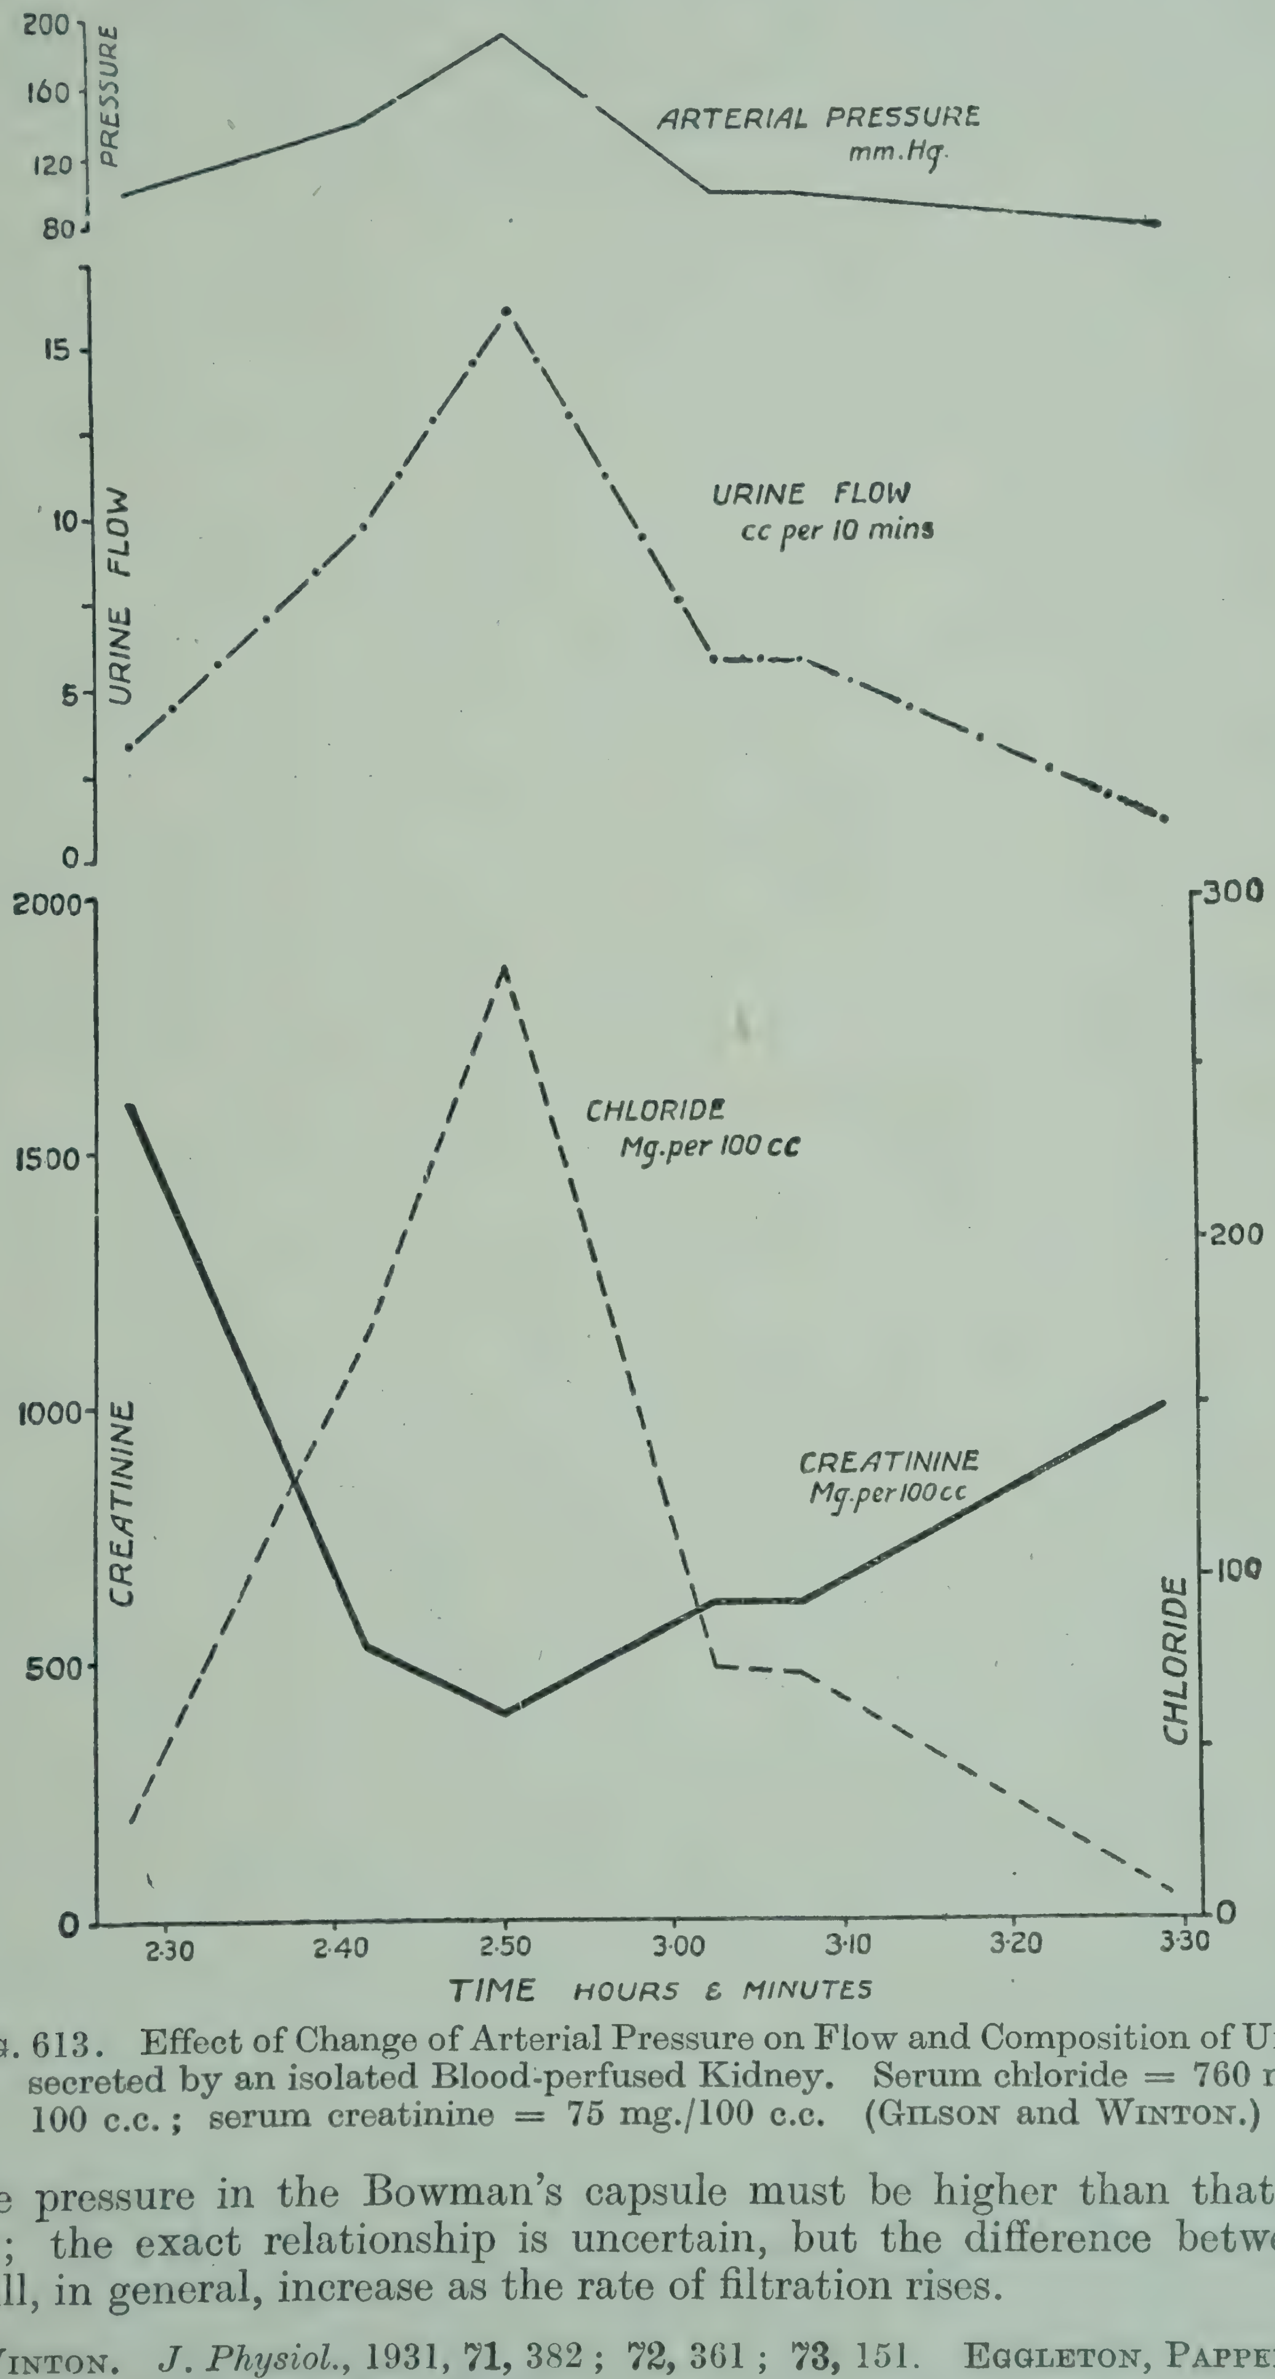

FIG. 613. Effect of Change of Arterial Pressure on Flow and Composition of Urine secreted by an isolated Blood-perfused Kidney. Serum chloride = 760 mg./100 c.c.; serum creatinine = 75 mg./100 c.c. (GILSON and WINTON.)

The pressure in the Bowman's capsule must be higher than that in the ureter; the exact relationship is uncertain, but the difference between the two will, in general, increase as the rate of filtration rises.

---

* WINTON. *J. Physiol.*, 1931, **71,** 382; **72,** 361; **73,** 151. EGGLETON, PAPPENHEIMER and WINTON. *J. Physiol.*, 1940, **99,** 135.

There may thus be, on the two sides of the glomerular membrane, a difference of pressure more than sufficient to cause a filtration of a protein-free fluid from the blood plasma coursing through these capillaries. On lowering the arterial pressure, or on raising the pressure on the tubule side, the filtration ought to come to an end when the pressure in the Bowman's capsule is still 30 to 40 mm. Hg below that in the glomerular capillaries. A number of observers have found that urinary secretion ceases when the arterial blood pressure falls to between 40 and 50 mm. Hg. But if the blood be diluted by the constant infusion of normal saline solution, so as to diminish its protein content, a secretion of urine may be obtained with a blood pressure as low as 18 mm. Hg.

The dependence of the urinary flow on the arterial pressure is shown very clearly in some experiments by Richards and Plant *; they placed a pump in the course of one renal artery of the rabbit, blood clotting having been prevented by hirudin. In this way, the circulation through the kidney was entirely under control, its pressure and velocity being known at any moment. The amount of urine varied directly with the blood pressure and did not depend on the amount of blood flowing through the organ. Similar results have been obtained † in experiments on the heart-lung-kidney preparation (p. 997). The results of such an experiment are shown in Fig. 613, in which it is again shown that when the rate of glomerular filtration is increased by raising the blood pressure, the composition of the urine approaches to that of the serum, *i.e.* chloride increases and creatinine diminishes.

All these considerations strongly support the view that the process occurring in the glomeruli is one of filtration, for which the energy is furnished by the blood pressure. But the glomerular capillaries require oxygen for the maintenance of their physical qualities as a filter. Complete obstruction of the renal artery not only stops the production of urine, but its effects last for some time after the obstruction has been removed, and the first portions of urine obtained when secretion is re-established are found to contain coagulable protein. In the same way, any damage to the glomeruli as a result of defective circulation, of imperfect oxygenation of the blood, or of inflammatory and infective conditions of the kidney, is invariably associated with the passage of protein into the urine.

Clearance Tests. Information of fundamental value, both theoretical and practical, as regards kidney function can be obtained by means of what are called clearance tests. In order to explain these, let us suppose that a given substance, capable of accurate estimation, is naturally present in, or has been artificially added to, the blood. Further, let us suppose that this substance can pass an ultra-filter, such as the glomerular membrane; hence, the glomerular filtrate will contain that substance in the same concentration as it is present in the blood plasma. Lastly, let us suppose that the substance is neither absorbed from nor secreted into the fluid by the uriniferous tubule as the stream passes along it. Then all the substance which was contained in the glomerular filtrate will be quantitatively recoverable from the urine.

Now if the urine, of volume V, formed per minute contained U g. per 100 c.c. of the substance, and if the plasma contained P g. per 100 c.c. of it, then it is clear that $\frac{UV}{P}$ c.c. of plasma have been filtered off through the glomerular membrane per minute and so cleared of the substance. This value $\frac{UV}{P}$ is called the *plasma clearance*, or *glomerular filtration rate* (G.F.R.). It will be evident that all substances which fulfil the above conditions should have the same clearance values; also that substances which are absorbed back into the blood again by the tubules will have lower clearance values, while those which are secreted out from the blood into the tubule will have higher clearance values than the G.F.R.

---

* Richards and Plant. *Amer. J. Physiol.*, 1922, **59**, 144.
† Verney and Starling. *J. Physiol.*, 1922, **56**, 353.

Much work has been devoted to finding substances which fulfilled the above-mentioned requirements and which were either normal plasma constituents, or else were non-toxic. It would appear that the polysaccharide inulin is a suitable substance. Sodium thiosulphate and creatinine have also been used, but in man some creatinine, and in the cat some thiosulphate, is secreted by the tubules and so gives too high a plasma clearance. In the dog, rabbit and sheep, creatinine and inulin give identical results.

When we speak of creatinine clearance, inulin clearance, etc., we mean the volume of plasma which may be regarded as freed from the substance in unit time (*e.g.* c.c. per min.) by the kidneys, as estimated by the employment of the substance named. Since the plasma clearance bears a direct relation to the body surface it is often expressed as $C = \frac{UV}{PA}$, *i.e.* in c.c. per sq. m. of body surface per min., where A = the body surface in sq. m., or as this figure C multiplied by 1·73 (the mean area of an adult in sq. m.).

Investigations by this method, using creatinine, inulin and ferrocyanide, were carried out by Van Slyke and his colleagues [*] on dogs with one kidney removed and the other transplanted to the surface of the body so that blood samples could be taken and the renal blood flow measured.[†] They showed that the actual plasma clearance was about 20 per cent. of the total plasma flowing through the kidney, *i.e.* about one-fifth of the blood plasma was filtered off in the glomeruli. This is called the "*filtration fraction.*" The actual clearance at any time depends, in dogs, and presumably also in other species, mainly on the pressure in the glomeruli. In the normal human male subject under standard conditions the following data have been found by Homer Smith *et al.*[‡] :—

	per 1·73 sq.m. body surface.
Blood flow through kidneys	1,189 c.c./min.
Plasma ,, ,, ,, (= c̄ 58 p.c. of blood)	688 c.c./min.
Inulin clearance (=glomerular filtration rate).	130 c.c./min.
Filtration fraction $\left(= \frac{130}{688} \times 100\right)$ . .	19 per cent.

Women have smaller kidneys than men, and hence the corresponding figures for women are about 84 per cent. of those for men when referred to the same standard area of 1·73 sq. m.

The study of clearances has yielded most valuable information on the functions of the kidneys under normal conditions in the human subject, as the above figures illustrate. In man we can now measure renal blood flow (= Diodrast clearance) (p. 1010), glomerular filtrate (= Inulin clearance), renal tubular mass (Tm_D), and correlate them with plasma concentration, urine flow and concentration, etc. (*v.* also p. 1009).

THE FUNCTIONS OF THE RENAL TUBULES

The glomerular filtrate, formed, as explained above, in Bowman's capsule, must undergo considerable changes on its way through the tubules. These changes might be brought about either by the addition, to a relatively small volume of the filtrate, of a concentrated secretion containing the specific urinary constituents in the required proportions, or else by the reabsorption, from a very large volume of filtrate, of water and various other substances, so that the fully formed urine represents the unabsorbed residue of the filtrate.

These two processes, secretion or absorption, would involve the performance of identical amounts of work by the kidney, and there is reason to suppose that both can happen, but that in man absorption is normally the more important.

Absorption in the Tubules. According to Cushny, the whole of the changes by which the glomerular filtrate is transformed into urine may be ascribed to processes of absorption occurring in the tubules. He assumed that the composition of the fluid absorbed is always the same whatever the needs of the organism at the moment. There would thus be but little absorption of urea and none of sulphate, while the whole of the glucose, a portion of the uric acid and the greater part of the sodium, potassium and chloride would be absorbed. According to this view, the constituents of the glomerular filtrate may be divided into two classes, "*threshold substances*" and "*no-threshold substances*," the former being completely reabsorbed when present in the blood in amount below the "threshold" value and hence only excreted in the urine so far as their concentration in the blood exceeds that value, while the no-threshold substances are excreted in proportion to their absolute amount in the plasma, because they are not reabsorbed at all. Thus, of the threshold substances, the glucose of the plasma is normally below the threshold, and it is therefore all reabsorbed and so not present in normal urine. The sodium chloride also comes within the threshold class, but its threshold is usually exceeded in normal conditions, and the excess is then excreted. When the sugar of the plasma rises, as in diabetes, to 0·3 per cent., or when phlorrhizin is given, so as to lower the "renal threshold," glucose appears in the urine and then undergoes concentration, just as urea does. It is doubtful whether there are in man any true no-threshold substances as normal constituents of the blood. The nearest to one appears to be creatinine. Most constituents have thresholds, and others are secreted by the tubules to a small extent.

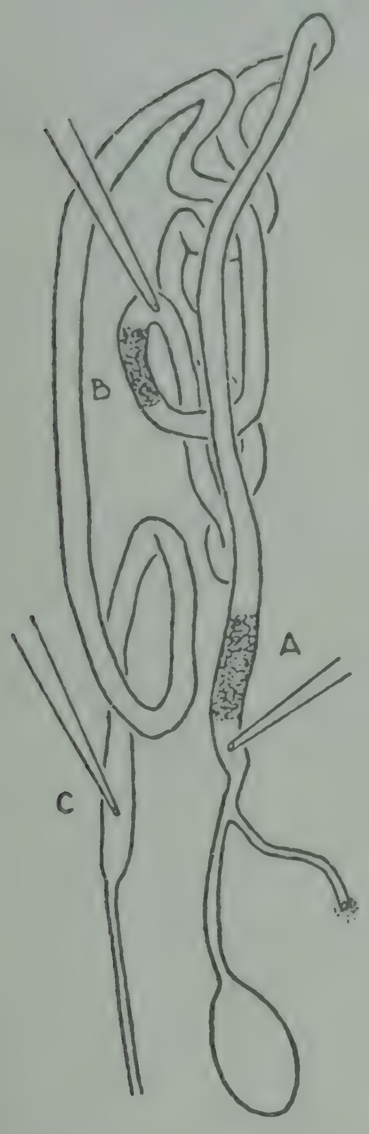

FIG. 614. Insertion of micropipettes for collection of tubule fluid from beginning (A), middle (B), and end (C), of a proximal convoluted tubule of *Necturus*. Stippling at (A) represents blockage of lumen by globule of mercury, at (B) by a globule of coloured oil. (RICHARDS. Croonian Lect., *Proc Roy. Soc.*, 1938, **126** **B**, 398.)

That reabsorption is, in most species of animals, the dominant function of the tubules is now generally conceded. The clearest evidence for it is given by experiments in which it can be directly shown that constituents present in the Bowman's capsule disappear, or are much reduced in amount, during the passage of the fluid along the tubules. We have already learnt that the fluid drawn by puncture from the Bowman's capsule of the frog contains chloride *; yet this substance is absent from the frog's urine. Similar results were obtained with *Necturus* kidneys.† The plasma of the latter animal contains about 0·36 per cent. of NaCl, whereas the urine contains only 0·026 per cent.; when dog's red blood corpuscles were injected into the Bowman's capsule, they were seen to be rapidly washed down into the tubules by the flow of glomerular filtrate; when the corpuscles entered the tubule they were at once laked, presumably because so much chloride had been abstracted from the fluid that it had become hypotonic. Glucose is likewise present in the glomerular filtrate of frog and necturus, but absent from the urine.

Direct proof of the absorptive functions of the tubules was provided by experiments in which the fluid was actually collected and analysed at different points along its course through the tubules. This was effected, in frog and necturus, by the use of capillary pipettes manipulated under the microscope, as shown in Fig. 614.

* WEARN and RICHARDS. *J. Biol. Chem.*, 1925, **66**, 247.

† WHITE and SCHMITT. *Amer. J. Physiol.*, 1926, **76**, 483.

Analysis of the fluids collected showed that the chief alterations in total concentration and in Cl occur during the passage along the distal convoluted tubule (Fig. 615), and are probably attributable to reabsorption of both water and solids.

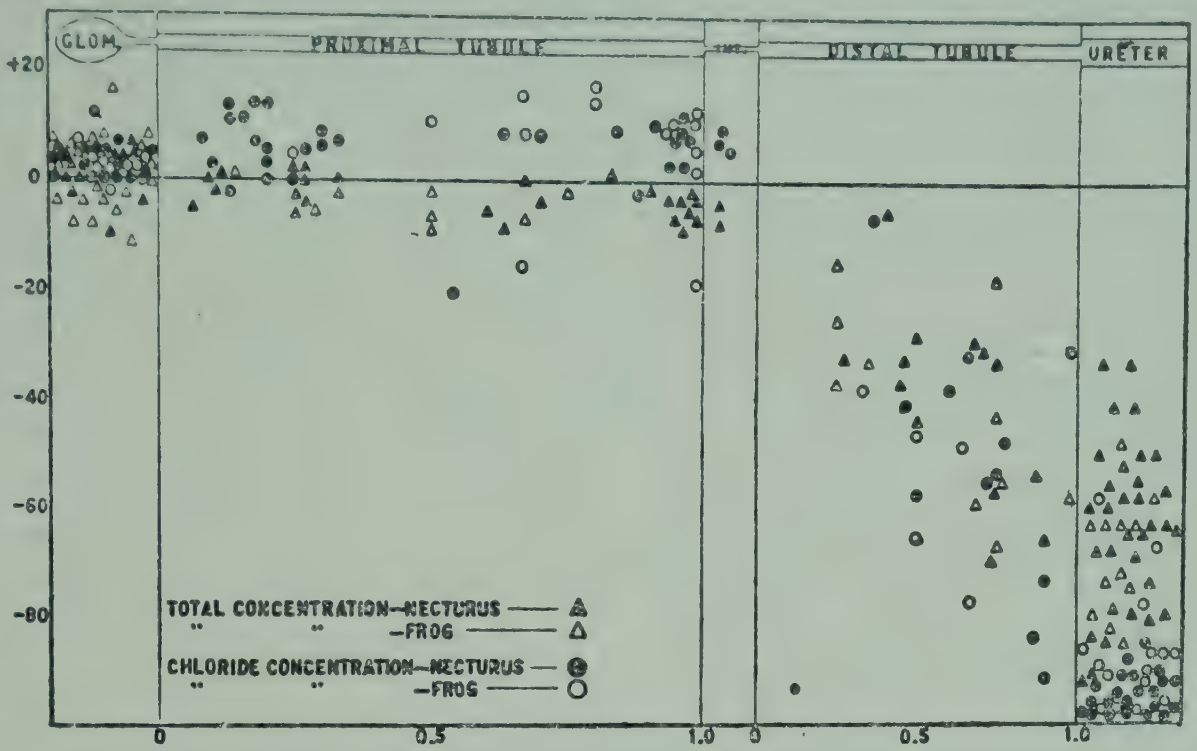

FIG. 615. Chart showing differences between blood plasma and fluid collected from various points on renal tubules, with respect to total solids and Cl concentration. Zero line represents plasma. Cl scale shows per cent. difference from plasma. Concentration of solids represents change in length of column of fluid equilibrated by Barger's method (Osmotic pressure) against plasma. (RICHARDS. Croonian Lect., 1938.)

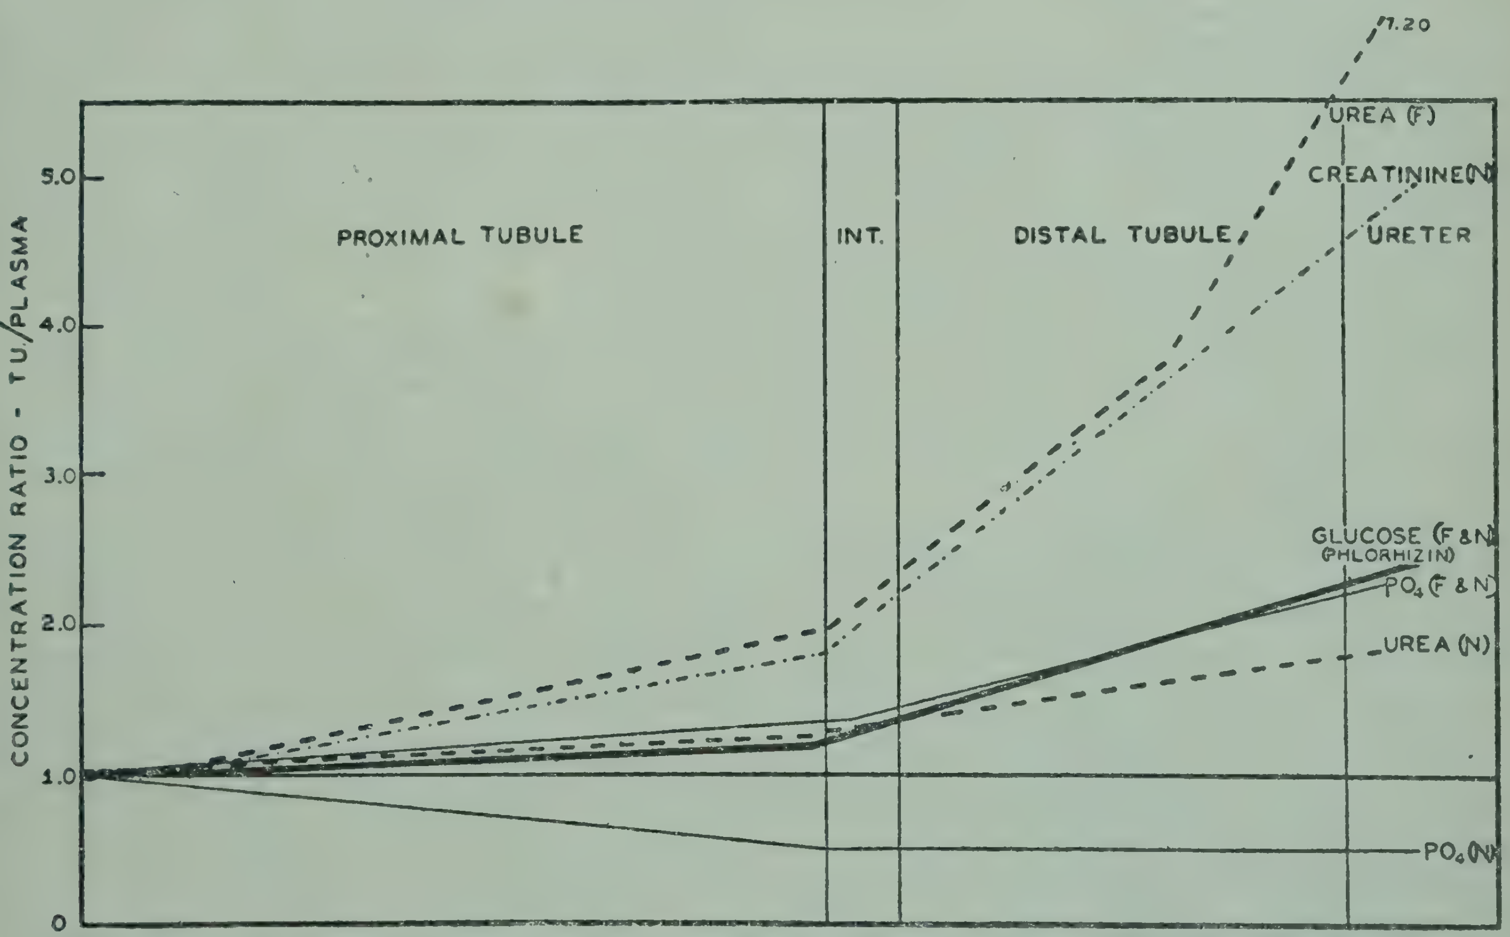

FIG. 616. Average curves of changes in concentration of urea, inorganic phosphate, and creatinine in passing the tubules in frog (F) and *Necturus* (N). Also changes in glucose after phlorrhizin. (RICHARDS. Croonian Lect., *R.S.*, 1938.)

In a similar way, creatinine, urea, glucose and phosphate have been followed. Glucose is absorbed completely, and chiefly in the proximal convoluted tubule ; after phlorrhizin poisoning, the absorption ceases, and there is then some concentration of glucose by loss of water, which occurs in the distal tubule (Fig. 616). As is shown in Fig. 616, inorganic phosphate is also usually concentrated in the distal tubule, but this is again due to absorption of water, and not to secretion. Sometimes phosphate is absorbed back again into the blood ; when this occurs it takes place in the proximal tubule, as is normally the case for Na, Cl, and glucose. Since urea in frog and creatinine in necturus concentrate more rapidly than corresponds with removal of water, it may be that these substances can also be secreted by both the tubules.

There is ample support of other kinds for the belief in the reabsorption of water in the tubules. In the first place, the fluid formed in one Bowman's capsule of the frog can be collected and measured, and when multiplied by the number of capsules, gives the total volume of glomerular filtrate formed in the kidney. Thus Richards calculated that if we take 1 c.mm. per hour for the rate of filtration in one capsule (it is usually higher than this), and the number of capsules in a kidney as about 2,000, most of which are probably functional under the conditions of the experiment, we should get 2 c.c. of glomerular filtrate formed per hour ; but the amount of urine formed per hour under the same conditions is rarely more than 0·2 c.c., so that we must conclude that 90 per cent. of the water passed out into the capsules is reabsorbed in the tubules.

In mammals there is evidence that water absorption occurs not only in the distal convoluted tubule, but also in the thin segment of Henle's loop. Thus pitressin does not exert an anti-diuretic action in amphibia and fishes, which have no thin segment.* It may be, since the thin segment always enters the medulla, that water absorption is passively effected into the vasa recta in the higher animals.†

The older experiments on the excretion of dyestuffs by the kidney were believed to prove that they were eliminated by active tubular secretion. This claim is now very generally admitted.‡ Nevertheless, some of the concentration of dye in the urine can be shown to be explicable by filtration followed by absorption of water. Proof of this has been provided by perfusion of the frog's kidney.§

We may accept, on the balance of evidence, presented here in somewhat biassed form for the sake of simplicity, that there is reabsorption of water and of some dissolved constituents from the glomerular transudate as it passes down the tubules. The dissolved constituents are reabsorbed to different extents ; creatinine little, if at all, and urea not greatly ; chloride, glucose and phosphates more than sulphates.‖

The power of concentration possessed by the cells of the tubules is not indefinitely large, and the urine can therefore never exceed a certain concentration, at which its osmotic pressure just equals the absorptive power of the cells. This limiting concentration differs in different animals, the cat being able to absorb against an osmotic resistance of fifty to sixty atmospheres, while the human kidney cannot concentrate against a resistance of more than twenty-five atmospheres. The presence of any difficultly absorbable substances in the glomerular filtrate, *e.g.* urea, sodium sulphate, or phosphate, must therefore limit the absorption owing to the osmotic resistance they offer to the absorptive powers of the cells. These substances will therefore act as diuretics. In the same way the threshold substances will act as diuretics, when they are present in the plasma in proportions above the threshold, and can no longer be absorbed by the cells of the tubules.

Secretion in the Tubules. Histological examination of the kidney tubules shows a great diversity of structure in the epithelium with which they are lined. Hence, it is quite conceivable that some portions of the tubule might absorb while other portions were capable of secreting : or the same cells might even absorb certain things and secrete others. Yet for one or two decades, physiologists appeared to be so satisfied with the evidence in favour of reabsorption as to forget that the demonstration that urine formation could not be explained wholly on the filtration-secretion hypothesis by no means put that method out of court as an accessory.

‖ Rehberg. *Bioch. J.*, 1926, **20**, 447, 461.

Once an instance had been produced of urine formation in which secretion indubitably played a part, the door was open to admit secretion as a possible collaborator with absorption, in the modification of the glomerular filtrate. Such an instance was produced when Edwards, Marshall and Homer Smith,* recalling the fact that certain fish had kidneys from which glomeruli were absent, pointed out that urine formation must in those species be a purely secretory phenomenon. Their further investigations on these aglomerular kidneys of at least twenty-five species of fish belonging to five different families have, more than anything else, provided the faith that was required for acceptance of the possibility of tubular secretion.

It is suggested that the explanation of the differences in kidney structure in different species of animals is bound up with their phylogenetic history, the glomerulus being developed when water was abundant, and reabsorption then being necessary to prevent loss of valuable solutes ; when water was scarce, or the animal living in hypertonic sea-water, kidney function could be carried out either by secretion alone, the glomeruli being lost, or by reabsorption with or without the addition of secretory power, the glomeruli being retained.

When the possibility of secretion by the tubules had been demonstrated, it was natural to re-examine the classical experiments of the 'seventies, which had once been thought to provide evidence in its favour, and which had in the meantime been explained in other ways. Heidenhain,† for instance, attempted to throw light on the excretory functions of the kidney by studying the mechanism by which it excretes sodium sulphindigotate (" indigo carmine.") If the dye be injected intravenously, it is excreted in a concentrated form by the kidney, which is dyed blue, especially in the medulla.

It has been objected to these results that they may equally well be brought about by absorption. If indigo carmine is turned out by the glomerulus, it will be in so dilute a solution that the glomerulus will not be stained. As the transudate descends the tubules it undergoes concentration, leading to precipitation of the dyestuff in the lumen of the tubules, and the granules in the cells may be the result, not of secretion but of absorption. Some experiments by Marshall, however, certainly point to the active secretion of phenol red by the dog's kidney. Phenol red is partly held in the plasma in combination with protein, and hence is only partly separable by ultra-filtration, 75 per cent. of it remaining behind. Yet the rate at which phenol red passed out in the urine was so large that in order to explain it by reabsorption, the blood flow through the kidneys would have to be over 1 l. per minute, even if half the plasma filtered through and was reabsorbed. Hence the phenol red must have been torn away from its colloidal union, either by secretion in the tubules, or, which is hardly likely, by active secretion at the glomerular membrane.

By taking advantage of the peculiarities of the renal circulation in the frog, claims of another kind have been made for the possession of secretory functions by the tubules. A number of renal arteries supply the glomeruli, the vasa efferentia from which pass, as in the mammalian kidney, into the intertubular capillaries. These, however, also have connections with the renal portal vein, shown in Fig. 617, and it is possible, by perfusing the renal portal vein at a high pressure, to cause a flow in that direction. If all the renal arteries be ligatured, the glomeruli were stated ‡ to have been entirely cut out of the circulation, though the tubules still receive venous blood through the renal portal vein. Ligature of all the renal

arteries caused cessation of urinary secretion, which could be reinduced by injection of urea, *i.e.*, urea, with water, was secreted by the tubules. This experiment has often been repeated,[*] and with similar results. There has been some difference of opinion as to the accuracy of the anatomical basis of them. Hayman,[†] and Bensley and Steen,[‡] however, consider that Nussbaum's original description is substantially correct.

Experiments by Bensley and Steen on the excretion of dyes by the frog's kidney, suggest that these are actually secreted by the cells of the proximal convoluted tubule, and that there is absorption of water, and perhaps of threshold substances, in the distal convoluted tubule. In these experiments, the kidneys were observed under the microscope at intervals after the injection of indigo carmine or phenol red. Some of the renal arteries were tied, and their nephrons were observed to have no glomeruli functioning. In these, the dye was seen to appear in the cells of the proximal tubule in vacuoles, *which then passed out* into the lumen of the tubule. When indigo carmine was given first, and phenol red after it, the first dye was displaced inwards into the lumen by the second, which followed it along the whole tube, both becoming concentrated as the distal tubule was traversed. Similar results have been obtained by observation, under the microscope, of frog's kidneys with glomeruli put out of action by ligature of the renal artery, and on rat's kidneys in which glomerular circulation was stopped by section of the spinal cord. The dye used was fluorescein, which was rendered visible by ultra-violet light.[§]

To sum up, it seems probable that secretion, when it occurs, is effected by the proximal convoluted tubule, which is also able to absorb some water and certain other constituents, such as glucose and salts. Concentration by withdrawal of water is effected chiefly by the distal convoluted tubule, as is also, probably, the formation of ammonia.

Secretion of the usual urinary constituents does not seem to occur to any great extent in the mammal, though in man some creatinine, and in birds and reptiles uric acid, are definitely excreted. Unusual substances, such as dyes, diodrast (organic iodine compound used for X-ray study of the kidneys), *p*-aminohippuric acid, penicillin, etc., are certainly excreted by mammalian tubules.

Urea Clearance. We have seen that plasma clearance may be used as a means of assessing the volume of glomerular filtrate, provided that the substance chosen for estimation is neither absorbed nor excreted by the tubules. As measured in this way, inulin gives clearances of the order of 123 c.c. per minute. Urea, on the other hand, gives values of only about 75 c.c. per min., so that there is apparently some reabsorption of this substance. If the urea level of the blood is raised by taking urea by the mouth the clearance is unaltered, *i.e.* the same fraction of the urea is removed. But if the glomerular filtration rate is reduced by reduction of the blood flow through the kidney, or by disease, the clearance is diminished. The urea clearance is thus a convenient practical index of the rate of glomerular filtration: it does not actually give us this, as inulin or creatinine clearance does, but it is proportional to it. In nephritis, urea clearance may be only 4 or 5 c.c. per minute.

To carry out a urea clearance test the subject drinks about a pint of water in order to produce a good diuresis. The bladder is emptied to begin with, and again after one hour and two hours, and the volume V in c.c./min. is noted. A blood sample is taken at one hour, and the urea content of blood (B) and urine (U) are determined. The clearance $C_{\text{ur.}} = \frac{UV}{B}$ c.c./min. or, in percentage of the normal clearance,

$$C_{\text{ur.p.c.}} = 1{\cdot}33\,\frac{UV}{B}$$

If the urine flow is less than 2 c.c./min. the formula is:

$$C_{\text{ur.p.c.}} = 1{\cdot}85\,\frac{U\sqrt{V}}{B}.\|$$

[‖] Peters and Slyke. Quantitative Clinical Chemistry, II., 1932, p. 564. (Williams and Wilkins, Baltimore.)

The normal range is from 75 to 130 per cent. of the average value of 75 c.c./min.

Instead of the urea clearance, we can determine the $\frac{\text{Urine}}{\text{Blood}}$ urea concentration ratio, using morning urine. This is normally about 50.

Various functional tests for the efficiency of the kidney have been proposed for clinical use. Most of them depend on the determination of the degree of concentration in the urine of substances present in or added to the blood, or of clearances of various constituents. Books on clinical chemistry should be consulted for an account of these tests.*

Rate of Tubular Transfer. If a given substance is absorbed, or secreted, by the tubules, the rate at which this transference happens cannot exceed a certain maximum value.† This value, in mg./min., is called T*m* for the given substance and kidney, and is constant. It is estimated, in the case of absorption, by finding the plasma concentration of the given substance, the rate of glomerular filtration (inulin clearance), and the amount of the substance passed out by the urine in a given time. The product of the first two gives the "filtered load"; this is raised in stages by increasing the plasma concentration, by injections of the substance concerned, the excretion rate at each stage being measured by urine analysis. Deduction of the excreted from the filtered load gives the amount of the substance transported, *i.e.* in this case, absorbed back into the blood. With rising plasma concentration or filtration rate, this amount increases from an amount practically equal to the filtered load until it reaches a maximum, beyond which further increase in the plasma concentration produces no further absorption, the additional amount filtered being all passed on into the urine. This maximum value is the T*m* for the substance and individual at the time.

The following example will illustrate :—

GLUCOSE PLASMA CONCENTRATION AND RENAL TUBULAR ABSORPTION (Dog, 24 kg.)
(Shannon and Fisher.)

Period, mins.	Plasma Glucose mg./100 cc.	Glucose Filtered mg./min.	Glucose Excreted mg./min.	Glucose Reabsorbed mg./min.
10	128	150	0·2	150
10	238	267	2·2	265
10	437	499	229·0	270
8	1234	1494	1212·0	282

(In the interval between each period and the next, glucose was injected intravenously.)

It will be seen that, as the plasma glucose is raised, the glucose reabsorbed rises until it reaches the maximum rate (T*m*), in this case about 270 mg./min. : the amount excreted, at first negligible, increases rapidly as soon as the filtered load exceeds the value T*m*, and thereafter all above this is passed out.

Maximal rates of absorption have been demonstrated to occur with several substances, *e.g.* for glucose and *p*-aminohippuric acid (T*m* for P.A.H. = 77·5 ± 13 mg./min. in man), ascorbic acid, sulphate, inorganic phosphate, etc., and the case probably applies to threshold substances in general.

A similar relationship holds good for substances which pass in the other direction, *i.e.* are secreted from the blood into the tubule, a maximal rate being reached when the plasma concentration and flow reach a certain figure. If diodrast, for instance, is given in sufficiently large amount, the T*m* for diodrast ($\text{T}m_{\text{D}}$) can be obtained ; it is nearly independent of the blood flow through the kidneys, and can be used as a measure of the amount of functional proximal tubule tissue (tubular excretory mass), *i.e.* of the size of (normal) kidneys.* It is often convenient to refer the other clearances, *e.g.* inulin (= glomerular filtration) to Tm_p (*i.e.* to kidney size) rather than to body-surface. When we do so we find that whereas in normal subjects inulin clearance ranges from 90–180 c.c./min./1·73 sq. m., the value, related to Tm_p, is almost constant at 2·6 c.c./min./unit Tm_p, in women as in men. The value of Tm_p is a measure of the mass of active tubule tissue, and its constancy shows that all tubules are probably in action all the time.

---

* HARRISON. "Chemical Methods in Clinical Medicine," 1947, p. 86. (Churchill ; London.)

† SHANNON and FISHER. *Amer. J. Physiol.*, 1938, **122**, 765.

These results are explicable on the hypothesis that the substance being transported across the tubular epithelium combines temporarily with a constituent of the cell, and that the limit to the rate at which this takes place is fixed by the laws of mass action and reaction velocity. Phlorrhizin, for instance, probably blocks the combination of glucose and so stops reabsorption.

It will be seen that the view here taken is the opposite one to that of threshold substance propounded by Cushny; he places the barrier to further absorption at the plasma concentration; the view of Shannon is that the determining factor is the absorbing capacity of the renal cells, as fixed ultimately by their chemical content.

Renal Blood Flow. Diodrast, or alternatively *p*-aminohippuric acid, is excreted so vigorously by the tubules as to be completely removed from the blood flowing through the kidney if the concentration in the plasma is low. Hence its plasma clearance will be equal to the flow of plasma through the kidneys, so that if the plasma content of the blood is also known the blood flow can be deduced. It has been found in this way that the plasma clearance for P.A.H. = 621 ± 133 c.c./min./1·73 sq. m., and hence the blood circulation through the kidneys of an average man of surface area of 1·73 sq. m. is about 1,000 c.c./min. or about 20 per cent. of the cardiac output.

THE ADAPTATION OF THE RENAL FUNCTIONS

When we examine the urinary secretion in the intact animal, we cannot but be struck by the manner in which its amount and concentration are adapted to the needs of the body as a whole. The behaviour of the tubule cells with regard to any given substance must therefore depend to a certain extent on the previous nutritive history of the body.

When a large quantity of sodium chloride is taken, the result is a temporary rise in the salt concentration of the plasma which may last a day or two. This is then succeeded by an increased excretion of salt by the kidney, but this occurs at a period after the salt concentration of the plasma has returned to normal. The salt ingested seems at first to pass into the tissues, and is only got rid of from these by an increased excretion after a considerable latent period. Moreover, when diuresis is produced in such an animal by the injection of equivalent quantities of sodium chloride and sodium sulphate, there is no diminution of the NaCl in the urine towards the end of the diuresis, but its percentage rises steadily as the rate of urinary flow diminishes. On the other hand, a total deprivation of sodium chloride extending over several days, although not altering to any large extent the percentage amount of this salt in the blood plasma, leads to a total disappearance of the salt from the urine, the whole of the sodium chloride present in the glomerular filtrate being now reabsorbed in the tubules. When large quantities of water are taken by the mouth, there is a rapid excretion of a very dilute urine, so that the constitution of the body, and of its fluids, is but little altered by the water ingested.

The endocrine organs play a considerable part in regulating the electrolyte and water balance of the body, and this they do in part by an effect on the kidney functions. Conspicuous among these actions is that of some adrenal cortical hormones, and of the steroids related to them, the most active being desoxycorticosterone and progestin. These hormones increase the absorption of Na and Cl in the proximal tubules, and so aid their retention in the body. This action is opposed by that of the antidiuretic hormone of the pituitary, which impairs electrolyte retention and augments water reabsorption; and is favoured by the thyroid hormone, which reduces water reabsorption.

The kidney plays an important part in the regulation of the hydrogen ion concentration of the blood. When there is increased production of acids in the body the excess of acid is excreted in the urine. Normally, fixed acid production exceeds available base increase by 50–100 M.Eq. per day.

---

* Smith *et al.* *J. Clin. Inv.*, 1938, 17, 263.

Three factors appear to control the rate of acid excretion by the kidney, viz. : the amount of buffer in the glomerular filtrate, the nature of that buffer, and the plasma alkali reserve (not its *p*H). The excretion of acid is assisted by the formation of ammonia (p. 932) in the kidney, as well as by alteration in the ratio of mono- to di-basic phosphate in the urine.

The formation of acid urine can only in part be explained by reabsorption of bicarbonate or phosphate. It is probably effected, in the distal tubule, by passage of H-ions into the tubule in exchange for Na-ions which leave it. In this exchange carbonic anhydrase seems to play a part,* as it does in acid secretion in the stomach : if the enzyme is poisoned by sulphanilamide, alkaline urine is formed.

Normal urine contains no sugar, but if the sugar in the blood rises to 0·2 per cent., the excess of sugar is at once excreted. The simplest explanation of the varying activity of the kidney would be to assume that this organ reacts to very minute changes in the composition of the circulating blood. For instance, Clark † perfused the arterial system of the frog with Ringer's solution containing 0·1 per cent. of glucose, and at the same time supplied the tubules *viâ* the renal portal vein with Ringer's solution of varying glucose content. When this solution contained up to 0·1 per cent. of glucose, all the glucose passed out into the Bowman's capsule was reabsorbed, so that none was present in the urine ; when it contained more than 0·1 per cent. there was less and less reabsorption as the amount supplied to the tubules was increased.

The kidney by itself has much less latitude in its activities ; nervous control can apparently be discounted as a party to such collaborative regulation, but the humoral control, through the endocrine organs, is important.

It should be noted that the kidney of the new-born infant is a relatively inefficient organ : the urine it forms is hypotonic, and clearances of inulin, urea and chloride are low : hence the importance of controlling protein, water and salt intake, and of avoiding saline infusions.‡

Adaptation to Reduction of Kidney Tissue. After removal of one kidney, the blood flow through the other one is increased by 70–100 per cent., but it is not known how this result is caused : the urine flow from the remaining kidney also increases, to be about equal to that previously produced by both : the remaining kidney soon shows hypertrophy. The adaptability of the kidney in performing its functions is well seen by the effect of removal of a portion of the kidney, or of deprivation of the blood supply to part of it by ligature of one of the branches of the renal artery. In either case the kidney thus reduced secretes no less urine than the other kidney, which remains intact.§ There is thus a considerable margin of reserve in the kidney. It has been suggested that some of this reserve is provided by the opening-up of glomeruli which had previously been closed down by constriction of their afferent arterioles. Subsequent work, however, discourages this opinion, and regards the intermittent functioning of the glomeruli as being confined to the cold-blooded kidney.

When kidney tissue is considerably reduced, as, for example, by removal of one kidney and half the other, the volume of urine excreted may even be increased,‖ the urine being of a dilute type more nearly representing the glomerular transudate. These results have been obtained also on the heart-lung-kidney preparation,¶ and are probably due to the effect of reduced intrarenal pressure.* The increased urine production of the remaining unit is accompanied by their failure to concentrate the urine formed, because of it more rapid transit along a relatively small number of tubules.

¶ Verney. *Lancet*, 1929, March 30th, July 12th.

A similar condition is seen in pathological states where there has bee destruction of a large amount of kidney tissue, and Verney has appropriatel compared this with the dilatation seen in a failing heart during exercise ; th remaining kidney tubules have, so to speak, become worked to the limit o their functional reserve. We therefore have two types of reserve in the kidne tissue—structural reserve by the occasional closing down of those glomerulo-tubular units whose services can be temporarily dispensed with, and, secondly, the functional reserve represented by the extent to which the tubules, in effecting their work of concentration, are working to the limits of their capacity.

DIURESIS

An increase in the rate of urine formation is called diuresis. It may be caused by copious water drinking, by pathological states, or by the action of alcohol, or of certain drugs.

Two types of fundamental factor might be concerned in promoting an increased flow of urine. These are :

(1) Increased glomerular filtration from mechanical causes, *e.g.* rise of pressure in the glomerular capillaries, reduction of protein content of the blood, or (hypothetically) by the opening-up of glomeruli previously closed by constriction.

(2) Reduced absorption in the tubules, such as may conceivably happen when the diuretic substance is not absorbed, or when the water absorption by the tubules is impaired, as when the post-pituitary hormone is reduced.

In fact, diuresis as commonly met with in man is due to the second of these causes.

Clues to the way in which diuresis is brought about are provided by the study of the osmotic work and oxygen usage, and so, from these, of the efficiency of the isolated kidney.

Pressure Diuresis. When diuresis is caused by an increase of arterial pressure, it would be expected that if the diuresis was only due to increased glomerular filtration, and not at all to altered tubular absorption, there would be no increase in the oxygen usage of the kidney, and no change in its efficiency. Actually, however, a rise of arterial pressure does cause an increase, not only in the filtration (creatinine clearance), but also in oxygen usage, osmotic work and efficiency.† Doubling the urine flow in this manner causes about 40 per cent. increase in osmotic work and 25 per cent. in efficiency. We may infer, therefore, that even in this apparently simple case of increased glomerular activity, there is a concomitant *increase* in tubular reabsorption. The concentrations of all the constituents of the urine during pressure diuresis move towards their concentration in the plasma, so that the work done per unit volume of urine produced is less, but owing to increased work on the part of the tubules, the work done per unit of time is raised. These facts were discovered by the use of the isolated kidney.

Dilution Diuresis. When the plasma colloids are diluted by the addition to the blood of Ringer's solution, the effective filtration pressure and glomerular filtration rate are raised. When compared with the effect of an equivalent increase of effective filtration pressure by raising the arterial pressure, however, the effect of dilution is found to be six times as great in isolated kidneys and fifteen times as great in intact anæsthetised animals.‡ This appears to be due o an increased permeability of the glomerular membrane in the dilution liuresis, but the osmotic work is also increased, viz. about 40 per cent. when he flow of urine is doubled. In the intact dog there is also diminished reabsorption of water.

Water Diuresis. When a large amount of water is drunk, the change in he composition of the blood plasma may be very slight, and mainly due to oss of electrolytes diffusing out into the intestine and tissues, though the kidney is secreting large quantities of extremely dilute urine.* The diuresis is believed to be due to a reduction in the reabsorption of water by the tubules, rather than to an increase in glomerular filtration. Even when dilution of the plasma does occur, the maximal rate of urine formation lags some 20 to 30 minutes behind the maximal dilution,† so that the kidney responds slowly to the increased water content or lowered osmotic pressure of the blood.‡ It is possible to bring about a lowering of molecular concentration by injecting water or a hypotonic salt solution directly into the blood. Under these circumstances there is increased secretion of urine,§ but again only after considerable delay.‖

It is a curious fact that if the water reserves of the body are reduced by thirst, the administration of the amount of water lacking from the body produces a normal diuresis ¶ after the usual lag. It is clear, therefore, that the kidney does not respond directly to plasma changes, and the suggestion is that it is probably an indirect hormone effect.

Rôle of Pituitary. We have seen that the isolated perfused kidney secretes urine containing only traces of sodium chloride, although the content of this salt in the blood serum is rising steadily throughout the experiment. Addition of a small amount of extract of the posterior lobe of the pituitary body at once reduces the volume of the urine and increases the amount of chloride in it.** If, in such a perfusion, the blood is also circulated through an isolated head, the volume of urine is speedily reduced, and its chloride content correspondingly increased, but this does not occur if the pituitary body has first been removed from the head.

In the disease known as *diabetes insipidus* the patient passes large quantities of watery dilute urine and suffers very intense thirst as a consequence. Diabetes insipidus is often associated with demonstrable alterations, of a destructive nature, in the pituitary posterior lobe.†† Excision of the posterior lobe of the pituitary body brings about a similar condition, namely, increased formation of urine and disappearance of chlorides from the urine.‡‡ The action of the anti-diuretic pituitary hormone is to accelerate water reabsorption (in the distal tubule) and to retard sodium reabsorption (and hence also that of chloride) in the proximal tubule. Injection of posterior pituitary extract into a patient with diabetes insipidus,§§ suspends the condition, the urine diminishing in amount while the chlorides in it rise considerably and in some cases even exceed the percentage amount of chlorides in the plasma.

One milliunit of the pituitary anti-diuretic hormone is enough to stop diuresis due to water drinking : amounts of that order are believed to be usually present in the circulating blood,‖‖ and it is probable that water diuresis is due to suspension of liberation of the pituitary secretion into the blood, the delay in onset of diuresis being occasioned by the slow rate of destruction of the hormone.* It has been shown by Verney that the release of the anti-diuretic hormone from the pituitary into the blood is regulated in response to changes in the osmotic pressure of the blood plasma; if this is lowered (as by water drinking) the release is checked, and *vice versâ*. The receptors sensitive to osmotic changes in the blood (osmoreceptors) appear to be in the branches of the internal carotid artery † and injection of hypertonic solutions into the carotid

(Verney. *Proc. Roy. Soc.*, 1947, **135B**, 85.)

artery soon cuts short a vigorous water diuresis. Water diuresis is also inhibited by emotional stress and this emotional inhibition is of two types, which together give a complex picture. One type of inhibition is again due to a reflex release of anti-diuretic hormone from the pituitary and is of slow onset and ending; it is abolished by a preceding injection of adrenaline, but not by sympathectomy. The other type is reflex, of quick origin and short duration and is abolished by denervation of the kidney or by splanchnic section.

Release of anti-diuretic hormone from the pituitary is controlled by impulses from the supraoptic nucleus of the hypothalamus. Injection of acetyl choline into this nucleus inhibits water diuresis in dogs with denervated kidneys, presumably by initiating such impulses.‡ These and similar facts remind us that the kidney is not an isolated organ, guided in its activity only through influences on the blood vessels, or by the presence of urinary constituents in the blood, but that it is played upon by hormones from distant parts of the body.

Action of Diuretics. Attempts have been made to illuminate the problem of renal secretion by studying the action of diuretics, *i.e.* substances which, injected into the blood stream or absorbed from the alimentary canal, increase the secretion of urine. In anæsthetised animals, a large increase in the urinary flow can be brought about by the intravenous injection of crystalloids such as sodium sulphate, potassium nitrate, or sugar. When a concentrated solution of salt is injected into the general circulation, water is drawn from the tissues, *i.e.* a condition of hydræmic plethora is set up. The kidney placed in an oncometer shows a great increase in volume. While the plethora lasts, there are mechanical conditions at work in the kidneys, *i.e.* rise of pressure, greater rate of blood flow, and diminished concentration of plasma—which would concur in producing an increased glomerular transudation. With certain salts, such as sodium chloride, the diuresis may be coterminous with the hydræmic plethora, but with other members of this class, such as glucose, the diuresis always outlasts the plethora, so that the continued augmentation in the secretion of urine leads to an actual concentration and diminution of the volume of the circulating blood. This behaviour in anæsthetised animals is due to the pituitary being out of action. In man, crystalloid solutions do not cause much diuresis.

As we have already seen, every substance which is not absorbed from the glomerular filtrate by the tubules should act as a diuretic since it will oppose osmotic resistance to the absorbing powers of the cells. Thus the low-threshold substances, urea, and sodium sulphate, nitrate, and phosphate, will, in any concentration, act as diuretics. The threshold substances will produce diuresis so long as their concentration in the plasma surpasses their normal threshold value. In urea diuresis, the glomerular filtration is almost unaltered, as is shown by the creatinine clearance ; the osmotic work is increased, but the oxygen consumption is not, *i.e.* the efficiency is increased. For a doubling of urine flow in the isolated kidney the osmotic work is increased 65 per cent. and the efficiency 60 per cent.* by urea diuresis.

Hayman and Starr † have counted in the rabbit's kidney the number of glomeruli which were open to circulation when in the normal state, and also after administration of caffeine. They find that, whereas in the normal state, from 50 to 90 per cent. of the glomeruli are patent, all of them are opened after a dose of caffeine. After adrenaline, on the other hand, only 10 per cent. of them may be in use, and the urine flow much reduced.

On the other hand, it seems certain that most diuretics—including caffeine—act on the tubules, causing a paralysis of their powers of absorption. Phlorrhizin may be assumed to paralyse the absorptive powers of the tubular cells for glucose. The glucose in the glomerular transudate, in passing through the tubules, may thus be concentrated sixty to a hundred times. We may assume that different diuretics have similar powers of paralysis on the absorptive mechanisms of the tubules, either general, or confined, as in the case of phlorrhizin, to one or other of the normal constituents of the plasma.

Renin. Saline extracts of alcohol-dried kidneys contain a substance which raises arterial blood pressure and accelerates urine formation owing to reduction of tubular reabsorption of water and sodium chloride.‡ The active substance, called *renin*, is an enzyme, and it has been suggested that it plays a part in the production of the rise of blood pressure, with diuresis, which is a feature of certain kidney diseases. Reduction of the blood flow to a kidney, by clamping, leads to a state of hypertension similar to the pathological condition, and is attributed to release of renin or some related substance into the blood stream. The release, into the blood, of a vasoconstrictor substance by isolated perfused kidneys has been demonstrated.§ (*v.* also p. 659.)

3. THE PHYSIOLOGY OF MICTURITION

The urine as it is formed passes through the ureters to the bladder, where it gradually accumulates, and is voided at intervals.

The Ureters enter the bladder at its base, at the two posterior angles of the trigonum. Their entrance is by an oblique valvular orifice which prevents reflux of urine from bladder to ureter. The plain muscular coats of the ureter show rhythmic contraction waves; these pass from the pelvis of the kidney to the bladder at a velocity of about 2 to 3 cms. per second, driving the contained fluid in front of them, so that the pelvis of the kidney is emptied of fluid. The intermittent injection of urine into the bladder as each wave of contraction reaches it can be seen on cystoscopic examination in man. The frequency of the contractions, normally about three per minute, is increased by warming the ureter, and by distension, so that the waves are more frequent when the secretion of urine is profuse. The ureters are supplied with nerve fibres from the splanchnic nerves by way of the renal plexus, and at their lower ends from the hypogastric nerves. Stimulation of the hypogastrics closes the openings into the bladder.

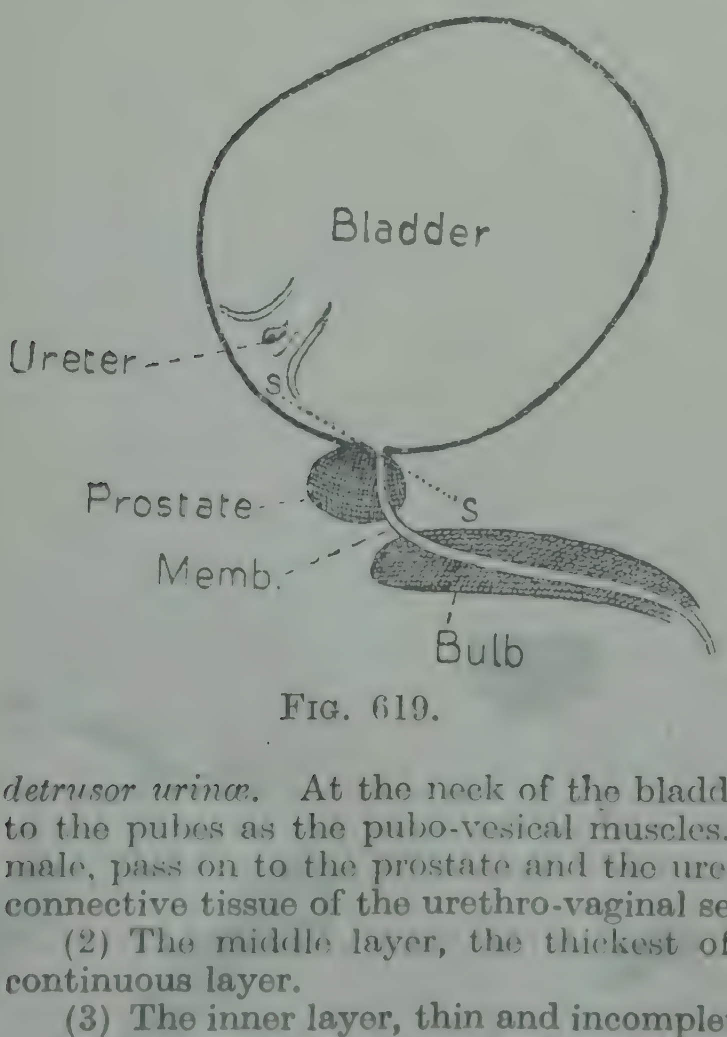

Fig. 619.

The Bladder is lined by transitional epithelium, closely adherent to the underlying muscular coat. In the latter are three layers of muscular fibres:

(1) An outer layer, running longitudinally from the neck of the bladder to the fundus, sometimes distinguished by the name of the *detrusor urinæ*. At the neck of the bladder these bundles send some fibres to be attached to the pubes as the pubo-vesical muscles. On the dorsal surface some bundles, in the male, pass on to the prostate and the urethra, while in the female they end in the tough connective tissue of the urethro-vaginal septum.

(2) The middle layer, the thickest of the three, arranged circularly and forming a continuous layer.

(3) The inner layer, thin and incomplete.

The name of *detrusor* ought physiologically to be applied to the whole of the three coats, which act as one in diminishing the capacity of the bladder.

THE SPHINCTERS. At the base of the bladder, the middle layer is modified over the trigonum by fibres, which serve as the most important sphincter, the *sphincter vesicæ*, or *internal sphincter*. Its fibres pass obliquely forwards and downwards and form a loop around the orifice of the bladder, lying on the ventral side of the bladder below and quite distinct from the thick coat of circular fibres belonging to the bladder itself (SS, Fig. 619; Fig. 620). If a catheter be passed into the urethra no urine escapes until its tip has passed the internal sphincter and actually entered the bladder. The sphincter muscle in the male is continuous with the muscular tissue of the prostate, and in the female with the muscle of the urethral wall; these continuations of the sphincter, by their tonic contraction, will also tend to prevent the escape of urine along the canal.

FIG. 620. Saggital Sections through Neck of Bladder. (METZNER after KALISCHER.)

A. In middle line (male). B. Slightly to left of middle line (male). C. Ditto (female).

This urethral muscle is strengthened by two other sphincter muscles, which are composed of striated fibres. Together they form the *external sphincter*. They can be closed voluntarily, but are only opened reflexly and as part of the act of micturition. The chief one, the *compressor urethræ*, forms a flat ring around the second part of the urethra, extending in the male from the prostate to the bulb, where its function is taken up by the *bulbo-cavernosus* (Fig. 620).

The bladder is therefore supplied with a powerful muscular wall, the contraction o which will cause its evacuation, and with sphincters of two kinds, one involuntary, th internal *sphincter*, at the neck of the bladder, and two voluntary external sphincters, th *compressor urethræ* and *bulbo-cavernosus* muscles, which can empty the lower parts of th urethra. In man, after destruction of the first part of the urethra by suprapubic prostatectomy, the compressor urethræ is the competent sphincter.

MAYO CLINIC

FIG. 621. Diagram of Innervation of the Bladder and Sphincters in Man. (After LEARMONTH.)

The Nerve Supply of the Bladder and internal sphincter (Fig. 621) is derived from two main sources, namely, from the hypogastrics (sympathetic) and from the pelvic visceral nerves or *nervi erigentes*. The upper two or three lumbar nerves send white rami communicantes to the lateral chain of the sympathetic, and thence to the collateral plexus of sympathetic nerves and ganglia which is connected above with the aortic plexus and which below forms a ganglionic mass often referred to as " the intermesenteric plexus." Most of the fibres then pass, by the plexus of hypogastric nerves, into the pelvis on each side of the rectum and in man end by relaying in the hypogastric ganglia, at the base of the bladder. From thence, fibres pass to the bladder wall. In the cat the hypogastric nerves are post ganglionic, with cell stations in the inferior mesenteric ganglia.

The pelvic visceral nerves are derived from the second and third sacral nerves. They pass directly to the vesical plexus and are carried with branches of this plexus to the neck of the bladder. The fibres do not run directly from the spinal cord to their ending in the bladder wall, but are interrupted by cells situated peripherally, partly in the vesical plexus, but chiefly in the walls of the bladder itself. Both sets of fibres carry efferent impulses to the bladder, and also supply the rectum and the colon. Afferent impulses from the bladder and urethra travel in both, but chiefly in the pelvic visceral nerves, and enter the spinal cord by the dorsal roots of the sacral nerves, particularly the second and third.

The afferent and efferent nerves of the urethra travel in the pudic nerves and in the hypogastrics.

The muscles of the external sphincter are supplied by the pudic nerve.

Action of the Pelvic Visceral Nerves. About a third of the fibres of the pelvic nerve are afferent. Excitation of the peripheral end of one pelvic visceral nerve causes a strong contraction of the same side of the bladder, sometimes extending also to a slight extent to the contralateral half. When both pelvic nerves are stimulated simultaneously, contraction of both sides of the bladder causes a rise of pressure in its interior (Fig. 622) which is sufficient to overcome the resistance of the sphincter and to cause a complete emptying of the bladder.

Relaxation of the sphincter is also believed to be brought about by impulses descending the pelvic visceral nerves. There is no doubt, therefore, that these nerves are most important for the act of micturition.

Section of the nerve on one side causes no abnormality in micturition. Section of both pelvic nerves paralyses micturition, but power of partial evacuation of the bladder may return in a few weeks. If the hypogastrics be now cut, or even the sacral cord extirpated, the bladder is not completely paralysed, though its evacuation becomes unconscious and incomplete.

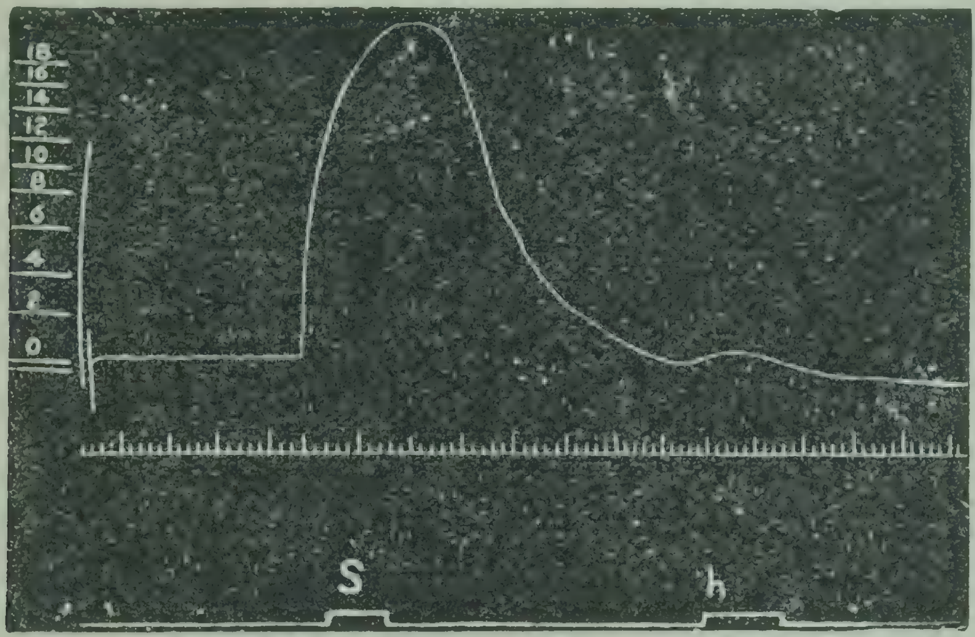

Fig. 622. Curve showing Rise of Pressure in the Bladder caused by Stimulation of S, Pelvic Visceral Nerves ; *h*, Hypogastric Nerves. (Fagge.)
The scale indicates centimetres of water.

Action of the Hypogastric Nerves. These nerves show differences in their action according to the animal and the conditions. In nearly all animals, including man, stimulation of the hypogastric nerves causes contraction of the trigone, ureteric openings, and internal sphincter. But in man, and many other animals, it may also excite either contraction or relaxation (or both) of the detrusor, and so cause either a rise * or a fall of pressure in the bladder. Complete removal of the sympathetic supply to the bladder in man appears at first to result in some weakness of the internal sphincter, but this soon passes off and normal micturition is restored. Further, since stimulation may relax the detrusor in some cases, the retention of urine and the distension of the bladder may be aided by a reflex relaxation of the bladder wall and a reflex constriction of the sphincter, excited in each case through these nerves. We may therefore regard these nerves as normally and chiefly exercising a tonic effect on the internal sphincter, and micturition must be associated with a central inhibition of this tonic activity.

Normally, therefore, both sets of nerves are essential. The hypogastrics, by their undoubted action on the internal sphincter, play an especially active part during the accumulation of urine in the bladder, while the pelvic visceral nerves are necessary for the complete evacuation of the bladder which occurs at micturition.

Sensory fibres run in both nerves : those for pain of stretching of the bladder in the sympathetic, and those for touch, together with afferents involved in the micturition reflex, in the pelvics.

The Contraction of the Bladder. The muscle of the bladder wall, being plain muscle, executes slow contractions. The nature and power of these vary according to whether the contractions are "isotonic" (constant pressure in bladder) or "isometric" (bladder contents kept at constant volume).*

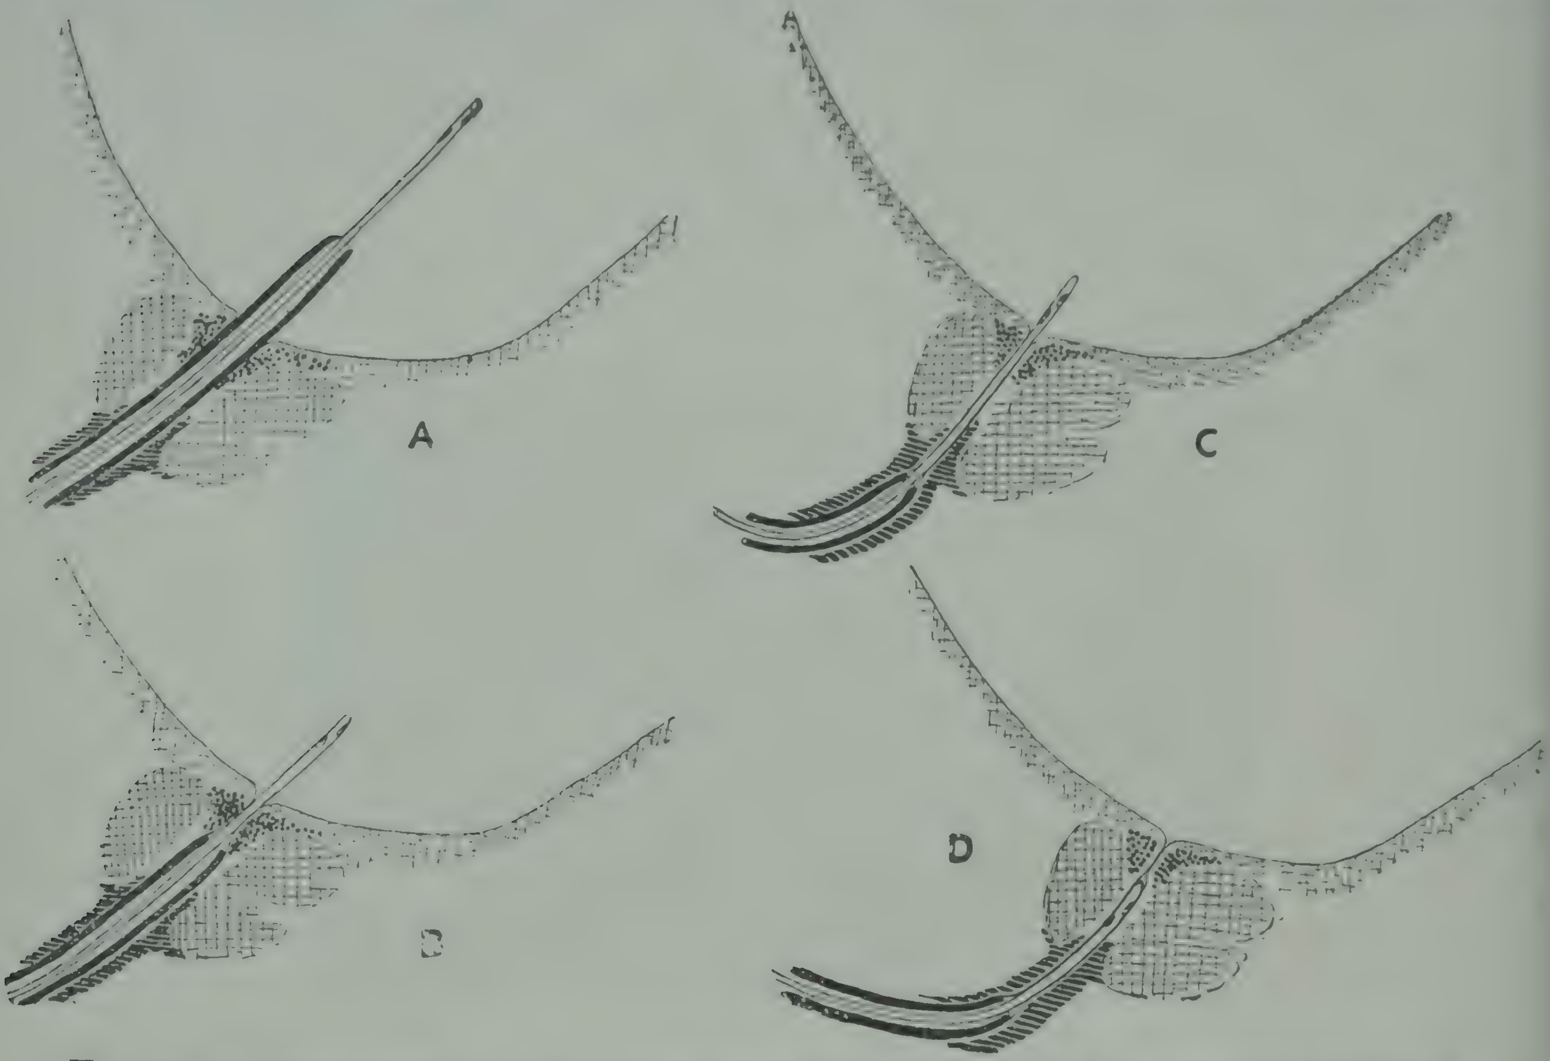

FIG. 623. Four arrangements of concentric double catheters for studying pressures in bladder, action of sphincters, etc. Internal sphincters stippled, external sphincter heavily hatched, prostate lightly cross-hatched. The wide catheter *a* is connected with the tube *f* (Fig. 624), and the narrow catheter *b* running inside it, with the bulb *l*. Fig. A: both catheters in bladder, one for filling or emptying, one for recording pressure. Fig. B: only internal sphincter functional. If a leak is arranged in the outlet of the larger catheter, a rise of pressure in that catheter shows that the internal sphincter is relaxing and allowing fluid to leave the bladder. Similarly in position C and D, the relaxation of the external sphincter can be demonstrated. (DENNY-BROWN and ROBERTSON, *Brain*, 1933, **56**.)

Under isotonic conditions, the normally innervated bladder exhibits regular rhythmic variations of volume, lasting some ten seconds, which increase in frequency and diminish in amplitude when the filling pressure is raised. Stimulation of the hypogastrics, or adrenaline in large doses, causes relaxation; stimulation of the pelvic nerves, or acetylcholine, causes contraction (but if the pressure maintained in the bladder is high, acetylcholine may cause relaxation).

Under isometric conditions, the bladder often remains quiescent for long periods, which alternate with powerful contractions, raising the pressure often to more than 100 mm. Hg, and lasting for a minute or more. These are abolished by section of the pelvic nerves and are probably reflex. Changing over from the isotonic to the isometric state at the moment when an isotonic contraction is developing leads at once to a powerful isometric contraction, but if the change-over is made when an isotonic contraction is subsiding, a period of isometric rest at zero pressure commences.

It is probable that the initiation of powerful isometric contractions whenever the pressure in the bladder rises suddenly is a reflex from stretch receptors in

the bladder wall. Afferent impulses along the pelvic nerves have been demonstrated when the bladder pressure is raised,* and once the reflex is started it is evidently self-exciting, and probably plays an important part in micturition.

The Filling of the Bladder. Except during micturition, both sphincters are in a state of tonic contraction. Thus, it requires a considerably greater pressure in the bladder to overcome the resistance of the sphincters during life than after death. The urine, therefore, as it is secreted will normally accumulate in, and distend, the bladder. Let us first consider the filling of the normal bladder. The filling and emptying of the bladder in man can be studied by the introduction of appropriate catheters as shown in Fig. 623, the catheters being connected with optical recording manometers, shown in Fig. 624. The normal bladder with its proper innervation accommodates a good deal of fluid before showing any considerable rise of pressure, or pronounced contractions. Even when fluid is introduced by a catheter 50 or 100 c.c. at a time, there is only a momentary tonic resistance, which soon subsides (Fig. 625). With a filling of about 400 c.c. the pressure rises more sharply, and at 600 to 800 c.c. there are powerful rhythmic contractions accompanied by painful sensations. By voluntary effort these can be suppressed for a time (Fig. 626), but when the pressure reaches about 100 cm. water micturition follows involuntarily.

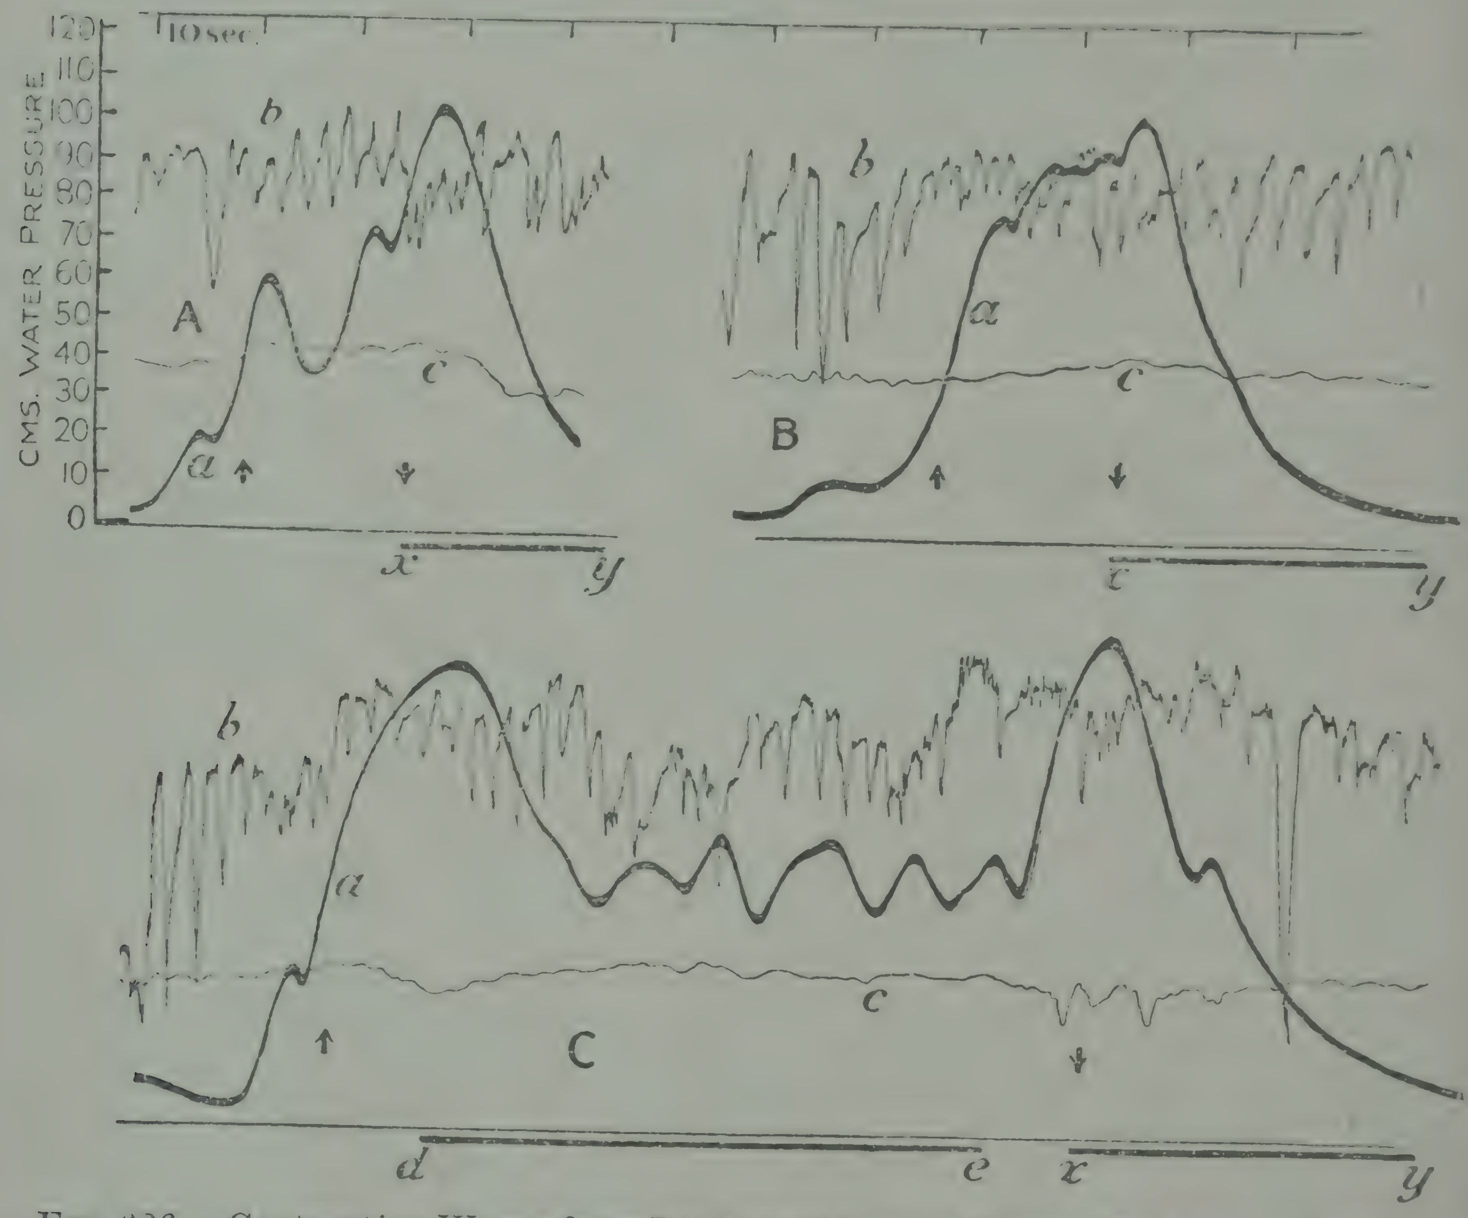

FIG. 626. Contraction Waves from Bladder of Normal Human Subject. *a*, vesical pressure (catheter in bladder); *b*, abdominal movements; *c*, rectal pressure. Arrows pointing up and down indicate opening and closing respectively of sphincters. $x - y$ = strong and $d - ɜ$ weaker, efforts at restraint. (Note reflex bladder contractions when sphincter is relaxed.) (DENNY-BROWN and ROBERTSON.)

The filling conditions are different in a bladder cut off from the central nervous system, as in patients some time after a lesion of the cauda equina and sacral cord. We may then regard the bladder as a tonic viscus with elastic walls containing plain muscle, and with a tonically contracted sphincter. If a distending force be applied rapidly, the sudden increase of tension acts as a direct excitant to the muscle, causing it to enter into contraction, which may be tonic or rhythmic. The effect of distension of the denervated bladder on the tension in this organ will depend, therefore, on the rapidity with which it occurs. In any case, the denervated bladder is highly tonic and shows a considerable rise of pressure when fluid is injected into it by a catheter; thus 200 c.c. will give a pressure of 70 cm. water, which later may fall by slow adaptation to 30 cm. or less. At such pressures the effect of the stretching of the muscular wall makes its appearance. A manometer connected with the bladder shows a series of rhythmic contractions of the muscular wall (Fig. 627, A), each lasting about a minute, and becoming more powerful as the distension of the bladder augments (Fig. 627, B). In the bladder entirely cut off from its connection with the central nervous system, these automatic rhythmic contractions gradually increase in force, until one of them suffices to overcome the resistance presented by the tonically contracted sphincter. A partial emptying of the bladder therefore takes place, but before the bladder has been emptied, the pressure falls below that necessary to overcome the resistance of the sphincter, so that there is always, under these circumstances, a certain amount of residual urine left in the bladder. This is the condition found in animals when the lower part of the spinal cord has been extirpated, or in man when it has been destroyed as the result of accident or disease.

Micturition. In the denervated bladder, the factor finally causing partial evacuation is the gradual increase in the intravesical tension from the accumulation of fluid. The same factor is prepotent in determining the onset of micturition at lower pressures in the normal animal. The desire to micturate generally arises in normal adults when about 400 c.c. of urine has collected in the bladder; it can be voluntarily overruled until the amount is much greater, but at about 700 c.c. becomes urgent and painful. The main path for these sensations is by the sympathetic, and the act of micturition is a reflex which is liberated from voluntary suppression. As a preliminary to this release the perineal muscles are relaxed. In the absence of restraint from the higher centres (*e.g.* in the infant) micturition will take place each time that the tension in the bladder has reached a certain height, the amount of fluid in the bladder at the time depending on the one hand, on the rate at which the fluid has entered this organ from the ureters, on the other hand, on the irritability of the bladder wall itself and of the nervous centres concerned with its motor innervation. The effect of the gradual accumulation of fluid and rise of tension i twofold. In the first place, it acts on the bladder wall, causing rhythmi contractions of ever-increasing intensity; in the second place, the mere stretching of the bladder originates impulses in the sensory nerve-endings in its wal and these, as we have seen with the "isometric" bladder, are reinforced a every rise of tension caused by the rhythmic contractions. These impulse travel up to the nervous centres, and are summated until, when released, they result in a sudden discharge of efferent impulses of two kinds, namely:

(1) Motor impulses to the whole musculature of the fundus of the bladder.

(2) Inhibition of the tonic contraction of the sphincter muscles. The resultant of these two processes, the contraction of the detrusor and the relaxation of the sphincters, is a complete emptying of the bladder, and the act is completed by the contraction of the involuntary and voluntary muscles surrounding the urethra and causing complete expulsion of the contents of this tube.

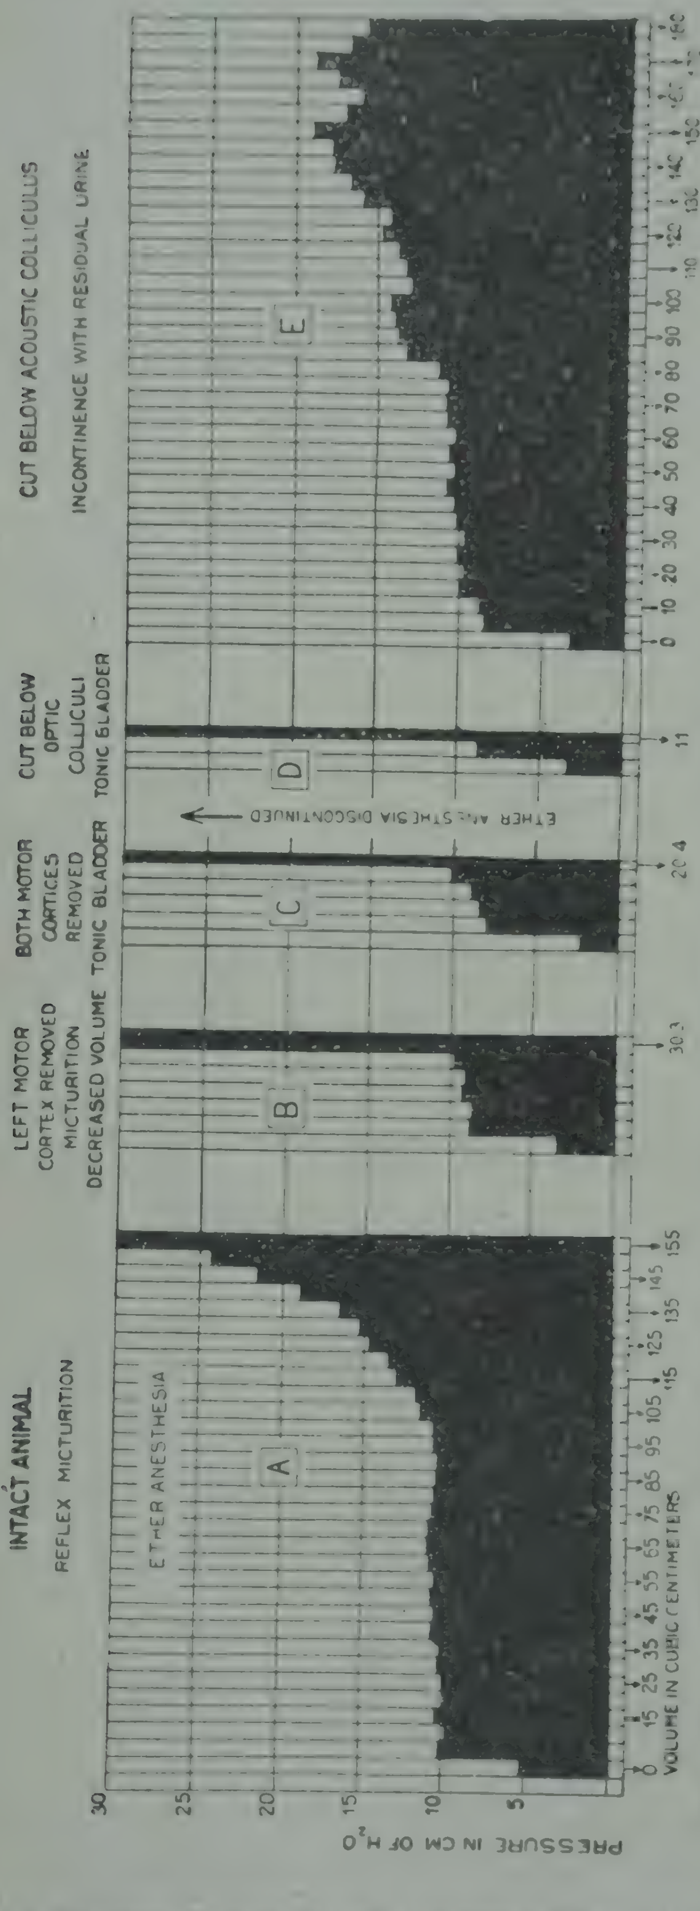

FIG. 628. Effect of brain sections on volume-pressure relations and emptying of bladder in etherised cat. (LANGWORTHY and KOLB, *Brain*, 1933, **56**, 731.)

Observations on man show that an active relaxation of the internal sphincter is a necessary part of the act of micturition. Thus a rigid catheter was introduced into the bladder, which was fully distended with fluid. On withdrawing the catheter until its opening lay just outside the internal sphincter, the flow of urine stopped. The man, however, was able to micturate directly he was told, and to stop again, though less suddenly, at will. It was impossible in this case for any of the urethral muscles to be concerned, since the rigid catheter impeded their action.

The Reflexes of Micturition. The investigations of Barrington * have revealed six closely co-ordinated reflexes concerned in micturition in the cat, viz.:—

(1) *Contraction of the bladder* when its internal pressure approaches 10 cm. of water. The afferent and efferent paths are in the pelvic nerves.

(2) *Contraction of the bladder*, even when only partially full, as a result of running fluid through the urethra. This ensures that when micturition is started by the first reflex, it will normally be continued to completion. The afferent path is the pudic, the efferent the pelvic nerve.

(3) *Contraction of the bladder* (slight), when the first part of the urethra is distended. Both paths are in the hypogastrics.

---

* BARRINGTON. *Q. J. Exp. Phys.*, 1914, **8**, 33; 1915, **9**, 261; 1925, **15**, 81; *Brain*, 1921, **44**, 23; 1922, **45**, 126; 1928, **51**, 209; 1931, **54**, 177.

(4) *Relaxation of the urethra* when fluid passes along it. Both afferent and efferent paths are in the pudic nerves.

(5) *Relaxation of the urethra* when the bladder contracts. The afferent path is in the pelvic nerves, the efferent in the pudic.

(6) *Relaxation of plain muscle of proximal third of the urethra*, when the bladder is distended. Both paths are in the pelvic nerves.

It will be seen that each of these reflexes, except the third, is capable of giving rise to the remainder, and so collaborating to ensure normal micturition. There is little doubt that similar reflexes are operative in man.

THE CENTRAL CONTROL OF THE BLADDER. Like many complex reflexes, micturition is under the joint control of higher and subsidiary nerve centres; in all there are at least four levels of control—namely, cortical, hypothalamic, brain-stem and spinal.

The nature of this control is illustrated in Fig. 628, which shows the progressive rise of bladder pressure in the cat as the contents are incremented in 5 c.c. steps, until finally evacuation occurs, complete or otherwise. With the intact animal the reflex occurred at 155 c.c.; after removal of one or both cerebral cortices the reflex was much more easily started and relaxation to accommodate the contents was slight. Section below the superior colliculi, led to so excitable a reflex that evacuation took place at only 11 c.c., but section below the inferior colliculi gave an inert bladder, showing retention with overflow, *i.e.* with incomplete emptying and no proper reflex.

In the human adult, the processes of retention and evacuation of urine are modified and controlled by reflexes and by voluntary effort. The human bladder shows a readier accommodation to increase of its contents without undue rise of pressure when its nerve supply is intact than when it has been denervated, even though connections with higher centres have been cut off as, for instance, after section of the cord in the mid-dorsal region. But its capacity is still further improved by the influence of the higher centres, which can exercise considerable restraint over the reflex micturition mediated by the lower centres. The normal action of the sphincter mechanism may be aided by the contraction of the perineal muscles, which keep the urethra closed. Under usual conditions, however, the intact subject micturates before much conscious restraint has had to be exercised. In normal micturition there is first of all a voluntary removal of restraint, so releasing the reflexes of micturition which are effected by the lower centres. These reflexes involve the contraction of the bladder and the release of the sphincters. If the contents of the bladder are small in volume, the reflex process of evacuation may be set in motion by voluntary contraction of the abdominal muscles, by which the pressure in the bladder is increased and the sphincter action reflexly inhibited (reflexes 5 and 6 above).

The third, fourth, fifth and sixth of the reflexes described by Barrington are spinal, the centre concerned being situated in the lumbo-sacral spinal cord. If this centre and its connections be intact, reflex micturition may be carried out even after section of the cord in the dorsal region, but according to Barrington, the process of micturition is always imperfect in animals and in man after section of the cord in any part of its course. In Barrington's first and second reflexes the dominant centre in the cat is in the hind-brain, and when the paths connecting the subordinate centre in the lumbo-sacral cord with the hind-brain are divided, or the higher centres injured, the emptying of the bladder remains incomplete. The spinal centre can be excited reflexly by stimulation of any sensory nerve, such as the sciatic or the fifth nerve. In many cases where, in consequence of obstruction to the passage of impulses from the higher parts of the central nervous system, micturition is delayed, this act may be excited by the application of cold or hot sponges to the perineum, and it is well known that irritation of the pelvic organs in children may give rise to reflex involuntary micturition.

Barrington finds in cats that normal micturition is lost after destruction of a small area of the midbrain situated a short distance ventral to the internal edge of the superior cerebellar peduncle, and extending from the level of the posterior end of the aqueduct in front to the middle of the motor nucleus of the fifth nerve behind.

CHAPTER XLVIII

THE SKIN AND THE SKIN GLANDS

In all classes of animals, the skin performs two functions. In the first place it serves to protect the underlying parts from injury and from invasion by foreign organisms. In the second place, it serves as a sense organ, and is richly supplied with nerves, by means of which the activities of the body as a whole may be brought into relation with the changes going on in the environment. In warm-blooded animals, the skin plays an important part in the regulation of the body temperature, since the loss of heat from the body must occur almost entirely through its surface. It also has important functions as a place for the storage of certain materials.

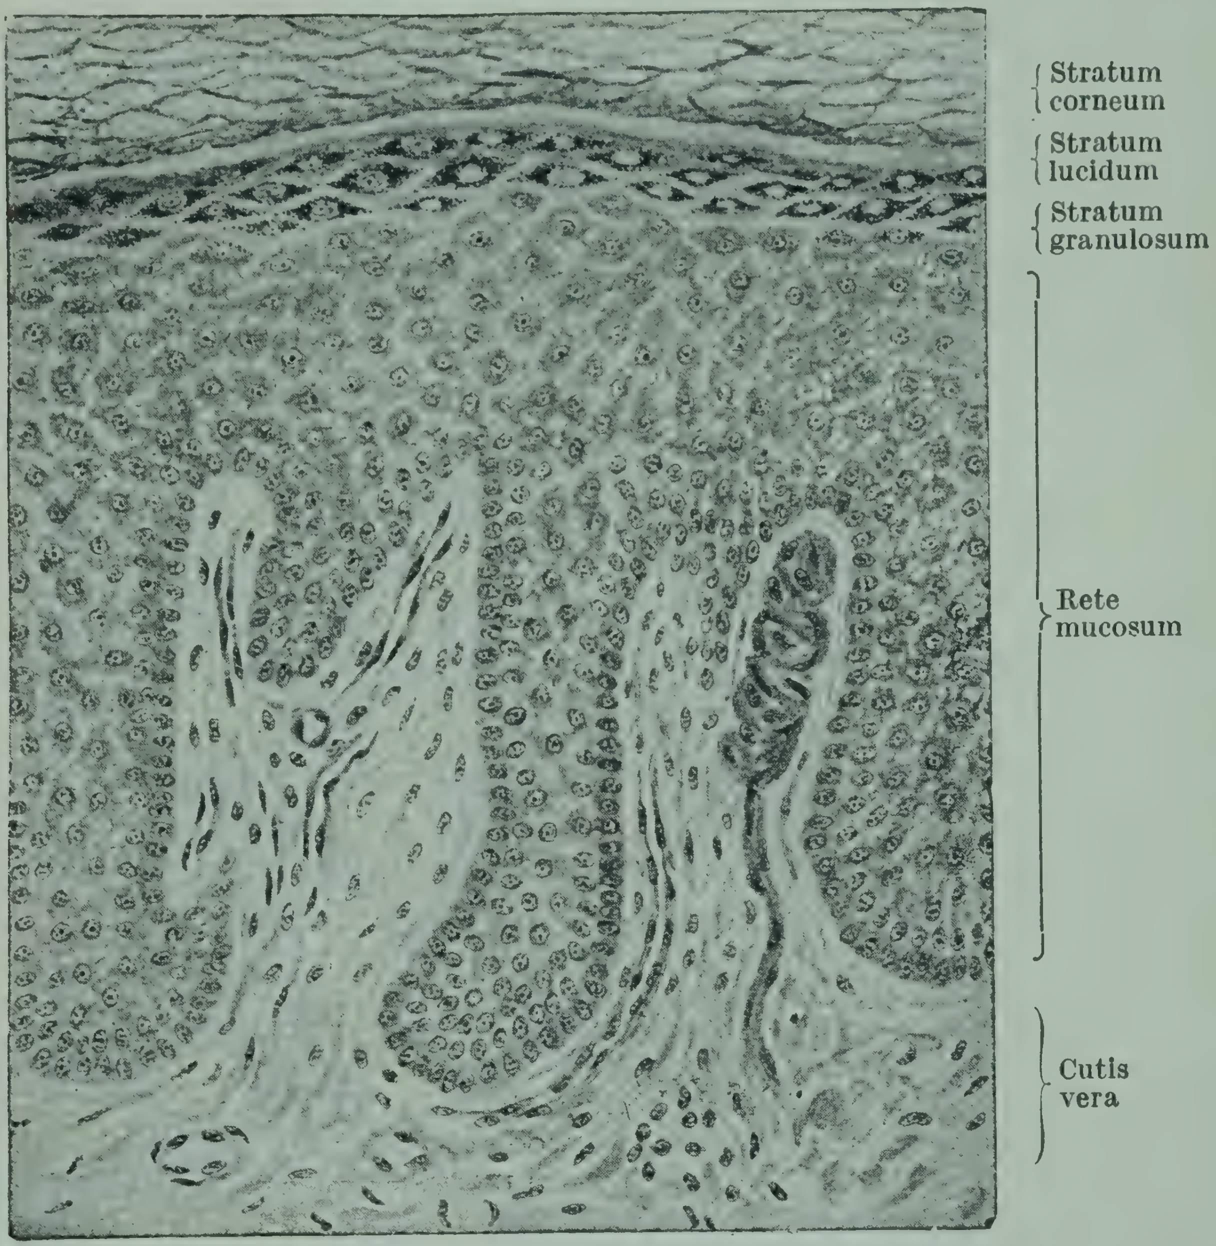

Fig. 629. Vertical Section through the Skin of the Palmar side of the Finger, showing two Papillæ (one of which contains a Tactile Corpuscle) and the deeper Layers of the Epidermis. Magnified about 200 diameters. (Schäfer.)

The development of the skin as an organ of protection shows wide modification in various classes of animals. Thus it may become the seat of formation of horny plates as in the alligator; of poisonous glands, as in the toad; or of mucous glands, as in many varieties of fishes. In warm-blooded animals, the development of hair from the deeper layers of the epidermis serves to diminish the loss of heat. Since the hair follicles are richly supplied with nerve fibres, the hairs act also as organs of sensation. In man, where the hairs are rudimentary, except in certain localities, practically only this tactile function is retained. The external layer of the skin in man consists of a tough horny layer formed by the keratinisation of the external layers of cells of the epidermis. The skin is composed of two parts, the epidermis and the cutis (Fig. 629). The epidermis is a stratified squamous epithelium. The deeper layers form the *rete mucosum*, being soft and protoplasmic, while the superficial layers forming the cuticle are hard and horny.

The deepest layers of the *rete mucosum* often contain granules of a pigment, *melanin* ; in the coloured races this is abundant, and it is also produced in white skins as a result of sunburn. The formation of melanin is due to the presence of an oxidase in the *melanoblast* cells ; fresh or formalised sections of skin rapidly form melanin in these cells if immersed in a solution of 3 : 4 dihydroxy-phenylalanine.[*] This substance is the first stage in the oxidation of tyrosine by the oxidase called tyrosinase,[†] and we may suppose that tyrosine is the parent substance of melanin.

The most superficial layer of the rete mucosum is formed of flattened cells filled with granules of a material staining deeply with hæmotoxylin and eosin, known as *eleidin*. This layer is called the *stratum granulosum*. Immediately superficial to this layer is another in which the cells are indistinct. The cells are clear in section and form what is known as the *stratum lucidum*. These two layers evidently constitute the intermediate stages in the transformation of the cells of the rete mucosum into the horny scales which make up the *stratum corneum*.

The cutis, or corium, is composed of dense connective tissue, which becomes more open in texture in its deeper part, where it merges into the subcutaneous connective tissue. The elasticity of the skin is due to the presence in the corium and subcutaneous tissue of numerous fine elastic tissue fibres. In old age this is diminished in amount, and the collagen fibres increased, especially where wrinkles occur. The most superficial layer of the corium is prolonged into minute papillæ, over which the epidermis is moulded. These papillæ contain, for the most part, capillary blood vessels ; a few contain touch corpuscles, special organs of tactile sensation. The blood vessels of the skin form a close capillary network immediately at the surface of the cutis, sending up loops into the papillæ. Direct anastomoses between arterioles and venules (arterio-venous anastomoses) are common in the skin in parts liable to become cold, *e.g.* the hands, feet and digits in man, the ear in rabbits, etc.[‡]

All parts of the skin, except the palms of the hands and the soles of the feet, are beset with hair follicles. The hair follicles are small pits which extend downwards into the deeper part of the corium, being downgrowths of the rete mucosum. The hair grows from a small papilla of cells at the bottom of the follicle, the part of the hair lying within the follicle being known as the hair root. The hair itself consists of long, tapering, horny cells, the nuclei of which are still visible, though the cell substance has been almost entirely converted into keratin.

THE SEBUM. The cuticle is kept supple and preserved from the drying effects of the atmosphere by being constantly impregnated with a fatty material known as *sebum*. This material is formed by the *sebaceous glands*, which are present wherever hair follicles are to be found, and to it the secretion of any local *apocrine* sweat glands is added. A sebaceous gland is a pear-shaped body, consisting of a secreting part and a short neck opening into the follicle. The gland proper is composed of a solid mass of cells. The outermost cells are flattened and generally show signs of proliferation. The cells lying internal to these are much larger, and their protoplasm is transformed into a network, in the meshes of which are granules which show the reactions of fat. Further inwards, the protoplasmic network diminishes in amount, while the fatty granules increase in size, so that, in the lumen adjoining the duct, we find only a mass of cell débris and droplets of fatty material. It has often been thought that the secretion of sebum depended simply on a fatty degeneration of the cells. The granules, however, when they first appear, stain with acid fuchsin, but not with osmic acid, and one must regard the formation of sebum as an act of true secretion, in which secretory granules are gradually transformed into the special constituents of the sebum. The fatty acids of the sebum are for the most part in combination, not with glycerol but with higher alcohols, including isocholesterol. Wool-fat or lanoline, which may be extracted from wool, as well as from the feather-glands of water birds, such as the goose and duck, consists mainly of esters of isocholesterol. It presents many advantages over ordinary fat as a protective salve for the surface of the body. It can take up as much as 100 per cent. of water ; it does not tend to become rancid ; it has a destructive action on streptococci, and other organisms, which it owes to certain fatty acids and soaps.[§]

The secretion of sebum is a continuous process, though it is probably quickened in conditions of increased vascularity of the skin. The extrusion of the products of secretion is determined by the presence of unstriated muscle fibres, the *arrectores pilorum*, which pass from the surface of the cutis obliquely over the outer surface of the sebaceous gland. They are supplied by sympathetic nerves. When these muscle fibres contract, the hair is erected and a certain amount of the sebum squeezed out on to the root of the hair and the surrounding skin. This contraction will occur on faradic stimulation, or whenever cold is suddenly applied to the skin. In some animals, including man, contraction also occurs in response to adrenaline.[||] The contracted condition of all the muscles of the hair follicles is shown by the " goose-skin " produced under such circumstances. There is no evidence that the secretion of sebum is in any way under the control of the central nervous system

The Sweat Glands. The sweat glands are distributed over the whole surface of the skin, and are especially abundant on the palm of the hand and on the sole of the foot. They are composed of single, unbranched, coiled tubes, which lie in the subcutaneous tissue and send their ducts up through the cutis, to open on the surface by corkscrew-like channels which pierce the epidermis. The secreting part of the tube consists of a basement membrane lined by a double layer of cells; the innermost of these are cubical and represent the secreting cells proper. Between the secreting cells and the basement membrane is a layer of unstriated muscle fibres. The duct of the gland has an epithelium, consisting of two or three layers of cells with a well-marked internal cuticular lining, but there is no muscular layer.

In addition to these, which are sometimes called the *eccrine* sweat glands, there are in certain situations, *e.g.* axilla, larger glands somewhat resembling sebaceous glands, and often, like them, associated with hairs. They are called *apocrine* glands and secrete a fluid containing a fatty material of peculiar odour. The *ceruminous glands* of the external auditory meatus are similar, and secrete a waxy material.

Insensible Perspiration. It has been known since the work of Sanctorius in 1614 that a person slowly loses weight between meals. Since loss of weight = loss of water + loss of CO_2 — gain of O_2, the net loss at usual values of R.Q. is chiefly due to loss of water by skin and lungs, and only to the extent of 10 per cent. or less, to the difference between oxygen intake and CO_2 output. It varies according to the metabolic rate, as would be expected, since it represents the means by which, in a majority of cases, about 25 per cent. of the body heat is lost.[*] It also varies with the temperature and humidity of the air. Benedict and his colleagues [†] estimate the loss at about 18 grams per hour for lungs and the same for the skin, in a man with a basal metabolism of 1,700 cals.: this would amount to about 430 grams from the skin and a like amount from the lungs in the twenty-four hours. In the more humid atmosphere of Europe it may be less. About one-quarter of the total loss from the skin takes place from the hands and feet, which lose moisture at about three times the rate found for equal skin areas elsewhere. These estimations refer, of course, to the condition in which there is no visible sweating, but only a loss of so-called "insensible perspiration" which is continually going on. It is apparently not due to slight sweating, but to a passage of water vapour by osmosis, through the skin,[‡] and, as it seems, not by way of the sweat glands at all.[§] Individuals lacking sweat glands lose as much by insensible perspiration, in cool surroundings, as normal controls do.

The Sweat, which mainly consists of the secretion of the eccrine glands, is the most dilute of all animal fluids. As collected, it generally contains epithelial scales and some sebum, and is usually acid in reaction; the *p*H, however, may range from 4 to 8, according to the extent to which the lactic acid is neutralised. The composition of sweat varies considerably, but the following results are typical:—

COMPOSITION OF HUMAN SWEAT.[§]

Water		99·742–99·221	per cent.
Solids		0·258–0·779	,,
Organic solids		0·03–0·290	,,
Ash		0·144–0566	,,
Chlorine (usually over 0·15 per cent.)		0·059–0·346	,,
Potassium	about	0·017	per cent.
Sulphate	,,	0·004	,,
Lactic acid	,,	0·070	,,
Urea		0·03	,,
Sodium	,,	0·15	,,
Sugar	,,	0·004	,,

The only plentiful constituent is sodium chloride, the amount of which varies, though sweat is always hypotonic. In profuse sweating a man may lose 10 g. or more of Cl in three hours. In winter, or in subjects unaccustomed to sweating, the chloride content is much higher (*e.g.* 50 mE. per l.) than in those acclimatised to heat or used to sweating (*e.g.* 25 mE. per l.). The more rapid the sweating the higher the chloride concentration. Urea is present in about the same amount as in blood, but lactate seems to be either concentrated or formed by the sweat glands. After filtration, sweat forms a clear colourless fluid of a specific gravity of about 1,003.

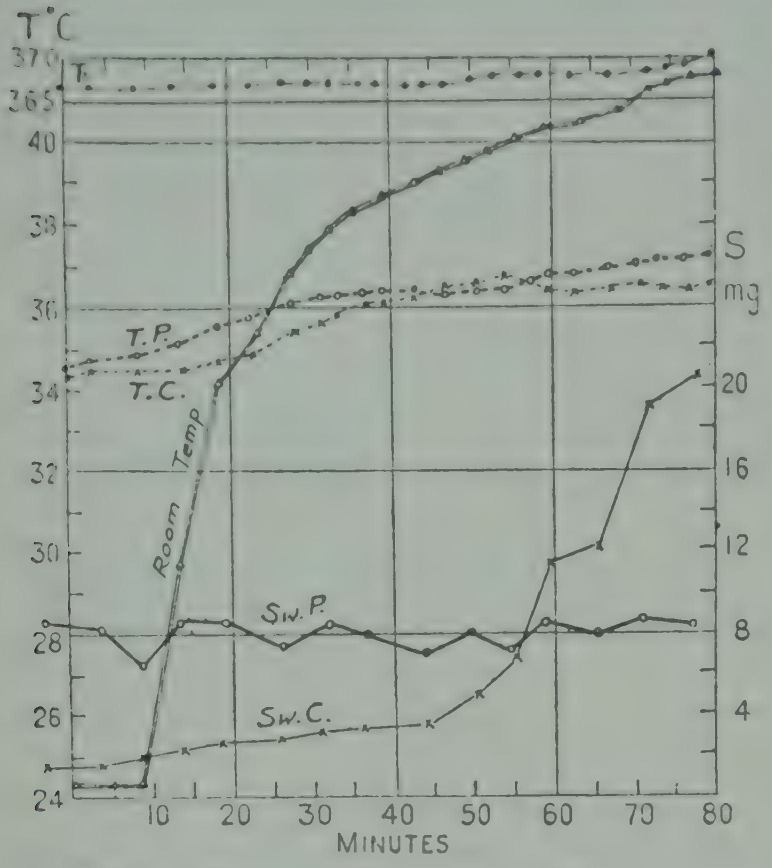

FIG. 630. Sweating in m.g. per 20 sq. cm. per 5 minutes from palm (Sw.P.) and chest (Sw.C.) with rise of room temperature. Tr. T.P., T.C. = temperatures in rectum, on palm and on chest respectively. (KUNO, *Lancet*, 1930.)

Sweating. Many sweat glands are inactive and incapable of secreting, but there are from 2 to 3½ million functional sweat glands in the body.* The excretion of sweat by the skin is mainly determined by the need for regulating the temperature of the body, so that the water lost in this way depends on the heat production of the body or on the external temperature, and is very little affected by alteration in the quantity of fluid drunk. If a man's body be enclosed in a vessel through which a current of air is passed, and the temperature of the air be gradually raised, it will be noted that the amount of water given off rises slowly up to a certain degree and then mounts rapidly. The sudden kink in the curve is due to the commencement of the activity of the sweat glands (Fig. 630), *i.e.* to onset of sweating.

The secretion is under the control of the central nervous system and, except for that of the palms and soles, has been shown by Kuno † to be almost entirely adapted to the regulation of the body temperature. In a hot humid climate a lightly clad man can sweat 200 g. per hour when at rest, and at work up to 900 g./hr. The nervous mechanism can be set in to activity either centrally or reflexly. The most usual cause is a rise of the body temperature. If a man sits in a warm room, *e.g.* in a Turkish bath, the secretion of sweat commences at a mean skin temperature of 34–35° C., or as soon as the mean temperature of the body has attained a height of 0·2° to 0·5° C. above normal. Sweating is not uniform in different parts of the body. The palms and soles do not react to the rise of temperature ; in profuse sweating about 50 per cent. of the total sweat is given by the trunk, 25 per cent. by head and upper limbs and 25 per cent. by the lower limbs.‡ It will be seen that most sweating occurs in those regions which, by reason of their exposure, offer the best opportunities for evaporation.

‡ WEINER. *J. Physiol.*, 1945, **104,** 32.

The palms and soles are peculiar inasmuch as they constantly secrete some sweat, but the amount is not increased by rise of temperature (Fig. 630). It does, however, show an increase under direct nervous control, as in exercise, anxiety, or mental stress of any kind (Fig. 631). This probably applies also to the pads of the cat, which cannot play an important part in the regulation of body temperature, since they are the only parts of its body provided with sweat glands.

Sweating is facilitated by muscular exertion, and the body temperature will generally be found to be raised if it be taken at the instant that sweating has commenced. The effect of rise of temperature may, however, be partly local, so that one arm enclosed in a hot-air bath may sweat more than the rest of the body. Under ordinary circumstances, the central stimulation by the warm blood is the predominant factor. Sweating may be induced in the cat's paws by warming the blood passing through the carotid arteries on its way to the brain, at a time when the temperature of the blood circulating through the rest of the body, including the paws themselves, has undergone no alteration. Sweating may also be aroused by asphyxia, and this result is found even in the spinal cat, *i.e.* after separation of the spinal centres from the medulla. The secretion of sweat, although generally associated with increased vascularity of the skin, is not entirely dependent thereon. Thus, even in the amputated limb, stimulation of the sciatic nerve may cause the appearance of drops of sweat on the pad of the foot. If the sciatic nerve be stimulated in the intact animal, the secretion of sweat which is produced is associated with constriction of the vessels of the skin, due to simultaneous stimulation of the vaso-constrictor fibres running in the sciatic nerve.

As Langley showed,* the nerves to the sweat glands are sympathetic. Leaving the cord by the white rami from the second dorsal to the third or fourth lumbar nerves, they pass into the sympathetic chain. Here the first relay of fibres ends in connection with the cells of the sympathetic ganglia, and a fresh relay of fibres, which are non-medullated, pass from the cells along the grey rami into the various spinal nerves, to be distributed to the whole surface of the skin. There are certain anomalies connected with sweat nerves, however. Thus adrenaline has, in man, no action, whereas pilocarpine, ¼ gr. (16 mg.) or mecholyl, 25 mg., which are parasympathetic excitants, cause abundant sweating, even after division of the sweat nerves, so that they must act peripherally on the glands. Complete section and degeneration of all the nerves to a limb, however, greatly reduces and finally abolishes the response to pilocarpine, and it also reduces the vasodilator response (Burn).† The action of pilocarpine, as well as the effects of artificial stimulation of the sweat nerves, is abolished by the administration of atropine. We may therefore suppose that, as in the case of the sympathetic ganglion synapse, the "chemical transmitter" in the case of the sweat glands, is not adrenaline, but acetyl choline, which substance does, in fact, cause sweating. The injection of pilocarpine or pituitrin into the cerebral ventricles also causes profuse sweating,‡ apparently by exciting the diencephalic centres connected with the origins of both sympathetic and parasympathetic systems.

Absorption by the Skin. In order to test the alleged influence of baths containing medicinal substances in solution, many experiments have been made to determine whether absorption is possible by the skin. It may be regarded as established that the uninjured skin is impermeable to watery solutions of salts or other substances, though ions can be carried through by an electrical current (ionophoresis). On the other hand, it is possible to produce a certain amount of absorption by the application of substances conveyed in fatty vehicles. Thus, the administration of mercury is often carried out by the inunction of mercurial ointments, and the fact that mercurial salivation may be produced in these conditions shows that a certain amount of the mercury must have been absorbed.

† BURN. *J. Physiol.*, 1922, **56**, 232; 1925, **60**, 365.

‡ CUSHING. Papers relating to the pituitary body, hypothalamus and parasympathetic nervous system. (Baillière, Tindall and Cox, 1932.)

It is difficult to imagine that any appreciable amount of cod liver oil will be available for the nutrition of the infant when this substance is administered by rubbing it on the skin. On the other hand, the moist mucous surfaces, such as the conjunctiva or the mucous membrane of the respiratory passages, as well as raw surfaces of the skin, *e.g.* which have been deprived of their epidermal layer by the application of blisters, permit the rapid passage of substances in either watery or oily solution.

Gaseous Exchanges through the Skin. In any animal with a thin moist skin, such as the frog, the absorption of oxygen and the excretion of CO_2 through the skin may be sufficient for the proper aeration of its blood, so that it may continue to live after the extirpation of its lungs. In man there is also a continuous output of CO_2 through the skin, but the amount leaving the body in this way is negligible compared with that which is exhaled through the lungs. The loss of CO_2 by the skin rises with increase of external temperature. Thus at a temperature of 29° to 33° C. the CO_2 output by the skin is about 0·35 g. per hour, *i.e.* about 8·4 g. in the twenty-four hours. When the external temperature rises above 33° C., the CO_2 output increases, so that at 34° it is doubled and at 38·5° it may amount to as much as 1·2 g. per hour (Schierbeck). It is just at this temperature of 33° C. that a secretion of sweat begins to be noticeable, so that it seems probable that the increased CO_2 output may be due to the secretion of sweat, which, like other body fluids, contains carbon dioxide that readily escapes from it on exposure to the air.

Storage Functions of the Skin. The corium, together with the subcutaneous tissue of the skin, has considerable capacity for storing various materials, provisionally or permanently. Of these the best known is fat, which is laid down in fat cells as a permanent store of subcutaneous adipose tissue.

The other type of storage which takes place in the skin is what has been called by Cannon *storage by inundation*, and which may be compared with the storage of water in a bog. The areolar tissue of the skin, and other organs, readily take up more water, and is an important place for its storage. Excess water retained in the body is held most conspicuously in the subcutaneous tissues, and, in pathological states, may lead to œdema ; conversely, in water deprivation the subcutaneous water stores are freely drawn upon. After severe hæmorrhage, this may happen very quickly, about half the water which leaves the tissues to enter the blood coming from the skin, the remainder chiefly from the muscles.

When the blood is flooded with soluble substances, these may likewise find temporary storage, accompanied by water or not, in the subcutaneous tissues. The most noteworthy instances are of glucose and salts. When the blood sugar level rises suddenly, considerable amounts of sugar may find temporary lodgment in the subcutaneous tissues, and as the heavy load of sugar is removed from the blood for utilization, or storage as glycogen, so the flood of sugar subsides from the connective tissues into the blood again. It is similar with chlorides. When a chloride-rich diet is given, or after intravenous chloride infusion, the heaviest storage of chloride is in the skin, while in chloride starvation, in which the blood chloride is preserved almost unchanged, as much as 90 per cent. of the chloride lost from the body may have come from the skin, though this tissue forms only 16 per cent. of the body weight.

THE HAIR

Hair in the lower animals has definite functions in relation to heat regulation, but in man this is of slight importance. The beard is a male secondary sexual character, as is hair on the chest and abdomen, and is not developed in men castrated before puberty. The hair of the axillæ and pubic regions is a secondary character of both sexes and is undeveloped after early removal of the gonads. There are considerable racial variations in hair.

There is no doubt that the growth and distribution of hair follicles is affected by hormones and vitamins, but exact knowledge of the effects is not yet available. The suprarenals seem to exert an influence, as in suprarenal tumours hair growth may be abnormal, but since sexual precocity is also a feature, an influence through the gonads may be more fundamental. The thyroid hormone is also essential to the proper growth and normality of the hair.

Curliness or straightness has not been satisfactorily explained ; the former belief that hairs curled because they were elliptical in cross section instead of circular appears to be inadequate to explain it. Artificial curling, as in "permanent waving," is due to elongation of some of the filamentous keratin molecules by stretching under heat (*vide* p. 43).

Pigmentation, due to deposition of melanin, may be diffuse, as in red hair, or granular, as in black. The pigment tends to bleach in sunlight.

Hairs do not grow indefinitely, but after a period of growth the length remains stationary and the hair sooner or later may fall, or be pulled, out, after which a fresh cycle begins. Each hair follicle has its own characteristic growth rate and cycle ; on the average the head hair grows about 0·4 mm. daily and normally reaches 65 cm. in length, if uncut, *i.e.* growth continues for about four years. Short hairs such as those on the forehead, grow more slowly. Shaving off the hair has not been proved to modify the rate of growth. Increased rate of growth is preceded by an increased metabolism in the hair bulb.*

CHAPTER XLIX

THE TEMPERATURE AND HEAT-BALANCE OF THE BODY

The temperature of the body of cold-blooded, or *poikilothermic*, species differs little from that of the surroundings. Their torpidity in cold surroundings, and the risk of heat damage in hot ones are hence considerable handicaps to them.

The birds and mammals, by contrast, are called *homoiothermic* animals: they have body temperatures which vary but slightly, even in the face of widely different surrounding temperatures. The actual mean body temperature differs according to species, *e.g.* in birds it is usually 39° to 40° C., and in mammals 37° to 40° C. Thus in man it is 37°; in the horse 37·8°; in the cow, cat and dog 38·6°; in the rabbit 39°; the pig 39·2°, and in the sheep 40° C. Their temperature is higher than that of their usual surroundings, and this is owing to the heat generated by oxidative processes continually going on within the body: in hot surroundings, however, the body may, for a time, be cooler than its environment, so there must be some active method of cooling.

The approximately even temperature is obviously due to the existence of a more or less perfect state of balance between heat production and heat loss. Since heat production = heat loss, which is approximately equal to heat leaving the skin, it is evident that all these values can commonly be related to the surface area of the body.* Accordingly they are expressed in terms of kilocalories per square metre of body surface per hour (Cal./sq. m./hr.)† as in the case of B.M.R. measurements.

It takes a smaller heat-exchange to warm or cool the body than to warm or cool an equal weight of water, because the specific heat of the body is only about 0·83; hence a man of 70 kg. has only the same thermal capacity as about 58 kg. of water.

The Body Temperature in Man. It should be understood that the idea of a stated body temperature (T_b) is somewhat of an abstraction, since the temperature varies from point to point in or upon the body. Active tissues, such as liver, or contracting muscle, have higher temperatures than inactive tissues, or than tissues which are losing heat rapidly, as the skin does. But, owing to the circulation of the blood, and to the conductivity and thermal capacity of the tissues, there is a constant tendency for the temperatures of the interior of the body to equalise, and for there to be a gradient of varying steepness from the deep tissues to the skin. This gradient is illustrated by the following temperatures.

SURFACE

Skin covered with clothes	33° to 35° C.
Naked skin in bath at 5° C.	17° C.
,, ,, ,, 25° C.	26·5° C.

MUSCLES 12 MM. BELOW THE SURFACE

In bath at 5° C.	36·3° C.
,, ,, 25° C.	36·9° C.

It is common practice to take the temperature of man in the rectum, or mouth, or occasionally in the axilla. The rectal temperature lies nearest to the mean deep body temperature: that in the mouth varies with rate of breathing, and with loss of heat through the cheeks: in determining it the thermometer should be left *in situ* beneath the tongue for (usually) at least three minutes, or until the maximum is reached. A thermometer placed in the axilla takes several minutes to reach its maximum reading. Usual temperatures are: rectal, 37·5° C.; mouth 37·0° C., and axilla 36·5° C., in healthy adults, resting, and well clad. It will be seen that the prevalent unqualified statement that the "normal temperature" is 98·4° F. (36·9° C.) is meaningless: many young adults, when up and at rest have temperatures below this, usually about 97·5° F., on the average during the day; fluctuations are definite, usually of at least ± 1° F., during the day. The highest temperature is usually at about 6 p.m., and the lowest at about 4 a.m., and the oxygen usages show parallel variations. They are probably caused by variations in the state of tension in the muscles, and in the activity of digestion. If the habits of a man be reversed, so that he sleeps by day and works at night, it is possible partially to reverse the diurnal rhythm of temperature.[*] The temperature may also be transitorily affected by various acts, such as the taking of hot or cold baths,[†] eating ice, taking hot food, or muscular work,[‡] the last-named often producing considerable rise. The temperature is often higher in females (except during eight to twenty-one days after menstrual periods) and in young individuals than in males or older ones.

---

* BENEDICT. "Vital Energetics." (Washington: Carnegie Inst.)

† 1 Cal. = 1,000 cal. = roughly 4 B.Th.U. or 0·00004 Therm.

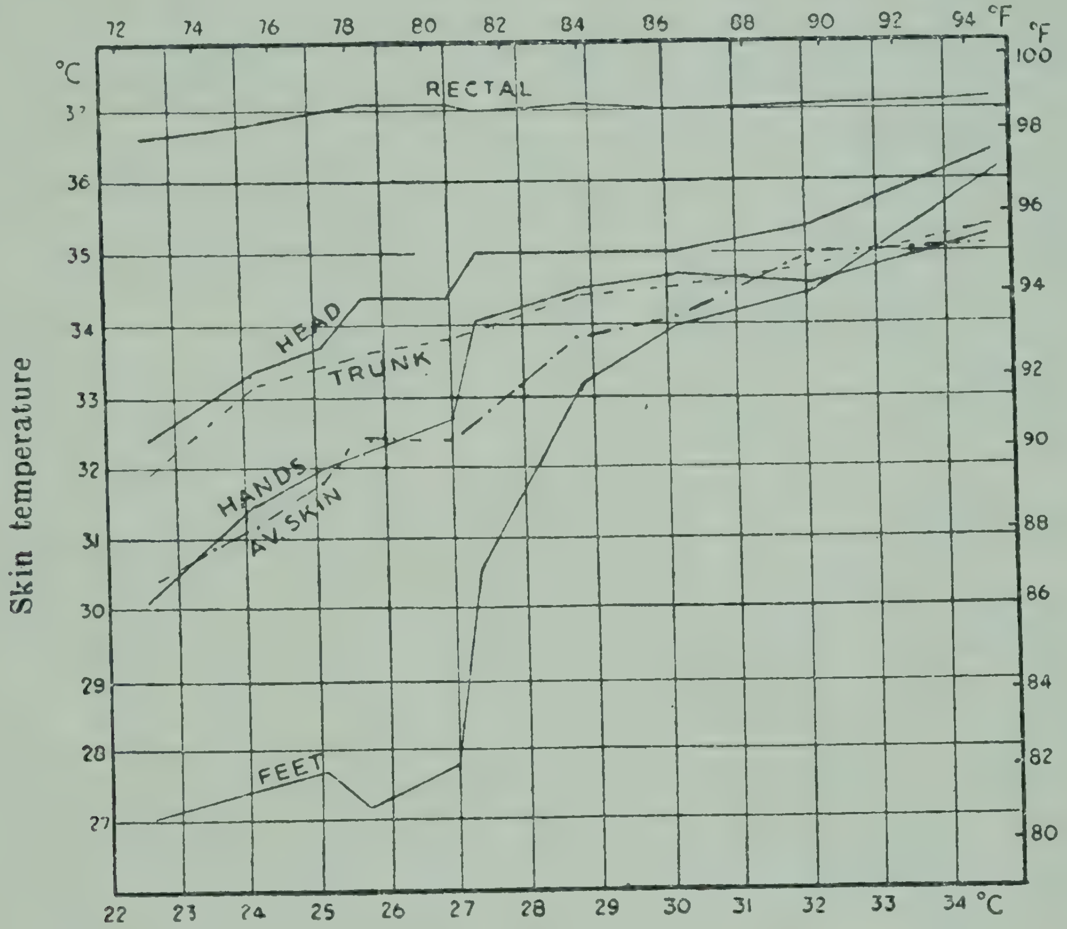

FIG. 632. Rectal and Skin Temperatures at Different Places, and mean temperature, after 1½ hours at varying Air Temperatures. (BRUNT, after HARDY and DU BOIS, 1941.)

There are limits to the power of the organism to regulate the body temperature even approximately when faced with excessive heat production from within, as in strenuous muscular exercise; or with greatly increased rate of heat loss, as in cold baths, arctic climates, or deprivation of clothing; or with increased production and much reduced rates of heat loss, as in exercise in hot moist surroundings. In these circumstances the body temperature may rise or fall considerably. Regulation is more imperfect in infants than in adults.

The Temperature of the Skin. Skin temperatures (T_s) can be measured by means of thermo-electric junctions, or, more accurately, by the Hardy radiometer. The temperature varies considerably according to position, state of local circulation, sweating, climatic conditions, clothing, etc. Beneath adequate clothing the trunk skin temperature is usually about 33° C.: with nude subjects the head and neck are warmest (33° in room at 24°), and feet the coldest (27°) (Fig. 632).

---

[†] DILL and FORBES. *Amer. J. Physiol.*, 1941, **132**, 685.

[‡] MACKEITH, *et al.* *Proc. Roy. Soc.*, 1923, **95B**, 413.

The *mean skin temperature* is the average temperature taken at 15 or more points suitably distributed on the skin surface. It rises about 1° for each 2° rise in surrounding temperature, until the latter reaches 28°–30°, after which it remains level for a while. The "comfort zone" of *mean* skin temperature is 30°–35° C. The *mean temperature of the body* can be calculated from the rectal and mean skin temperatures. These data are valuable in dealing with the physical aspects of heat balance.

REGULATION OF BODY TEMPERATURE

The small variation in the body temperature of mammals connotes an equalization of heat production and heat loss by adjustment of one or both. It will be convenient to deal under separate headings with these two methods of regulation. But first a prevalent misconception must be cleared up. This is the belief that a raised temperature necessarily means increased heat production or diminished heat loss, or both.

A *rising* temperature means that the rate of heat production is greater than that of heat loss, and conversely for a falling temperature. But a steady *raised* temperature means that once more heat production and loss are balanced, though the regulator is, for some reason, set to a different level; the raised temperature by itself tells us nothing about the rate of production and loss, except that they are equal when it is constant.

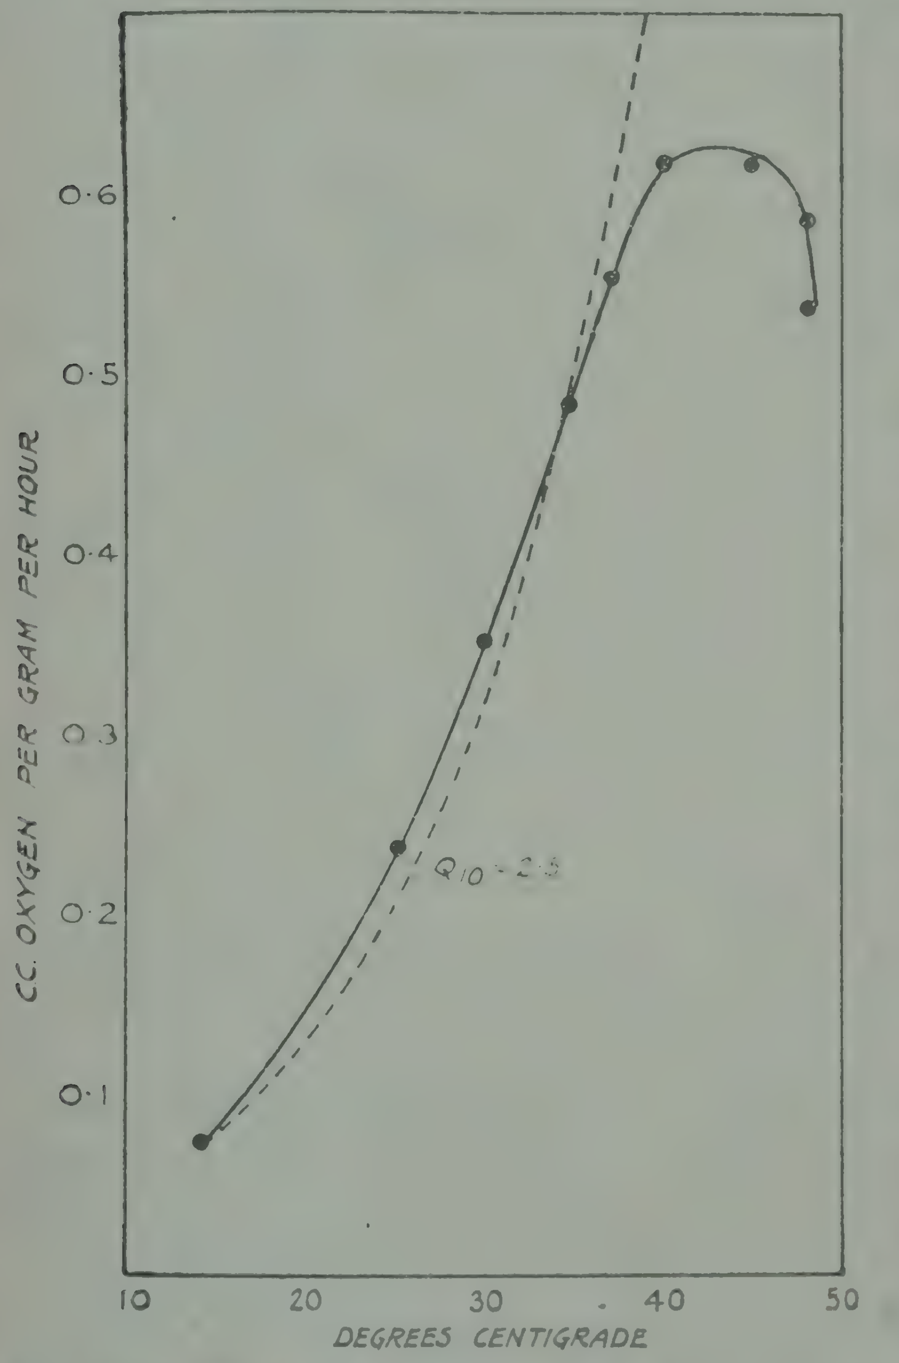

FIG. 633. Effect of Alteration of Temperature on Oxygen Usage of Plain Muscle (Guinea-pig Uterus). Abscissæ = temperature. Ordinates = c.c. oxygen per gram per hour. The dotted line represents the theoretical curve if the oxygen intake were increased two and half times for a rise of 10° C.

The Regulation of Heat Production. In the oxidative processes responsible for heat production all the tissues participate. In the regulation of heat production the muscles probably play the leading part: even during rest these are the seat of a restricted heat production, which is largely increased with every active contraction and with heightened states of tonus. Weight for weight, the liver is probably one of the most constant and active sources of heat: the temperature of the blood of the hepatic veins is often the highest in the body. If the oxygen utilisation of the body is increased, the heat production is also raised, and if the heat loss is not also proportionately increased the body temperature will be increased until loss again equals production. Thus the intravenous injection of 0·02 g./kg. of dinitro-α-naphthol may cause the body temperature of dogs to rise to 45° C. and of pigeons to 50° C.; the oxygen consumption in such cases may be increased several-fold.*

When isolated tissues are subjected to alterations of temperature, their oxygen utilisation, and therefore their heat production, increases with rise, and decreases with fall of temperature, a rise of 10° C. increasing the oxidative processes two- to three-fold, as for many chemical reactions (Van't Hoff's law) (Fig. 633). Above a certain temperature (40°–45° C.) damage is done to the tissues, and the oxidative processes fall off again. The behaviour of intact cold-blooded animals is much the same: the change in their metabolism with change of temperature therefore tends to augment, rather than to counteract, the effects of environmental temperature upon the body temperature.

Since the homoiothermic animals maintain an (almost) even temperature despite very wide variations in their environment, we have to enquire whether, in cold surroundings at all events, there may not be some mechanism (quite apart from that brought into play by increase of voluntary movement) by which the rate of metabolism is adjusted, so that increased tendency to cool is met by an increased rate of heat production; the opposite response, of reduced metabolism when surrounding temperatures are raised, might also enter into the account. These responses do, in fact, occur, and constitute what has been called the *chemical regulation* of temperature: it is purely a regulation of production, and not of loss, of heat. But if, for any reason, the various regulative processes *fail* to prevent a change of body temperature, then the tissues will behave like isolated tissues, and so produce more heat the warmer they become, and *vice versâ*.

The heat production in the muscles is dependent on their connection with the central nervous system. If this connection be severed, either by curare or by section of the cord, or if the reflex play of impulses on the muscles be abolished by anæsthetics, the animal will react like a cold-blooded animal.† The total metabolism of the body and the total production of heat then sink to a minimum, and are diminished by application of cold, or increased by application of warmth. On the other hand, in the intact mammal, moderate changes of temperature in the environment reflexly provoke changes in the *opposite* direction. Thus, exposure to cold below a critical temperature of about 15° C. for the nude subject, increases the heat production of the body.

The effects of variations in the external temperature on the metabolism of warm-blooded animals are well shown in the experiments of the Tables given below on the oxygen usage of a rabbit and of a curarised dog.

Rabbit (Pflüger).		Curarised Dog (Krogh).	
Rectal temperature °C.	c.c. Oxygen per Kg. and hour.	Rectal temperature °C.	c.c. Oxygen per Kg. and hour.
22	457	14·1	134
26	608	22·7	300
37·5	888	28	495
37·6	839	32·3	620
38	763	37·2	812
38·8	738	39·9	700

In the rabbit, cooling even to 26° only reduces the metabolism by 18 per cent. of that at 38·8°, while at 37·5° (a lowered body temperature), the metabolism is actually increased by some 20 per cent. The dog, deprived of its heat-response by curare, however, shows a fall of metabolism at all temperatures below that normal for the species, and also at the higher one.

---

* Heymans and Bouckaert. *Arch. inst. Pharm.*, 1928, **35**, 63; Euler, *ibid.*, 1932, **43**, 67.

† Pflüger. *Pflüger's Arch.*, 1878, **18**, 305; Kennaway and Pembrey. *J. Physiol.*, 1912, **45**, 82.

The immersion of a man in a cold bath for a minute or two considerably increases his oxygen usage, but his temperature may show little change. It is possible, however, by an act of the will, to keep all the muscles in a state of relaxation. Under these circumstances the temperature of the body rapidly falls, and with it the rate of metabolism.

Nude men or women, lying down in surroundings below 29° C., lose heat faster than they produce it, and soon respond by a rise of metabolism. In an environment between 29° and 30° heat loss and production are equal in both sexes, and up to that point their B.M.R.'s are equal. Between 30° and 32°, however, the B.M.R. of women falls to 14–20 per cent. below that of men: women, therefore, show a better chemical regulation of body temperature, and hence sweat less, in hot surroundings than men.* Moreover, the thick layer of subcutaneous fat insulates them more from cold, so that their skin temperatures may be 1° C. lower than in men, by which they lose less heat; in higher temperatures, on the other hand, the flushing of the skin raises its temperature 1·7° above that of men, which gives them further advantage.

SHIVERING. A much more vigorous response to cold is that due to increase of general muscular tone, and ultimately to shivering. For example, a dog exposed to sudden cold may only show a 7 per cent. increase in oxygen usage prior to the onset of shivering, but as much as 30 per cent. increase when shivering sets in.†

Though temperature changes no doubt affect the state of activity, and the tone of the muscles, and cold may also produce shivering, moderate exposures to cold lead to some increase of metabolism by other means. Probably a discharge of adrenaline from the suprarenals is one of the chemical factors which brings about an increase in general metabolism under these circumstances.‡ It has been found that the basal metabolism is considerably raised by adrenaline injection §; after removal of both suprarenals the body temperature is lowered and regulation is less precise. Further, certain drugs, *e.g.* tetrahydro-β-naphthylamine, which cause great rise of body temperature, evoke general sympathetic excitation and discharge of adrenaline from the suprarenals ||; again, exposure to cold causes reduction of the adrenaline content of the suprarenals.¶ Nitro-bodies, however, cause a rise of temperature after removal of the suprarenals, and must act directly on the tissues. An increased activity of the thyroid has also been claimed to result from prolonged exposure to cold **; this would also raise the metabolic rate.

This adjustment of the body temperature by variations in the heat production is extravagant of energy if the difference in temperature between animal and environment is considerable. In man it is mainly a response to cooling. But in the very good adjustment of the temperature which is present in the higher mammals, regulation of the heat loss plays a greater part than regulation of heat production.

The Regulation of Heat Loss. In warm-blooded animals the regulation of heat production is dominated by physiological factors; the control of heat loss is the resultant of closely interwoven phenomena, some physical, some physiological. It is convenient, as a first approximation, to consider these separately.

Physical Factors. The modern approach, by the appraisal of the purely physical aspects, owes much to the work of Du Bois and Hardy, and of Gagge, Herrington and Winslow.

Heat loss from the body can occur by Conduction, Convection, Radiation and Evaporation. The relative part played by each will vary with such conditions as clothing, posture, temperature of air and walls, movement and humidity of air, etc. For simplicity, let us first consider the nude body, at rest in a room with walls and air at equal, and moderate, temperatures.

Heat is produced, chiefly in the deeper tissues, and is diffused by *conduction* to the cooler parts, and ultimately to the skin, in accordance with the relation :

$$\left.\begin{array}{c}\text{Total heat flow to skin}\\ \text{(in Cal./sq.m./hr.).}\end{array}\right\} = \left\{\begin{array}{l}\text{Conductance of superficial tissues (in Cal./sq.m./hr./°C.)}\\ \qquad\qquad \times \text{ Temp. gradient to skin } (T_b - T_s).\end{array}\right.$$

The value for minimal conductance of the superficial tissues is about 11.

A descending temperature gradient, of varying steepness in accordance with the varying conductance of the tissues, will evidently obtain from within outwards. Since epithelium and fat have a low thermal conductance (say, about ·00047–·0005, which compares well with cork = 0·0007), the gradient through tissues of and beneath the skin is especially steep, the maximum gradient being about 8° C. in 2·2 cm. : in some places a gradient may be detected to 10 cm. depth. This simple picture is apt to be modified by the circulation of the blood, which tends to even out such differences of temperature, so that the gradient may be reduced to as little as 1° C. over 2·2 cm.

Conductivity in most fluids is low (air = 0·00005 ; water = 0·0013 ; copper = 1·0), and is obscured by convection. Hence conduction proper only occasionally accounts for *loss* of heat from the body, as, *e.g.* when one sits on a cold marble slab (conductivity = 0·007).

Convection is much more important. Owing to the low specific heat of air (0·24 cal./g.), the temperature of air in contact with the skin rapidly rises ; in free convection a thin layer of air in contact with the body is moistened and warmed, thereby becoming lighter ; it rises, and its place is taken by cooler, drier air. The flowing layer of air is only 1 to 2 mm. thick : a layer next the skin clings to it and remains warm, so that the gradient from skin to air over 0·5 mm. is only about 1° C.

As a result of these convection currents, heat is continually being conveyed from the body surface to the air, at a rate proportional to the difference between their temperatures. At air temperatures of 34·5° C. the convection loss becomes zero, and at temperatures over 37° C. it becomes negative, *i.e.* the body is warmed by convection. If the surrounding air is in movement (or the body in movement through the air) the convection effect increases, and except at high speeds varies roughly as the square root of the air speed (usually $C = 16v^{\frac{1}{2}}\ (T_s - T_a)$ where v = air speed in m./sec.) ; it shows no further increase at speeds above 30 m./sec. (say, 70 mi./hr.).

Radiation is also an important source of heat loss. Human skin, of whatever colour, behaves in regard to long wavelengths as a perfect " black body," *i.e.*, it radiates strongly, and at a rate proportional to the fourth power of its absolute temperature (Stephan's law) : its radiations have a wavelength of 5 to 20 μ, with a peak at about 9 μ. The body surface, therefore, exchanges heat with its surroundings, such as walls, at a rate proportional to the difference between the fourth powers of their temperatures. If the temperature of the walls falls considerably, therefore, the radiation loss for a given skin temperature rapidly increases : but when the difference of temperature between walls and skin is not great the radiation loss may be taken as being approximately proportional to the difference between their temperatures (usually $R = 3{\cdot}6\ (T_s - T_w)$). It is, of course, only the area of projection of the body that radiates (it is often about 70 to 80 per cent. of the total body surface), and, therefore, the radiation loss will vary with posture, and from subject to subject.

Combined Effects of Radiation and Convection. When the difference in temperature between a warm object and its cooler surroundings is not large, the object cools, by radiation and convection together, at a rate proportional to the difference between their temperatures (Newton's law). From the physical properties of the object, and of its surroundings, which are expressed jointly in the form of a cooling constant (k), and from the differences of temperature, the actual loss of heat by radiation and convection can be calculated according to the expression $H = k\,(T_1 - T_2)$.

So long as the air is still, and the temperatures of air and surroundings identical, the human body also loses heat by radiation and convection in the same predictable manner, *i.e.* $R + C = K_o(T_s - T_a)$, and the "*environmental constant*" K_o for the nude is roughly $3{\cdot}6 + 16v^{\frac{1}{2}}$, which in nearly still air, has a value of about 8·45, where heat loss is in Cal./sq.m./hr. But when the air is warmer or cooler than the walls, or is in considerable motion, the problem is not so simple, for we cannot know what to consider as the "surrounding temperature," whether that of the walls to which the body loses by radiation, or that of the air, to which it imparts heat by convection. A solution was worked out by Gagge, Herrington and Winslow, by the use of an abstraction in the form of a weighted mean, called the "*operative temperature.*" This gives us a measure of the physical demands of the environment on the body, so far as radiation and convection are concerned, and the sum of these is predictable if the skin temperature (T_s) is also known. The standard operative temperature of a given place, when walls and air are at the same temperature, and with standard air movement of 5 m./min., is its dry bulb temperature: operative temperatures (T_o) for other conditions are deduced so as to give an imaginary environment with air and walls at equal temperatures and air movement at 5 m./min., and in which losses of heat by $R + C$ would be the same as in the actual environment. If T_s and the heat loss are known, $T_o = T_s - \dfrac{\text{heat loss to environment}}{5{\cdot}2}$.

Evaporation (E) contributes, according to conditions, to a very variable extent to heat loss. At environmental temperatures below 25° C., resting individuals do not sweat, and the evaporative loss, which is proportional to the metabolic rate, is entirely due to loss of water vapour from skin and lungs as "insensible perspiration": little sweating occurs at temperatures below 28°, but at 29° air temperature it definitely begins, and becomes of increasing importance with rising temperatures, so that in air at and above 35° C. *all* the body heat is lost by evaporation. The mean T_s at which sweating begins is about 34°, and it rises sharply at 35°: body temperature is also a factor that controls sweating, which is generally profuse at T_b of 37·2° C. or over.

When sweating sets in, the insensible perspiration probably ceases. Whatever the origin of the water *evaporated*, the heat abstracted from the surface of evaporation is 0·58 Cal./g.; if sweat runs off without evaporation it has, of course, no cooling effect. It is self-evident that if the relative humidity of the air is low, there will be a greater difference in vapour pressure between the skin (P_s) and the air (P_a) than when P_a is high, and, in fact, the rate of evaporation of the sweat can be shown to be proportional to ($P_s - P_a$), and also to increase with the speed of movement of the air (μ). The total amount of water evaporated will obviously vary with the area of skin which is wetted with sweat. The total vapour loss can be determined by weighing the body, and it is convenient to calculate from this, and from P_s and P_a, a figure designated $W\mu$, which $= \dfrac{E}{P_s - P_a}$, and is a measure of the area of wetted skin from which evaporation of moisture, sensible or insensible, may be supposed to be taking place at a given air speed. An alternative method of expressing the evaporative conditions is to calculate the *relative humidity of the skin*, (rh_s),* which depends on diffusion of water through the skin, the skin temperature, the relative humidity of the atmosphere, and air movement.

---

* Mole. *J. Physiol.*, 1948, **107**, 399.

The Heat Balance and its Partition. We may now consider the balance of heat production and heat loss of the body, and the extent to which the various factors contribute to the loss. The allocation of the different fractions of heat loss to their respective factors is called *partitional calorimetry* by Winslow, Herrington and Gagge.* By altering the temperature of the air and of the walls of an experimental chamber independently of each other, they were able to study the parts played by convection and radiation under varying environmental conditions.

It is usual to express rates of heat transfer between the body and its surroundings in terms of kilocalories per sq. m. of body surface per hour (Cal./sq.m./hr.),† as in the case of B.M.R. Typical figures for the heat production (M), which can be measured by determination of the oxygen usage of the subject are :

Basal rate	40 Cal./sq.m./hr.
Awake, resting	55 ,, ,, ,,
Light work	75 ,, ,, ,,
Walk four mi./hr.	190 ,, ,, ,,
Strenuous exercise	300–600 ,, ,, ,,

Expressing, in the same units, the heat loss by convection (C), Radiation (R) and evaporation (E), we have the general equation for heat balance, *i.e.* for maintenance of uniform body temperature :—

$$M = C + R + E$$

in which it is agreed that R and C shall have positive values when they cool, and negative when they heat the body (as when surroundings are above skin temperature) : E is always positive.

If thermal equilibrium is not reached, and the body temperature rises or falls, the equation of thermal balance must be adjusted by the introduction of a term indicating the deficit or surplus of heat. This new term is called *storage* (S), whatever its sign, the latter being accounted positive when the body is cooling. The equation now runs :

$$M + S = C + R + E$$

Now M can be measured directly by the rate of oxygen consumption, together with a computation of body surface, as explained in Chapter XLI. We can also measure E from the loss in body weight (*v.* p. 1029) by insensible or sensible perspiration. The value of S (for states of thermal imbalance) can be calculated from the change in mean body temperature and the mean specific heat of the body (0.83). Hence the value of C + R can be calculated.

The following will serve as an example :—

A lightly clad man weighing 65 kg., and 178 cm. height, sits still in a cool room for an hour. During that time his respiratory exchange is found to be at the rate of 302 c.c. O_2 and 257 c.c. CO_2 per min. (R.Q. = 0·85). At the end of the hour his body weight had decreased by 42 g., and his mean temperature by 0·1° C. From these data we calculate as follows :—

(1) Body surface (from Fig. 527, p. 794) = 1·79 sq. m.
(2) Oxygen usage = 18·15 l./hr. At R.Q. 0·85, one l. O_2 = 4·881 Cal. (p. 792).

$$\therefore \quad M = \frac{18{\cdot}15 \times 4{\cdot}881}{1{\cdot}79} = 49{\cdot}\ 5 \text{ Cal./sq. m./hr.}$$

(3) Oxygen intake = 18·15 l. = 26 g./hr. and CO_2 = 30 g./hr.
Now, insensible perspiration = loss of body weight − loss of CO_2 + gain of O_2
= 42 — 30 + 26 = 38 g./hr., which, when vapourised at 0·58 Cal./g. gives

$$E = \frac{38 \times 0{\cdot}58}{1{\cdot}79} = 12{\cdot}3 \text{ Cal./sq. m./hr.}$$

---

* Winslow, Herrington and Gagge. *Amer. J. Physiol.*, 1926, **116**, 641.

† 1 Cal. = roughly 4 B.Th.U. or 0·00004 Therms. It has been proposed to introduce a new unit called a *met*, which = 50 Cal./sq. m./hr.

(4) Body Sp. ht. = 0·83. Cooling = 0·1° C.

$$S = \frac{0{\cdot}83 \times 0{\cdot}1 \times 65}{1{\cdot}79} = 3 \text{ Cal./sq. m./hr.}$$

(5) From the equation

$$\underset{(49{\cdot}5)}{M} + \underset{(3)}{S} = \underset{(40{\cdot}2)}{(C + R)} + \underset{(12{\cdot}3)}{E}$$

we infer that loss by radiation and convection together $(C + R)$ = 40·2 Cal./sq. m./hr.

In further analysis, R can be determined directly by radiometric observation, and so C deduced. Or, alternatively, R and C can be calculated approximately from a knowledge of environmental conditions, skin and clothing temperatures and constants.

When the body is outdoors the problem is greatly complicated by the effects of wind, sun, cloud, etc. For example, surfaces normal to the June mid-day sun in London receive incident radiation at the rate of about 780 Cal./sq.m./hr.

The main regulation of heat loss thus takes place by radiation, conduction and evaporation from the skin. Besides these channels of heat loss, others play a minor part. Thus heat is lost to the body in warming the food and air taken in, and in the setting free of CO_2 from the blood in the lungs, but these are relatively small sources of loss. The following balance sheet represents an example of possible daily losses in an adult man by these different ways :—

EXAMPLE OF HEAT BALANCE SHEET

HEAT PRODUCTION	Cal.	HEAT LOSS	Cal.	P.c. of Total	
Respiratory exchange for twenty-four hours = 497·2 l. O_2 used and 397·8 l. CO_2 produced. R.Q. = 0·8, at which the calorific value of O_2 = 4·827 Cal./l. Hence heat production = 497·2 × 4·827 = approx. . .	2,400	A. *Insensible water loss :* (i) *By breath.* Assume insp. air half sat. at 15° C. (= 6·4 g./cu.m.) and that exp. air saturated at 37° (= 45 g/cu.m.). Then approx. 440g. water is evaporated from resp. passages : at 0·58 Cal./g. . . =	255	11	25
		(ii) *By skin.* Assume loss of 580g. insensible loss at 0·58 Cal./g. =	336	14	
		B. *By Radiation,* say . =	890	37	66
		C. *By Convection,* say . =	711	29	
		D. *Warming Food and Air.* (i) 1,500g. water at 15° warmed to 37°, *i.e.*, by 22° . . =	33	1·5	5·0
		(ii) 1,500g. food at 25° warmed to 37°, *i.e.* by 12° (Sp. ht. = 0·8) . =	14	0·5	
		(iii) 11,500 l. air (= 14,100g.) insp. at 15° and warmed to 37° (Sp. ht. = 0·2374) . =	75	3·0	
		E. *Evaporation of CO_2.* Liberation of 398 l. (= 781g.) CO_2 at 0·108 Cal./ g. . . =	86	4·0	
	2,400	Total . .	2,400	100	

We may say that, under such conditions, about 5 per cent. of the total heat loss of a man not sweating takes place by warming the food and air, 4 per cent. by evaporation of CO_2 from the lungs, about 25 per cent. by the evaporation of insensible water, and about 66 per cent. by radiation and convection. The proportion represented by evaporation of water will, in dry air, increase very largely with high external temperatures, or when heat production is excessive in consequence of violent muscular exercise, because in these cases sensible perspiration will occur.

The relative importance of conduction + radiation and of evaporation, and the extent of storage at different operative temperatures for nude and clothed subjects are illustrated in Fig. 634. In this figure, M and S are given their proper sign: (R + C) and E are, for convenience of plotting, reversed in sign. A few measurements will show that at any ordinate M + S = (R + C) + E, as the equation of heat balance demands.

Physiological Factors. The simple physical picture outlined above is modified by phenomena of a purely physiological nature. These are the result of primary adaptative reactions, *e.g.* changes in the vascularity of the skin, the onset of sweating, or alteration in the water distribution in the tissues. There are also various secondary adaptative responses.

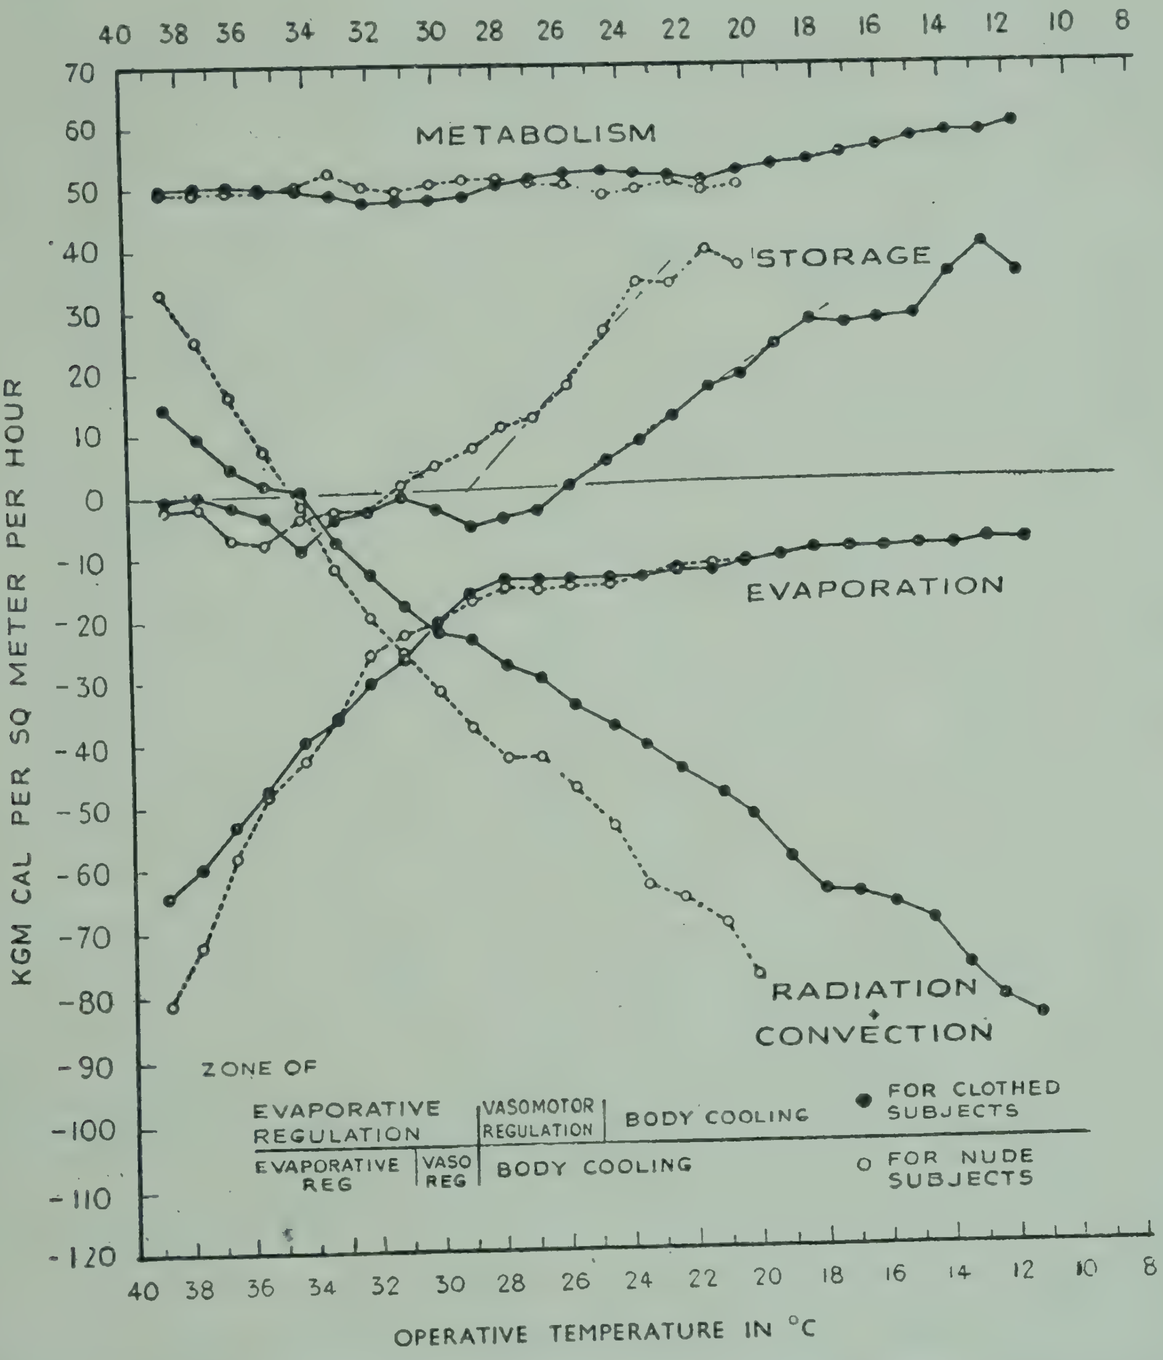

FIG. 634. Thermal interchange for nude and clothed subjects at varying operative temperatures. (GAGGE, HERRINGTON and WINSLOW. *Amer. J. Physiol.*, 1938, **124,** 30.)

At any given level of heat production there are environmental conditions which are nearest to the physiologically neutral, in that they allow of easy and delicate regulation of the body temperature. The further the departure from these conditions, the more physiological factors are called into play: beyond certain limits these prove inadequate, and the body loses or gains in temperature. Thus, resting and lightly clad subjects at a metabolic level of 40–50 Cal./sq.m./hr. will have easily stabilised temperatures when in still air at about 27° C.: if the air temperature rises above that, the skin vessels can be flushed, so that more heat is lost, and if it falls, they can be constricted, so that heat is conserved. This *zone of vasomotor regulation* extends only from about 25°

to 29° C.* Below 25° body cooling begins : above 29° convection can cool the body very little, and at that temperature sweating sets in, and increases in extent and intensity until the maximum is reached : above 35°, all the body heat loss is by evaporation. At a given temperature, which varies widely according to the relative humidity of the air, even evaporative cooling fails to cope with the situation (which may be further worsened by the fact that radiation and convection are now tending to *warm* the body), and the body temperature then begins to rise. We thus have four possible results at progressively increasing surrounding temperatures, viz. body *cooling*, *vasomotor regulation*, *evaporative regulation*, and body *warming*.

Since the rate of loss of heat depends greatly on the difference of temperature between the body surface and the surroundings, and since the temperature of the skin depends on the thermal conductance of the superficial tissues, it follows that a rise of that conductance, due to a diversion of blood to the surface will greatly facilitate the heat loss from the body, and *vice versâ*. In surroundings at 34° C., it has been shown that as much as 12 per cent. of the total cardiac output may be sent to the skin. The supply of blood to the skin of a given area may, in fact, vary over a fifty-fold range, and the conductance of the superficial tissues over a five-fold range (*e.g.* from 11 to 58 Cal./sq.m./hr./° C.), with the consequence that in hot surroundings, or when large amounts of heat are being produced by doing work, the skin temperature *may* be as much as 3° C. above that in temperate surroundings.

These changes in skin vascularity are under the control of the central nervous system, through the vasoconstrictor and vasodilator nerves.† In cold weather, or when the heat production of the body is low, the skin vessels are constricted, the skin is cold, and the heat loss is reduced. The largest fluctuations in vascularity are in the extremities ; here, in the cold, although at first there is vasoconstriction, excessive skin cooling, with risk of ensuing damage to the tissues, is largely prevented by the opening up, by an axon reflex, of arterio-venous anastomoses. In this way the skin surface is flushed with blood, and its cooling delayed. Hence, after handling snow the skin becomes red, warm and hyperalgesic.‡ The anastomoses are controlled, probably centrally, by constriction or dilatation of the arterioles.§ The reaction is closely related to the hyperalgesia in which the " nocifensor " nerves play a part, and also to the spreading flare seen on local damage to the skin.

Plethysmographic measurements of the blood flow through the hand show that the rate of blood flow may range from 0·22 c.c. to 28·3 c.c. per 100 c.c. tissue per minute with change in ambient temperature from 15° to 38° C.‖ In skin it may reach 75 c.c. (finger) ; in muscle it is less per 100 c.c., viz. an increase of 5–10 c.c., but owing to the large bulk of muscle the increase for the whole body may be about 1·5 l/min.¶

At very high external temperatures, vasoconstriction may reappear, and is then useful, since it now, by reducing the skin conductance, retards *intake* of heat by the body.

Evaporative cooling, which undergoes a rapid increase when, at a certain temperature, insensible water loss gives way to sweating, is the method by which heat loss can be effected after other methods have become inadequate. It is well known that the body temperature can remain almost unchanged even in surroundings much above 37° C. Thus Blagdon,** in 1775, showed that a man " could sustain, for a period of fifteen minutes, an exposure to a dry

* These and many other figures apply to persons acclimatised to the conditions of life in the U.S.A. They may be slightly different for European conditions.

† PICKERING. *Heart*, 1932, **16**, 115.

‡ LEWIS. *Heart*, 1930, **15**, 177, 351.

§ GRANT *et al.* *Heart*, 1931, **15**, 385 ; 1932, **16**, 69.

‖ FORSTER *et al.* *Amer. J. Physiol.*, 1946, **146**, 600.

¶ BARCROFT *et al.* *J. Physiol.*, 1947, **106**, 271.

** BLAGDON. *Phil. Trans.*, 1775, **65**, 111, 484.

atmosphere of 250° F. without ill-effects, while a beefsteak exposed to the same temperature was cooked in thirteen minutes."

This is because there is a profuse secretion, and evaporation, of sweat over a large surface of the body. The critical air temperature for sweating is, for nude subjects, 31° C., and for lightly clad ones 29° C., the *average* skin temperature being 34°: sweating increases sharply with skin temperatures of 35° or over. Since the evaporation of 1 g. of water absorbs 0·58 Cal., the evaporation of 120 g. of sweat would lower the body temperature of a 70 kg. man at least 1° C.; this often results in the skin temperature being below that of the surrounding atmosphere. The skin temperature of a man in hot surroundings may for this reason be lower when he is doing work than when at rest: this, by reducing his loss by R + C would be a slight disadvantage.

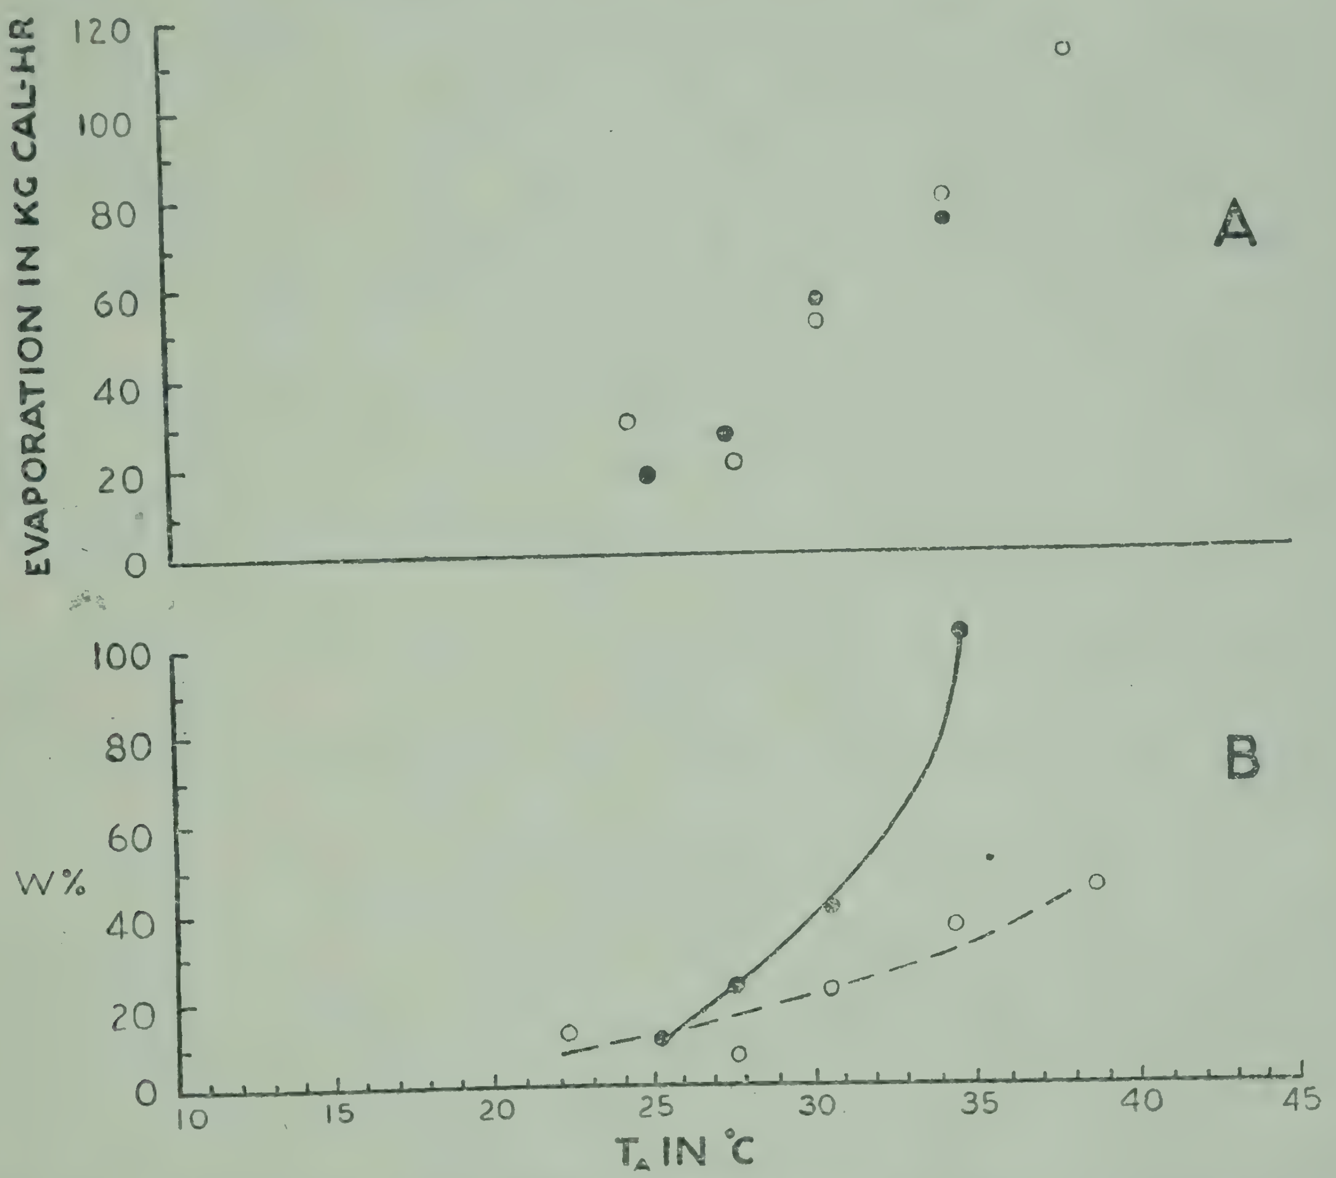

FIG. 635. Evaporative heat loss (A) and per cent. of maximal possible area of wetted skin (B), at varying air temperatures: nude subjects. Solid circles = high humidity (40–80 per cent.): open circles = low humidity (14–40 per cent.). (After WINSLOW, HERRINGTON and GAGGE. *Amer. J. Physiol.*, 1937, **120**, 288.)

If, as happens in rare cases, a man has no sweat glands,[*] or if evaporation be impeded by placing him in a hot atmosphere saturated with aqueous vapour, the temperature of the body runs up rapidly, and death may ensue from hyperpyrexia or heat-stroke. Although a man can stand exposure to a temperature of 120° C. (250° F.) for a short period if the air is dry, a temperature of 32° C. (90° F.) may in time be fatal if the air be saturated with moisture. Possibly the reports that death may result from entirely coating the skin with an impervious layer may be due to a similar cause. Cases are on record of boys dying after being varnished and gilded in order to feature in carnivals, *e.g.* one in Rome in 1473, and one in Florence in 1513, with fatal results.

Sweating also comes into play when the heat production of the body is very largely increased, as by violent muscular exercise, and a man may then sweat profusely at air temperatures below freezing point.

---

[*] RICHARDSON. *J. Biol. Chem.*, **1926**, **67**, **397**.

The vasodilatation of the skin which accompanies sweating also assists in cooling by bringing heat to the skin, and by providing the necessary water for formation of the sweat.

The value of $W\mu$, which is a measure of the wetted area of the skin, is small and constant below 30° C., because the evaporation is all insensible; above this, its value at a given temperature and air speed increases with increase in the humidity of the air, until it reaches a maximum, *i.e.* as the evaporative power of the air is reduced, there is a compensatory increase in the wetted area, so that the total evaporative heat loss tends to remain constant (Fig. 635). Or alternatively, we may say that the relative humidity of the skin increases with the humidity of the air, and this again keeps evaporative loss constant.

The maximum evaporative cooling, reached when the maximum area is wetted, is about 30 Cal./sq.m./hr./cm.Hg difference of water vapour pressure $(P_s - P_a)$ and is reached at about 43° C. nude, or 52° C. clad, with low humidity. With high R.H. of air, the clad subjects adapt less well, and temperature regulation fails at T_o 35° C. or lower.

Shifts of fluid within the body also play a part in the heat regulation of the body: the best indicator of fluid shift from cell interspaces to plasma is the concentration of serum protein.* This shows a fall soon after exposure to heat, followed by a rise if sweat loss is not made good. The effect of the initial dilution of the blood is to keep the vascular system filled well, despite vasodilatation and deflection of blood to the skin, and to augment the thermal conductance of the surface tissues. Conversely, exposure to cold at first leads to passage of "water" from blood to tissues; later, due to chilling of the nervous centres, the trend is reversed, and the excess of extracellular fluid may lead to œdema.†

THE EFFECT OF CLOTHING

Clothing protects from high, as well as from low, environmental temperatures. It protects in proportion to its low conductivity for heat (*e.g.* linen 0·00021, silk 0·000095) so that there is a steep temperature gradient from skin surface to clothing surface, from which the heat is dissipated by R and C to the surroundings, at a rate depending on their respective temperatures. Since the thermal conductivity of air (0·00005) is even lower than that of most clothing materials, while its specific heat is also low (0·24 cal./g.), it is evident that the air beneath and between layers of clothing, and within its pores, has great value as a thermal insulator. This explains why two layers of thin clothing are better than one layer of double the weight. Solid and impervious materials are, for a similar reason, poor in insulating power, and are avoided as clothing materials, unless they have some special advantage, such as that of being waterproof: they have the further drawback of not allowing of ready evaporation from the skin. Clothing increases the effective radiating surface by about 16 per cent., but lowers the temperature of radiating surfaces more than proportionally, and so cuts down radiation loss indoors by about 40 per cent. (Fig. 634).

The distribution of temperature on the skin of the clothed body is different from that in the nude, the skin of the extremities being cooler, and that of the trunk warmer, than in the nude. But the mean skin temperatures are about the same in the two states, when the rates of heat loss by R + C are equal.

It is evident that, if the body temperature is to remain constant, all the heat passing through the skin must, where clothing covers it, also pass through the clothing. When sweating begins, skin temperatures and conductances are higher for clothed than for nude, and evaporation of sweat mainly occurs at the skin surfaces, and not from folds of the clothing: hence the clothed body loses heat by R + C, and in general responds in much the same way as the nude, though at a different level. When at rest, body cooling sets in at $T_o =$ 8° C. below that of the skin, as compared with 4° below for the nude.

---

* Lee and Mulder. *J. Physiol.*, 1935, **84**, 279, 410.

† Barbour *et al.* *Amer. J. Physiol.*, 1943, **140**, 9.

Thus, for M − E = 40 Cal./sq.m./hr., and at $T_o = 25{\cdot}1°$ C., the gradients for light clothing would be :—

Skin temp. .	33·1°	T. diff. = 2·5°. Physical conductance of clothing = 15·8 Cal./sq.m./hr./° C.
Clothing temp. .	30·6°	T. diff. = 5·5°. Actual conductance for loss by R + C 7·3 Cal./sq.m./hr./° C.
Operative temp. .	25·1°	

The physical conductance of the clothing is 40/2·5 = 15·8 units per ° C. diff. in temperature between the skin and clothing temperatures, while the actual conductance by R + C from the surface is 40/5·5 = 7·3 units. We may take it that ordinary light clothing at indoor temperatures at rest transmits about 38 out of 50 Cal./sq.m./hr., which = 76 per cent. of the heat production, for subsequent dispersal by R + C. Under common conditions indoors, for clothed persons at rest, about 45 per cent. of the total loss by R + C is effected by convection : for the nude it would be about 52 per cent., *i.e.* clothing chiefly reduces the relative convection losses. At temperatures below 30° C. skin conductance is lower for nude than for clad : above that the conductance rapidly increases, especially for the clad.

ASSESSMENT OF THE EFFECTS OF ENVIRONMENTAL CONDITIONS

The physiological properties of a given environment depend essentially upon the cooling (or warming) power of the surroundings upon the skin. This varies over an extremely wide range, since it depends upon differences of temperature, humidity, and rate of movement of the air. There is further the influence of the interchange of radiant heat between skin or clothing and surroundings.

The conditions indoors and outdoors, are, under ordinary circumstances, fundamentally different, the cooling and evaporating powers being greatly reduced indoors, owing to the stillness of the air.

Air temperature is obtained by use of an ordinary thermometer, but this gives only a limited indication of the physiological aspects of the atmospheric conditions.

Air humidity is given by use of the wet- and dry-bulb thermometer (or, better, by the whirling psychrometer); this gives more information, because the evaporative power of the atmosphere is indicated by the depression of the wet-bulb instrument. The average of the percentage humidity and dry bulb temperature ("humature" scale) has been used as a rough guide to tolerability.

Radiation can be assessed most simply by the globe thermometer.* This is a hollow 6-in. metal sphere, painted matt black, and having an ordinary thermometer with its bulb at the centre of the sphere. The reading of this thermometer will be higher or lower than air temperature according to whether the surroundings are at higher or lower temperatures than the air.

Air velocity can be measured by the anemometer, or by the rate at which a warm silvered surface (silvered Kata thermometer) cools down.

Dufton's scale of *equivalent temperatures* takes into account the air temperature, air movement, and radiation. It is defined as that temperature of an uniform environment in which, in still air, the body would lose heat at the same rate as in the environment in question. It can be measured by the *Eupathioscope*, or comfort indicator, which is a heated blackened cylinder 22 inches high by 7·5 inches diameter : its heat input, electrically run, is so regulated that, in the particular environment under study, the surface temperature of the instrument is that of the mean surface of the clothed body. Th equivalent temperature can also be estimated from readings of the globe thermometer (radiation), the kata-thermometer, and the ordinary thermometer, and reference to tables or nomograms.

---

* Bedford and Warner. *J. Hyg.*, 1934, **34**, 458.

The use of *operative temperatures*, and of partitional calorimetry, is probabl the most scientific method of approach in studying the thermal relationshi of the body to any given environment, since it enables the problem to b regarded chiefly as a physical one.

Effective Temperature. Another method of assessing climatic conditions * is by the estimation of what is called the effective temperature of Yaglou. This has been empirically devised by direct observation on human subjects and takes into account temperature, humidity radiation and movement of the air.

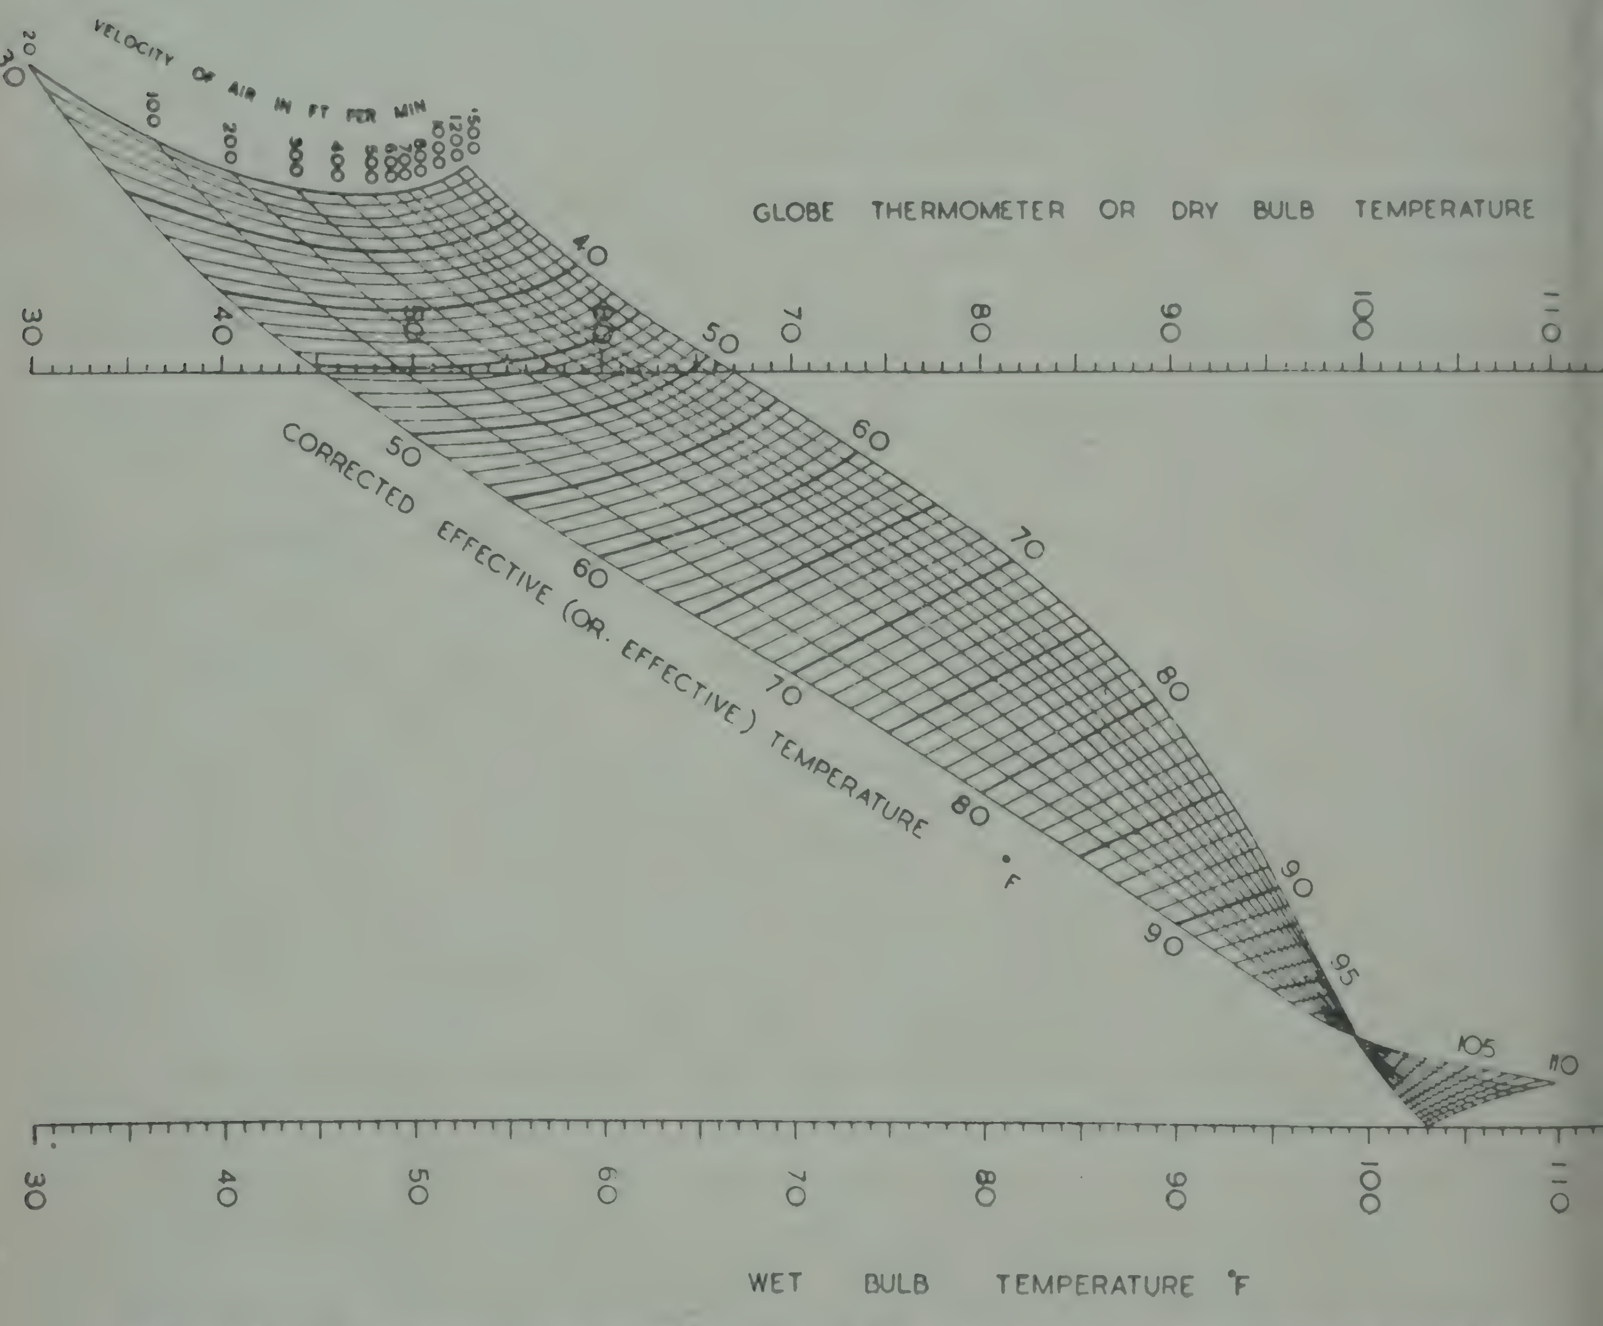

FIG. 636. Nomogram for determination of effective temperature on men normally clad and doing light work. (Scales in deg. F.) (BEDFORD. M.R.C. *War Memo.* No. 17, 1946.)

The effective temperature of an atmosphere is the temperature of a still, saturated atmosphere which would produce the same feeling of temperature as the atmosphere in question. It is thus a practical comfort criterion derived from subjective experience. It is found by determining globe or dry-, and the wet-bulb temperatures and average air velocity. Then by reference to a nomogram (Fig. 636) the effective temperature is read off directly. The result is called the corrected effective temperature when the globe thermometer replaces the dry-bulb air thermometer, because it allows for radiation effects. Thus a globe thermometer temperature of 76° F. (24·5° C.) and a wet bulb of 62° F. (16·5° C.), with air velocity of 100 feet per minute, gives, a corrected effective temperature of 69° F.

* LEE and COURTICE. *Trans. R. S. Trop. Med. Hyg.*, 1940, **33**, 601; BEDFORD, M.R.C. *War Memo.* No. 17, 1946 (H.M.S.O.).

Climate and Comfort. The important physiological effects of climates were recognised by Hippocrates, but still present many problems. The tolerability of a climate depends on the balance of the effects upon the body of temperature, relative humidity, radiation, and air movement : the effects are modified by clothing, and by physical exertion.

Extremes of temperature or humidity are usually unpleasant, as also is a monotonously uniform climate. Probably ideal conditions for light exertion would be at a temperature of 19·5° C. (67° F.) and relative humidity 50 per cent. : countries at present occupied by races that regard themselves as the most energetic and civilised have variable climates, with rather low mean temperatures, though man is very adaptable in these respects.

It is possible to calculate the limiting conditions for heat stroke for an individual under given conditions of climate if we have certain data, such as the value of M, the metabolic rate : v, the air velocity in m./sec. ; T_s and T_w, the temperatures of skin and surroundings, and I_s and I'_d the total heat content of air saturated at temperature T_s, and at the wet-bulb temperature respectively. At " rest " M is normally about 47. If work is being done at the rate of 1,000 × W. ft./lbs. per minute, then, approximately, $M = 64 + 35W$, Cal./sq.m./hr.

The curves showing limits beyond which control of body temperature is lost are derived from the use of the formula $M = 3{\cdot}6\,(T_s - T_w) + \dfrac{200}{3}\, v^{\frac{1}{2}}\,(I_s - I'_d)$, and some are given in Fig. 637.

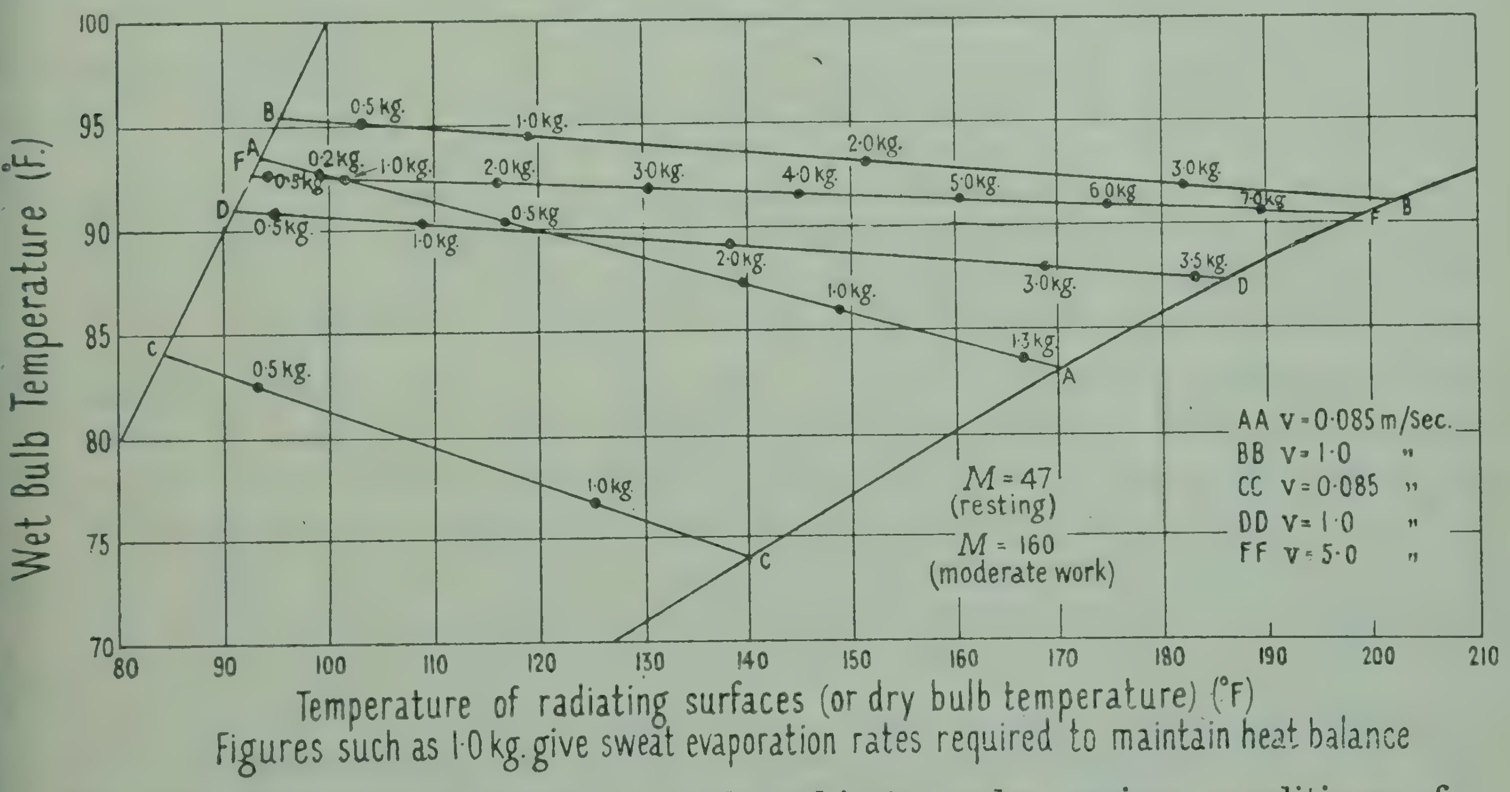

FIG. 637. Heat-stroke limits for nude subjects under various conditions of physical activity and air-movement as shown in figure. A and B at rest. C, D and F at work. Above the lines heat stroke is liable to occur. Figures such as 2·0 kg. show sweat per hour needed to maintain heat balance. (BRUNT. *Proc. Physical. Soc.*, 1947, **59**, 713.)

Thus curve AA shows that men resting in nearly still saturated air cannot tolerate a temperature over 93·5° F. The temperature in the Black Hole of Calcutta has been said to be 34° C. (93·2° F.). Comparison of curves C and F shows the large effect of increasing air movement from 0·085 m./sec. to 5 m./sec.

In Fig. 638 is shown a tentative classification of climates derived from these curves. The line AA shows the heat-stroke limits for a nude man resting in still air ; BB the same but with air moving at 200 ft./min. ; CC, the limiting conditions for clothed man resting in sunshine, and with about a third of the skin wetted with sweat ; DD, the same, except that he is walking at 3 mi./hr.

To the left of these lines temperature and humidity are such that the body temperature will not rise, while to the right of them there will be a rise of body temperature. Each line is thus a climatic boundary of tolerability for this subject. For example, a temperature of 90° F. at 80 per cent. humidity is risky for a clothed man, although 100° F. at 20 per cent. humidity could be borne, though, of course, it would be "very hot." The "rawness" of damp, and the "keenness" of dry, air in cool climates are also illustrated in the figure.

The reduction in risk from tropical diseases which advance in medical science has wrought now raises the question whether many tropical areas might not now be more densely populated. The study of climate is thus of great importance. Hot climates show two extremes, which differ profoundly in physiological effects, according to whether the air is dry or moist. In hot desert climates the air is dry and clear: radiation conditions are good, and the ground, being dry, heats and cools quickly, so that surface ground temperatures may be 180° F. (82° C.) by day and 60° F. (15·5° C.), or less, at night: the air temperature, therefore, also shows large fluctuations, *e.g.* 113–68° F. (45–20° C.). Relative humidity varies from 5 to 30 per cent., and winds are frequent.

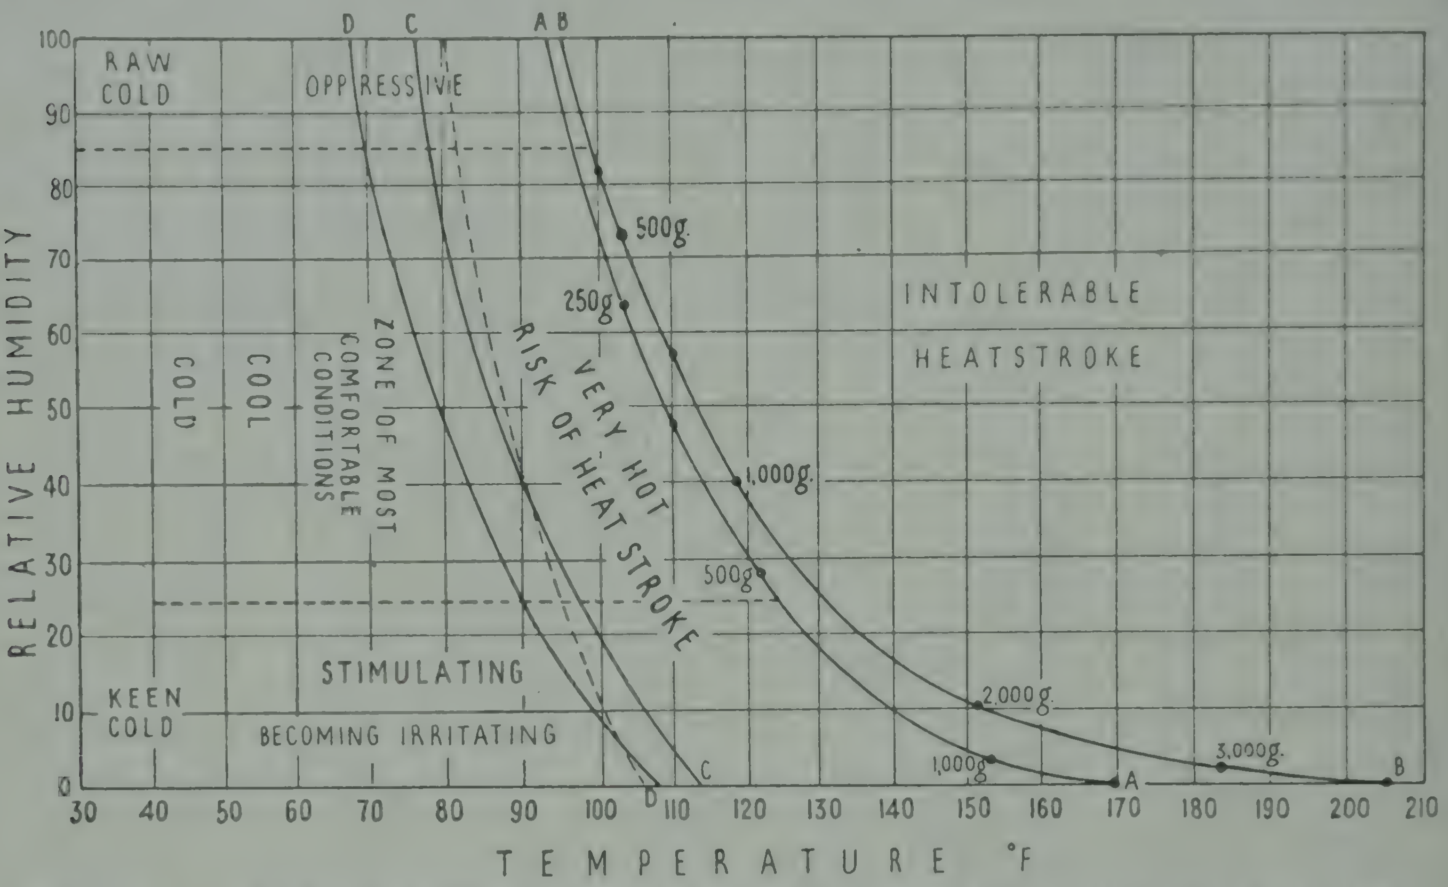

FIG. 638. Tentative classification of climates. For description see text. The broken line = equivalent temp. 80° F. The figures, 500 g., etc., indicate rate of evaporation of sweat in g./hr. necessary to maintain heat balance in man of average size. (After BRUNT. *Proc. Physical. Soc.*, 1947, **59,** 713.)

Wet tropical (jungle) climates differ from the above in all save the high temperatures. These, say 71–92° F. (22°–33° C.), are not often so high as in desert climates, but are likely to remain uniform for long periods, ground and air temperatures in the jungle often varying less than 1° C. in the twenty-four hours. There is frequent and heavy rain, cloudy skies are common, and, in jungles, with their foliage cover, the air is stationary, and, most of the time nearly saturated with moisture (R.H., *i.e.* relative humidity, at least 80 per cent.).

Reference to Fig. 638 will enable us to predict that the jungle climate, say, 85° F. and 85 per cent. R.H., is likely to be much more trying than that of shade in the desert, say 100° F. and 15 per cent. R.H.: light work would be possible in the latter conditions, because, although radiation and convection both *add* heat to the body, the evaporation of sweat would be rapid, especially when there was wind. It must be remembered that in sunshine, however, the body may be heated by radiation at a rate considerably greater than its own metabolism. Artificial cooling and air-conditioning of dwellings in the tropics is mainly a matter for the future.

The unpleasantness of cold, raw days is due to an increase in the conductivity of the clothing owing to rise in its moisture content.

Except for the risk of frost-bite, cold climates, though often less comfortable, are more readily dealt with than hot ones, since heated dwellings, increased clothing and physical exertion can largely compensate for the conditions.

For *comfort*, the skin temperature of resting subjects should be about 33° C., and during work about 31° C., and these would be the conditions when at rest at about 82° F. and 50 per cent. R.H., or during moderate work with slight air movement at 61° F. and 50 per cent. R.H.

For indoor conditions, habituation is an important factor: the Japanese in winter regularly support degrees of cold most uncomfortable for Europeans, and the French shiver in our rooms, as we do in their out-door cafés. In the U.S.A., 72° F. and 50 R.H. is considered ideal for winter, but in Great Britain, as many Americans can now testify, 65° F. is considered warm in winter rooms, and 60° F. with R.H. above 80 per cent. is not unusual. Clothing in the two countries is adjusted to suit these different standards. Probably a summer temperature of 66° F., R.H.50, is ideal for resting subjects indoors.

Acclimatisation to Heat. Study of the adaptation to altered climatic conditions is of greater importance now than ever before, because by air transport a person can in a few hours be translated to a totally unfamiliar climate.

The chief immediate physiological responses to exposure of the body to heat are :—increase of respiratory ventilation, with rise of blood pH, excretion of alkaline urine, increased pulse and circulation rate, sweating, dilatation of arterioles and capillaries in the skin, usually a fall of arterial pressure, an increase of blood volume, rise of body temperature, and in extreme cases rise of basal metabolic rate. If exposure is continued, say for several days, either the climate proves insupportable, or acclimatisation occurs. Sweating then occurs more easily, and the sweat is more dilute. The urine becomes more concentrated and may at times be free from chlorides. Skin temperatures may remain high, but the resting body temperature returns to normal, though exercise may lead to a rapid rise, especially in humid climates.

How the acclimatisation is brought about is obscure, but when it has occurred, temperature regulation is more prompt and efficient. One factor is probably a loss of body weight, whereby a smaller mass of metabolising tissue now exposes a greater cooling surface. Adjustments of the central nervous system, of endocrine activities, of circulation, and of water distribution are other factors. Acclimatisation to work in hot, dry climates, whereby comfort is increased, pulse rate reduced and skin and rectal temperatures lowered, occurs in a matter of a few days, some 80 per cent. of that reached in three weeks being attained in one week *: the acclimatisation once established may last for two or three weeks.†

BREAKDOWN OF HEAT REGULATION

Regulation of the body temperature is only possible if the demands of the environment are not unreasonable. Beyond a certain point in either direction it breaks down, the body temperature alters, and may ultimately reach a point at which death occurs.

The human body, with its artificial aids, can tolerate a greater alteration of the surrounding, or of its own, temperature, towards cold than towards heat. Thus the environmental temperature can fall 55° C. below a temperate level, and the body temperature 12° C. below "normal," without inevitable death: in the upward direction the limits would be about 30° C. above temperate for environment, and 6° C. above "normal" in body temperature.

---

* Robinson *et al.* *Amer. J. Physiol.*, 1943, **140**, 168.

† Henschel *et al.* *Ibid.*, p. 321.

Lowering of body temperature can be effected by removal of clothing, cold baths or ice-packs, general anæsthesia, eating ice, or exposure to cold air. As the temperature falls the nervous system becomes sluggish, consciousness is gradually lost, and, at rectal temperatures of about 25° C. most reflexes have disappeared. Recovery has been known after a fall of body temperature to 18° C.

Increase of body temperature can be brought about by exercise, increase of clothing, hot moist air, hot baths, hot drinks, radiant heat, diathermy, heat puncture of the nervous system, or by the injection of pyrogenic substances, *e.g.* nitro-naphthol, tetrahydro-β-naphthylamine, yeast, bacterial toxins, or in fevers. When the high temperature is maintained, so that adjustment ultimately fails, the effects take one of the following five forms: hyperpyrexia, heat exhaustion, heat cramp, dehydration and thermal anhidrosis.

Hyperpyrexia, or true "heat-stroke," is due to damage to essential tissues. The rectal temperature is above 104° F., and may continue to rise. Various nervous phenomena are seen, *e.g.*, nausea, headache, stupor or convulsions.

Heat exhaustion is a circulatory failure. There is low arterial pressure, fatigue, syncope, often a subnormal temperature, and sweating.

Adequate NaCl ingestion is an important factor in preventing heat exhaustion.*

Heat cramp is due to chloride deprivation and loss through sweating: There are muscular cramps, low Cl in blood serum and urine, normal temperature and pulse, vomiting, polyuria, diarrhœa and loss of weight. It is rectified by administration of salt.

Dehydration may occur alone, without salt loss: there is thirst, reduced salivation, oliguria, normal temperature, shrunken appearance, exhaustion and various nervous phenomena.

Thermal anhidrosis is preceded by profuse sweating (hyperhidrosis): then sweating ceases except on face and neck. There is no Cl loss, hyperpyrexia, or increase of pulse and respiration rate. Collapse and unconsciousness may follow: recovery is rapid when removed to cool surroundings.†

Fever. In fevers, the body temperature is raised for hours or days, although the environment provides no explanation for it. Opinions have differed as to the respective importance, in the production of febrile states, of increased heat production and of diminished heat loss. One thing is certain, that in many cases the heat-regulating mechanism is deranged, and is "set" at a higher level than normal.

It is true that an increased rate of metabolism is found to accompany most febrile states, but it is more likely to be as a result, rather than the cause, of the rise of temperature. In the case of some pyrexias of chemical origin, however, *e.g.* as a result of the injection of pyrogenic toxins, there is some evidence of a primary stimulating effect on the general metabolism, of which the rise of temperature would then be the consequence.

As regards heat loss there is less room for doubt, since it has been shown in a variety of ways, and in divers pyrexial states, that disturbance of heat loss is an important factor. The skin is pale, and at first cooler than usual (the subject shivers), and the circulation rate in the skin has been shown to be reduced. The skin is also dry, in spite of the ultimately high body temperature, so that evaporative cooling is in abeyance. The rising temperature, together with the shivering, creates a vicious circle by increasing the heat production. Sooner or later the body temperature rises to such a level that, in spite of the steep gradient to the skin, the latter has got hot enough for loss by R + C to be adequate to balance the heat production, and at this high level the body temperature may remain fairly constant, though with exaggerated diurnal fluctuations.

Usually, at the onset of fever, there is definite loss of water from the blood:

---

* Taylor *et al.* *Ibid.*, *p.* 439.

† Wolkin *et al.* *J. A. M. A.*, 1944, **124**, 478.

this has been ascribed to an increased binding of water by the other tissues, such as muscle. Its effect is to reduce the blood volume, favouring its withdrawal from the skin to the internal organs and thus aiding in the restriction of heat loss. In fact, the importance of anhydræmia may be very great, as is shown by the fact that pyrexia can be produced by the mere abstraction of water from the blood as a result of intraperitoneal injection of hypertonic salt solutions.

As the fever passes off, quickly or slowly (crisis or lysis), these causes cease to operate : sweating occurs from a flushed skin, water is recalled from the tissues to the blood, the vicious circle is broken, and the temperature falls to normal.

Antipyretic drugs, such as aspirin, act by lowering the setting of the deranged heat regulating centres to the normal level, and mainly increase heat loss by sweating, vasodilatation and hydræmia.*

THE NERVOUS REGULATION OF TEMPERATURE

The accurate balance between heat production and heat loss involves co-ordination by the higher levels of the central nervous system. A spinal, or a "decerebrate" animal cannot regulate its body temperature, but an animal merely deprived of its cerebral cortex can do so ; so also can one deprived of all brain substance anterior to the middle of the optic thalamus.†

There is good evidence that the important function of integrating the various mechanisms concerned with temperature regulation is located in the hypothalamus, and in man is probably located in the substantia grisea, near the floor of the third ventricle.‡ Both heat production and heat loss are there controlled, and there are separate centres for response to heat and to cold. That for heat is situated in the anterior hypothalamus, and that for response to cold in the caudal part of the lateral hypothalamus.

If the anterior part of the hypothalamus is warmed, the processes causing heat loss, *e.g.* vasodilatation, panting, sweating, etc., are brought into action § ; this suggests that some nuclei here act as thermoregulators, responding directly to a change in temperature of the blood. Electrical stimulation of the hypothalamus may also produce similar responses, while lesions of the anterior hypothalamus lead to a loss of power to withstand high temperatures.‖ It may be concluded therefore that the general response to rise of temperature is directed from the anterior hypothalamus.

Lesions of the posterior part of the hypothalamus tend to cause subnormal body temperatures ¶ ; animals so operated exhibit vasodilatation, and fail to shiver as the temperature drops. It is inferred, therefore, that responses to falling temperature are controlled mainly by the posterior or sympathetic group of hypothalamic nuclei.

The lower centres for heat loss must be placed in the medulla and cord, at any rate so far as concerns control of heat loss by alterations in the blood supply to the skin, or by the secretion of sweat. The same is true for the heat production arrangements, such as shivering, vaso-constriction, metabolic changes, etc. But these lower centres can only function in a co-ordinated manner when under the higher control of the hypothalamus.

It is evident that the heat-regulating centres are put into action as a result of a change in the temperature of the blood reaching the brain : but it is probable that they are also reflexly affected, as *e.g.* by the application of heat or cold to the skin. If one leg is placed in hot water, a reflex vasodilatation occurs in the other limb, even if the return of heated blood from the warmed leg is prevented by occlusion of its circulation.** Local sweating of a reflex nature can also be caused by application of heat to the skin.

** DUTHIE and MACKAY. *Brain*, 1940, **63**, 295.

The reflex vascular and other responses to temperature changes at the surface are probably more delicate than those due to direct effects of altered temperature of the blood on nervous centres. This is especially so with responses to cold, the skin receptors for which are more numerous and more superficial than are those for heat: the threshold difference for sensations of cold is also very small, viz. a drop at the rate of 0·004° C./sec. The skin of the forehead is very sensitive and can detect a rise of 0·003° C. in three seconds.

Shivering is a reflex phenomenon, though it may also be of central origin, and due to fall of blood temperature. A fall of temperature of 0·5° C. to 0·7° C. almost always results in shivering, together with a feeling of internal cold. Administration of alcohol can postpone the onset of shivering until the mean body temperature has fallen by 1° C. or more; taking ice, or iced water, advances it, so that it may occur with a lowering of only 0·2° C. The application of a cold stimulus to an area of skin may, however, cause shivering, although the change of body temperature may be almost inappreciable, or even if the body temperature is rising as a result of heating another area. It would appear, therefore, that sensory stimulation by cooling the skin is a more delicate and potent cause of shivering than is a fall of general body temperature. The cooling of an area of insensitive skin, *e.g.* in a subject with divided spinal cord, does not cause shivering unless there is a definite fall in body temperature as well.*

It has been shown that the reflex of shivering is controlled, not from the spinal cord, but somewhere anterior to the mid-brain,† and almost certainly in the posterior hypothalamus. The efferent paths are not the pyramidal tracts, since damage to them does not affect it, but some tracts in the anterolateral columns, probably the tectospinal or rubrospinal tracts.‡ Normal shivering depends on the integrity of cerebellar function, and on the presence of intact afferents from the muscles.

When shivering occurs, the heat production may be more than doubled; but the heat loss is also increased somewhat, because the increased air movement raises the loss by convection.

BOOK VIII

THE PROVISION OF SPECIAL CHEMICAL STIMULANTS, AND OF MEASURES FOR CONTINUANCE OF THE SPECIES.

THE ENDOCRINE ORGANS AND REPRODUCTION

HISTORICAL NOTE

The Endocrine Organs. The subject of endocrinology belongs entirely to the present century, although, among the speculations of earlier writers was that of RUYSCH, about 1690, that organs such as the thyroid produced important substances which entered the blood stream. Also, in 1849 BERTHOLD induced comb growth in a capon by testicular grafting. The name "*internal secretion*" was, moreover, introduced by CLAUDE BERNARD in another connection, *i.e.* the glycogenic function of the liver: and in 1889 BROWN-SÉQUARD tried, upon himself, injections of testicular extract. The name *hormone* was introduced by BAYLISS and STARLING about 1905, and secretin was the first one to be recognised by a name.

The Thyroid was variously regarded during the 19th century as having to do with voice, as a regulator of blood flow to the head, or as of merely cosmetic purpose. It was first removed from animals about 1840 by ASTLEY COOPER, and SCHIFF, in 1856, showed that its removal (and with it the then undiscovered parathyroids) was fatal in most species. The relation of the thyroid to myxœdema was suggested by ORD in 1878; and REVERDIN in 1882, and KOCHER in 1883, showed that the condition of "*cachexia strumipriva*" followed thyroidectomy in man: HORSLEY, 1884, confirmed this on monkeys.

In 1884, SCHIFF resumed the subject, showing that the effects of thyroidectomy could be alleviated by a graft of thyroid, and MURRAY (1891) and FOX (1892) started thyroid therapy by oral administration in man. The success of this replacement therapy discredited the theory that the thyroid function was concerned with the removal of toxic substances produced in the body.

The discovery of iodine as an essential constituent of the thyroid, by GLEY in 1889, led, in 1895, to the finding by BAUMANN and ROOS, that the iodine was in organic combination. The active principle, thyroxine, was isolated by KENDALL in 1914, its structure was found by HARINGTON in 1926, and it was prepared synthetically by HARINGTON and BARGER in 1927.

The Parathyroids were discovered by SANDSTRÖM in 1880: in 1897, GLEY showed that many of the effects of "thyroidectomy" were attributable to the simultaneous removal of the parathyroids. These effects were at first thought to be due to accumulation of toxic substances (such as guanidine) which it was the function of the parathyroids to eliminate. A clear clue was given as to their functions when HOWLAND and MARRIOTT showed, in 1918, that the state of parathyroid tetany was accompanied by a fall in blood calcium. A hormone which raised blood calcium was extracted by COLLIP in 1925.

The Suprarenals were discovered by EUSTACHIUS in 1543, but no hint of a function came until ADDISON (1849) described the symptoms of the disease which bears his name. BROWN-SÉQUARD, in 1856, showed that their extirpation was soon fatal, and OLIVER and SCHÄFER, in 1894, found that extracts showed powerful physiological properties. This discovery focussed attention on the medulla, and ABEL and CRAWFORD discovered adrenaline in 1897. The affinity between the actions of adrenaline and those of the sympathetic system was demonstrated by LANGLEY in 1901.

Modern ideas regarding the function of the cortex began with the preparation, by SWINGLE and PFIFFNER in 1929, of an adrenal cortical extract capable of suspending the effects of adrenalectomy: the researches of KENDALL and others showed that a whole series of steroids were the responsible active ingredients.

The Pituitary was shown to be concerned in the disease acromegaly by MARIE in 1886, but the manner of its action was not established until about 1935, when the growth-promoting hormone was extracted by H. M. EVANS and others. Outstanding among other discoveries concerned with the anterior lobe were also those of H. M. EVANS and LONG (1921) and P. E. SMITH (1926), which demonstrated the important effects of specific anterior lobe hormones on the reproductive system, and on other endocrine organs.

The discovery, by OLIVER and SCHAFER, in 1895, of a pressor principle in the pituitary—

shown by HOWELL in 1898 to be confined to the posterior lobe, attracted attention fo many years to the posterior lobe, to the exclusion of the anterior: pressor and oxytoci principles of the posterior lobe were separated by KAMM and others in 1928. Hypophysectomy was first performed, on the cat, by MARINESCU, in 1892.

The Gonads. The striking consequences of removal of the gonads on sexual activity, and on the secondary sexual characters, has been known from the earliest times. Th explanation of the effects which was most popular in the 19th century was that o a "trophic" nerve effect. A chemical causation, due to the presence of an "internal secretion" was suggested, but BROWN-SÉQUARD'S experiments on administration o testicular extracts as a treatment of senile impotence which lent some colour to it, wer soon disregarded.

Success first attended experiments on the ovary, *e.g.* the effects of ovarian extracts on the œstrous cycle, and on ovariectomised animals: positive effects of such extracts wer obtained, for instance, by MARSHALL and JOLLY in 1906. The introduction of the vaginal smear technique by STOCKARD and PAPANICOLAOU in 1917 made easy the following of the œstrous cycle, and ALLEN and DOISY, in 1923, announced the presence in *liquor folliculi* of hormone(s) capable of inducing œstrus in ovariectomised animals. The first crystalline preparation of such a hormone was obtained by DOISY in 1929. The isolation and chemical identification of other hormones from the ovary and testis soon followed.

The male hormone androsterone was isolated from male urine by BUTENANDT in 1931.

Reproduction. Until almost within living memory, opinions on reproduction were largely of a mystical character, and rested on little experimental foundation.

In the Hippocratic writings (*ca.* 400 B.C.) the view was that seeds from all parts of the body of man and woman, flow together, and, uniting, form the fruit, which then develops.

ARISTOTLE (*ca.* 350 B.C.) believed that a male factor provided movement, and a female one material, the sex of the offspring depending on which predominated. GALEN (*ca.* A.D. 200) postulated the mixing of a male and female semen: heart and liver were formed from the blood of the mother, the brain from the male semen. FABRICIUS (1621) believed in the fecundating efficacy of an emanation from the semen, because, in birds, the egg was fertilised far from the site at which the semen was deposited. This theory of the *Aura seminalis* was further developed by HARVEY (1651): the uterus was brought by copulation to a state of ripeness, and acquired properties akin to those of the brain, and, like it, could "conceive": the stimulus to conception was the *Aura seminalis.* The conception was, as Hensen said, essentially a "ghostly" one. The notion of the *Aura* has lasted in the popular mind right up to comparatively recent times. The human egg, according to Harvey, was the result of the union of male and female semen, and was intermediate between living and non-living things.

For long a theory of "evolution" held sway. According to this, the egg contained the fully formed embryo, and, therefore, all the embryos of all the later generations. HALLER defended this view, which, however, received its death-blow at the hands of BLUMENBACH in 1784, and was replaced by the theory of "epigenesis."

From time to time there was fluctuation of opinion as to the contribution, by male and female, to the formation of the embryo. According to the one school the male element only provided a stimulus: according to the other, the male element was a seed, for the development of which the mother merely provided the soil.

Early notions on reproduction were also bound up with a belief in spontaneous generation. This latter belief was attacked by HARVEY (1651), and REDI, MALPIGHI, SWAMMERDAM and others in the 17th century brought additional evidence against it. SPALLANZANI'S researches in 1765 showed that many supposed instances of spontaneous generation of lif could be explained by the presence of viable, though dried, spores or seeds, but it was not until PASTEUR'S work in the latter half of the 19th century that the idea of spontaneous generation was almost universally abandoned by educated people. Understanding of the nature of reproduction evidently awaited the application of adequate histological technique.

The ovary, called *testis muliebris* by GALEN, was renamed *ovaria* by STENSON in 1664, and in 1672 DE GRAAF saw its follicles, and regarded them as eggs. The actual ovum was seen in 1827 by V. BAER, who also traced its course, in the bitch, along the Fallopian tube into the uterus, though De Graaf had also already seen them in the Fallopian tubes and uterus.

Spermatozoa were discovered by a Dutch student HAM and were studied in detail by LEUWENHOECK in 1678; the name was given because (even till 1835) they were thought by some to be small parasitic animals; the error of this was exposed by KÖLLIKER in 1841 when he followed their development in the testis.

The first demonstrations of the feasibility of artificial insemination (JACOBI, 1764, SPALLANZANI, 1786) were supposed to have shaken the belief in the *Aura seminis.* The essential feature of fertilisation as the entry of the spermatozoon into the ovum was appreciated by BARRY in 1853, and was of the greatest biological importance.

The relation of ovulation to menstruation was first recognised by BISCHOFF in 1844. The physiology of erection was founded on the work of J. MULLER (1838), ECKHARD (1863–76) and others, and is of classical significance, chiefly in relation to the vaso-dilator action involved.

The considerable body of present-day knowledge concerning the physiology of reproduction is largely the product of the last few decades of investigation.

A. THE ENDOCRINE ORGANS

CHAPTER L

WHEN, in a primitive organism, the reaction of distant parts of the body to a change occurring in any one part depends on the diffusion of some substance from the stimulated part, the total reaction must require a considerable time for its full development. A much more effective method of correlation was acquired by the evolution of a nervous system, but this second mode of correlation did not do away with the necessity for the more primitive method. Even in the higher animals, when sustained, rather than evanescent reaction is required, we often find response to some change in distant parts of the body, the message being chemical and not nervous in character (*e.g.* the secretin mechanism for pancreatic secretion).

When we speak of the chemical correlation of the activities of the different parts of the body, it is important not to confuse processes which have little or nothing in common. In one sense, we may say that every cell in the body is chemically connected with, and dependent on, all the other cells in the body. Thus, one organ may receive and modify any substance or foodstuff so as to prepare it for more ready assimilation by other tissues. It may shield other tissues from the poisonous effects of certain waste products, either by converting them into harmless substances or by excreting them from the body.

We are probably justified in treating apart a group of phenomena in which the substance transmitted from one part of the organism to another is significant almost entirely as an excitatory or inhibitory agent, and has little or no value as a source of energy. In previous chapters, we have already come across several examples of correlated activities of different tissues, effected by chemical means. Thus *secretin*, which is heat stable and diffusible but is easily destroyed by oxidation, is absorbed into the blood and carried to the pancreas, where it acts as a specific stimulus for the secretory cells. This was the first discovered example of chemical co-ordination, *i.e.* a response effected by chemical means rather than by impulses passing along nerves. When the adaptation to a change at A consists in increase or diminution in the activity of an organ B, the change in B can be evoked by the production at A, as a direct consequence of a stimulus, of a specific chemical substance, which passes in the circulating blood to B, where in its turn it will produce the required state of action. Such chemical messengers may be called in general, *autacoids ;* when the effect is to cause excitation they may be called *hormones*, from ὁρμάω, "I excite." * The same autacoid may exert a stimulating action on one organ and a depressant one on another, however. Usually they are now all called hormones, irrespective of the direction of their action. It may be interesting here to consider what must be the characters of substances which fulfil the part of chemical messengers.

Since they must be carried by the blood stream to the reacting organ, they must be susceptible of passage through the walls of the capillaries, and rapidly so, if they are to excite a reaction within a short time. Such substances would need to be of small molecular size, and actually, some of them have a comparatively simple chemical and molecular constitution. Some, however, are of high molecular weight, and act slowly.

Chemically the hormones fall into three groups, (1) *Phenolic derivatives*, *e.g.* adrenaline and thyroxine, (2) *Steroids*, *e.g.* the sex hormones and the adrenal cortical hormones, and (3) *Proteins*, *e.g.* the hormones of the pituitary, pancreas and parathyroid.

---

* STARLING. Croonian Lect. R.C.P., 1905 ; JAYLE. *Bull. de l'académ. de Méd.*, 1937, 117, 73.

Hormones fall into two rough groups according to whether their actions are fugitive or lasting. In those of the former group, the chemical messenger must excite a state of activity (or of inhibition) in response to a change in some other part of the body, *e.g.* when adrenaline is thrown out from the suprarenals in states of sympathetic excitation. When the primary change passes away, the action of the hormone should also disappear. On this account it is necessary that the hormone should either be susceptible of easy destruction, by oxidation or otherwise, in the fluids of the body, or be readily excreted.

In the other group of hormones, which are more stable, the effect is protracted, appearing and disappearing slowly, as, *e.g.* is the case with the hormone of the thyroid, with the sex hormones, and with some of the pituitary hormones.

In the form in which they are liberated in the body, the hormones must not be *antigens, i.e.* their presence in the blood stream must not involve the production of an antibody. If this were the case, the hormone, on entering the blood stream, would meet its antibody and would be unable to exert any effect on the appropriate reacting organ.

The production under experimental conditions of anti-hormones to the active principles of the pituitary or parathyroid, when these are injected, is an apparent exception. The hormones in question are proteins, and the production of the anti-hormones is only observed, or is most evident, when the pituitary material is derived from a different species of animal from that receiving the injection.

The hormones show a fairly well-defined *specificity* as regards the tissues on which they act, but not usually as regards the species of animal. Thus adrenaline from any species of animal has the same actions in general on the tissues of any other species. But the tissue specificity is not absolute : thus sex hormones of one sex may produce some effects on the other sex.

There is one class of organs in which the production of hormones is the only function with which we are acquainted. These are included under the term *endocrine organs*. As examples, we may cite the suprarenal bodies, the thyroid and parathyroids and the pituitary body. Structural proximity, however, does not mean relation of function. Thus we have the cortex and medulla of the suprarenal, each with distinct endocrine functions ; similarly the anterior and posterior parts of the pituitary body, while the thyroids and parathyroids are often as close in situation as they are remote from one another in function. In other cases, an organ may have multiple functions. Thus, the pancreas gives an external secretion, the pancreatic juice, and an internal secretion, insulin, which, passing into the blood, exercises an important influence on the metabolism of carbohydrate. Other instances of these chemical correlations may be cited, *e.g.* the gastric hormone. In the reproductive system, we have many instances of such chemical correlations.

Methods of Investigation. The investigation of the functions of the endocrine organs consists essentially in studying the effects, on the various functions of the body, of augmenting and of diminishing the amount of active principle of the organ in question. There are several directions along which this information may be obtained. Thus, in certain diseases, the endocrine organ concerned produces less of the active principle than it does in the normal state, or, conversely, in conditions associated with overgrowth or overaction of the gland, it may produce more. Careful study of the clinical effects of the hypo- or hyper-function of the particular endocrine organ therefore throws light on the functions which it normally performs.

The effects of lack of the endocrine principle can be studied, in experiment on animals, by the removal by operation of the gland in question, such operations being sometimes performed in stages, so that the resultant change is a gradual one. Then, having produced the effects of lack of the active substance, we may attempt to make good this lack by the administration of the substance, either by feeding with the gland, by administering extracts of it intravenously or by subcutaneous injection (insoluble substances being implanted subcutaneously, or injected suspended in oil); or by the surgical grafting of a portion of the gland from another animal of the same species. We can also, of course, study the effects of similar administration of the active principle to the normal animal or man, and thus learn the physiological effects of an excess of the hormone.

Next, chemical investigation seeks to isolate and to ascertain the nature of these active principles, with the view to their ultimate synthesis in the laboratory, an end which has already been achieved in several instances. It is also essential to find some method by which the amount of the active principle present in a tissue or extract may be estimated. This is usually a method of biological assay, as, *e.g.* in the case of the standardisation of insulin preparations, as chemical methods are not delicate enough. A unit of biological activity is decided upon (often by international agreement), and, when possible, this is related to a known weight of the pure active substance.

The presence, in extracts of tissues, of substances which exert definite physiological effects when administered in appropriate ways, is, however, no proof that the organ in question normally produces that substance for the benefit of the whole body, or that the substance is ever passed, as such, from the organ into the blood or lymph. Strict proof would require evidence that the organ in question, (*a*) contained an active chemical substance, which (*b*) acts upon some other parts of the body, so that (*c*) definite effects would ensue, if the tissue which forms this active principle were all removed, but (*d*) these effects would disappear if the active principle was suitably administered; (*e*) the active substance should be demonstrable at certain times in the blood or in the lymph leaving the organ in which it is produced.

Another important line of enquiry is that which concerns the paths by which the hormones are produced in the body—their precursors, mode and place of synthesis, etc., and also the means by which they are removed or destroyed in the body.

Finally, it is important to study the means by which the formation or liberation of the hormones is effected. In general the liberation of hormones into the blood stream appears to be a continuous process, and to be independent of influences of the nervous system. But there are important exceptions to this, *e.g.* the release of adrenaline into the blood. Usually the regulation of hormone secretion is controlled by chemical factors, such as the presence of other hormones or blood constituents.

THE SUPRARENAL BODIES

The suprarenal bodies, or adrenals, in mammals are two small masses lying on or near the upper or oral pole of the kidneys. They consist of two parts, the cortex and the medulla. The cortex is composed of cells arranged in columns or in a reticular fashion; in the female in some species, and notably in mice, the cortex is much larger than in the male. It is doubtful whether any nerves supply the cortex. According to the arrangement of its cells the cortex is divided into three zones, the zona glomerulosa, zona fasciculata, and zona reticularis. The cells themselves are distinguished by the large amount of granules they contain, which probably consist of lecithin and sterol compounds. These granules stain with osmic acid, and are dissolved out by turpentine. The cortex cells stain black with silver nitrate on account of their high content of vitamin C. In some animals, *e.g.* the guinea-pig, the cells, especially towards the inner part of the cortex, contain many yellow pigment granules.* In others, especially in young female and castrated male mice, the inner layers of the zona reticularis are increased in thickness, and consist of small deep-staining cells: this is called *the X-zone.* It shows degeneration in older, and in pregnant, females.

The medulla, much less extensive than the cortex, presents irregularly shaped cells, the outlines of which are but slightly marked. These cells contain granules which stain darkly with chromates and give a green colour with salts of iron. It is hence easy to delimit the area of the medulla in any section of a gland which has been hardened in a fluid containing chromates. The substance giving this reaction is known as chromaffine substance.[*] Fine osmic-staining granules are also present in abundance in these cells, but are *not* dissolved out by turpentine. All these reactions are due to the presence of adrenaline.

---

* Cramer. *J. Physiol.*, 1918, **52**, Proc. viii.

The suprarenals are richly supplied with blood, especially in the medullary part, the cells of which impinge directly on the endothelial lining of dilated capillaries. The blood supply is probably the most abundant in the whole body. They also receive an abundant nerve supply from the sympathetic system (splanchnics), and some from the vagus, and perhaps from the phrenics.[†] The nerves form a thick meshwork in the medulla; this contains also a few ganglion cells, which may either be isolated, or combined to form small ganglia.

A study of the development of the suprarenal glands shows that we have here to do with two distinct tissues, which have different origins and different functions in the body. Whereas the cortex is derived from that portion of the mesoblast, the "intermediate cell mass," from which the mesonephros is also developed, the medulla is produced by an outgrowth from the sympathetic system, and may indeed be said to consist of profoundly modified nerve cells. In many fishes, these two elements of the suprarenal gland remain separated throughout life, the cortex being represented by a series of paired inter-renal bodies lying on the front of the spinal column, and the medulla by a number of collections of chromaffine cells, lying in close juxtaposition to the spinal nerves.

In some animals, accessory suprarenals, in which both cortex and medulla may be represented, are not infrequent. In all animals we find masses of tissue, the so-called para-ganglia, in close association with the sympathetic system, which present the chromaffine reaction typical of the medulla. Since a watery extract or decoction of these bodies has the same influence, on injection into the blood stream, as an infusion of the medulla of the suprarenal body itself, we are probably justified in regarding these bodies as equivalent to accessory medullary portions of the suprarenal. They have the same origin, the same staining reactions, and the same physiological effect as the latter.

Scattered portions of cortical tissue are also found in many animals, usually near to the gonads.

FUNCTION OF THE CORTEX

Extirpation of one suprarenal (single adrenalectomy) has no effect beyond that of sometimes leading to hypertrophy, especially of the cortex, of the other one. This may be due to a mutual reaction between suprarenal cortex and anterior pituitary, resulting in increased formation by the latter of the adreno-corticotropic hormone. The extirpation of both suprarenals is fatal in a few days if all accessory cortical tissue is also removed. In the cases where animals survive double extirpation, small masses of accessory cortical substance have been found embedded in the kidney or elsewhere in the neighbourhood of the suprarenals or gonads. Old male rats, on suitable diets, and some rabbits, may survive double adrenalectomy indefinitely because of accessory tissue left behind. To cats, dogs, young rats and guinea-pigs, however, the operation is fatal in, at most, a few days; death is accelerated in cold environment. It is certain that the rapidly fatal effect of extirpation of both suprarenals is to be ascribed to the removal of the cortex and not of the medulla. After recovery from the operation the basal metabolism of the animal, as measured by oxygen consumption, remains normal for a few days, and then, when symptoms of weakness appear, falls considerably.[‡] When death occurs it is sudden, and is preceded by rapid rise of blood urea and non-protein nitrogen, loss of appetite, imperfect fat and carbohydrate absorption, weakness of muscles, lowering of arterial pressure and of blood sugar, fall of body temperature, collapse, and a shock-like condition, with great concentration of the blood. It was shown by Loeb [§] that there is an increased rate of loss of sodium salts by the kidneys after adrenalectomy; the general dehydration and reduction of blood volume is to some extent a consequence of this lowered blood sodium. Since the urea clearance is reduced, and the excretion of other substances also disturbed, it would appear that there may be some primary interference with kidney function.[||] Thus blood potassium, creatinine, phosphate and sulphate are raised, while excretion of injected phenolsulphonephthalein is reduced. Any factor which augments loss of water from the blood aggravates the condition of circulatory collapse, *e.g.* it can be evoked very easily in an adrenalectomised animal by the administration of a small dose of histamine, to which such animals are abnormally sensitive. A similar loss of fluid and electrolytes from the blood occurs in wound shock.* Conversely, the injection of salt solution into the blood stream, or administration of NaCl by the mouth improves the condition for a while.

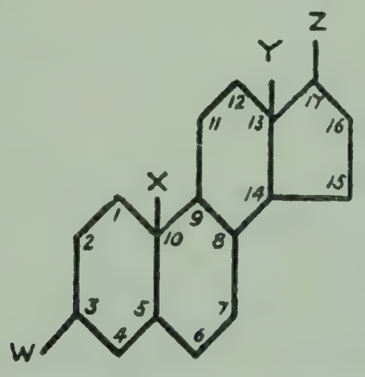
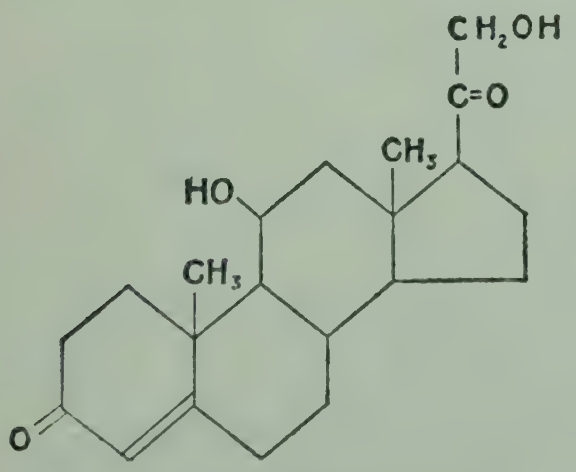
Addison in 1855 drew attention to the coincidence of degenerative destruction of the suprarenals with a disease which since that time has been known as Addison's disease. The three cardinal symptoms of this disorder are (1) bronzing of the skin and mucous membranes, (2) vomiting, (3) excessive muscular weakness and prostration. The disease is almost invariably fatal if untreated. Addison's observations have been amply confirmed since that time, but we are not yet in a position to account for the occurrence of all these symptoms as a result of interference with the suprarenals since it has been impossible experimentally to reproduce the bronzing which is so characteristic of Addison's disease.

Among many attempts to isolate from the cortex a substance capable of prolonging indefinitely the life of adrenalectomised animals, the first clear success was reached by Swingle and Pfiffner in 1929. They extracted fresh ox suprarenals with alcohol, concentrated the extract and re-extracted it with benzene and various other solvents, and finally obtained a water-soluble extract of sufficient purity to permit of administration by intraperitoneal injection.† Daily injections of small doses of extract suffice to maintain in health a previously adrenalectomised dog. Large doses given by mouth are effective.‡ When the administrations are withheld, the animal rapidly goes downhill, and dies in a few days: but even moribund animals are very soon restored if the dosage is recommenced, and sodium chloride given.

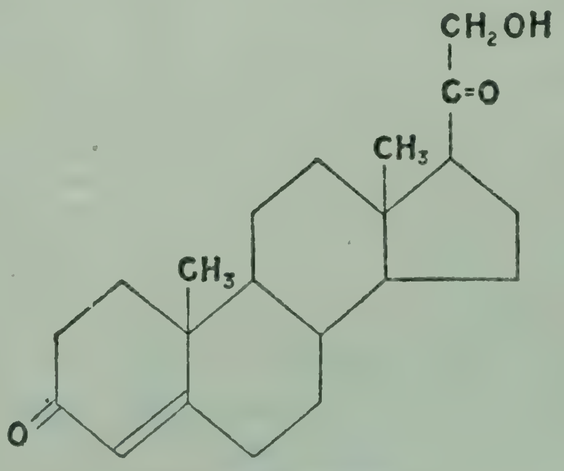
Cortical Hormones. From the researches of Kendall,§ and others, it has been found that some twenty sterols are present in the suprarenal cortex. The cholane ring which represents the steroid skeleton is :—



Chief among the cortical steroids are *Corticosterone*, *Desoxycorticosterone*, *Dehydrocorticosterone*, and, in small amounts, *Progesterone* and *Androsterone*



Corticosterone.



Desoxycorticosterone.

(the last two also being known among the sex hormones). They differ in their activity in replacing the hormone lost by adrenalectomy, though at least six of them are more or less active. They are almost certainly manufactured, in the cortical cells, from cholesterol.

The cortical steroids fall into two groups, one typified by corticosterone having a keto- or hydroxy-oxygen at C-11, and one typified by progesterone and desoxycorticosterone, which lack such a group. Their actions are different.

The essential activity of the cortex is probably to be attributed to the three hormones, Corticosterone, Desoxycorticosterone and Dehydrocorticosterone. In some ways the most active, though not most abundant, of the cortical steroids is desoxycorticosterone, which is now made synthetically and placed on the market as its acetate. The desoxycorticosterone type is more potent than corticosterone in affecting the salt and water balance, though it has less effect on carbohydrate and protein metabolism. The effect on carbohydrate metabolism is possibly due to its relation to phosphorylation.

A steroid compound, or complex, containing ascorbic acid, and behaving like dehydrocorticosterone, has also been isolated.*

Clinically, the solid hormone may be implanted under the skin in cases of Addison's disease.†

Desoxycorticosterone can restore an adrenalectomised animal or a patient with Addison's disease to a reasonably normal state of health. Testosterone can also cause improvement in strength, positive N-balance, and lowering of serum K‡; so can other cortical sterols, though in some cases, *e.g.* with androsterone or progesterone, the amounts needed are relatively large.

In muscular exercise, and as part of a generalised response of the body to damaging influences, such as trauma, cold, reduced atmospheric pressure, and certain toxic substances, there is evidence of increased activity of the suprarenal cortex, and the administration of cortical hormones in large doses has been used in combating surgical shock.

The cortical hormone, which is probably present in the lipide granules of the cells, is released into the blood stream, and can be assayed in the venous blood leaving the gland.§ The assay is made by determining the prolongation of life of suprarenalectomised rats kept in cold surroundings when the plasma of the sample of blood is injected: the results show that a large amount of the hormone is continually being released, the amount from one suprarenal in the dog being estimated as equal in twenty-four hours to the commercially extractable hormone content of no less than 17,300 g. of gland. It is evident, therefore, that either the usual methods of extraction are very inefficient, or else that new hormone is continually and rapidly being produced in, and liberated from, the cortex. The rate of liberation is independent of the rate of blood flow through the gland, or of the arterial blood pressure, but is augmented to several times its resting value by the injection of physiological amounts of adrenaline,‖ and hence also by splanchnic excitation. It is also accelerated by addition to the blood of K· ions, A.T.P. or creatine phosphate.¶ There is no direct action of the sympathetic on the cortex, but the indirect effect, through production of adrenaline, provides a means of supplying, with that adrenaline, a second hormone which plays an important part in enabling the body to withstand stress. The hormone rapidly disappears from the blood and so is not detectable in any blood but that of the suprarenal vein. This is so even if the alimentary canal, liver and kidneys have been removed: it can therefore in all probability be removed by the tissues generally, but normally part is excreted, in active or inactive form, in the urine.

Relations between Gonads and Adrenals. In view of the fact that some of the adrenal corticosteroids exhibit androgenic or œstrogenic properties, or are even identical with sex hormones, it is not surprising that close and complex relations should exist between the cortex and the sex organs and secondary sex characters. These relations can here only be touched upon, but perhaps the most striking illustration is that of the disturbance of secondary sex characters seen in tumours or hyperactivity of the adrenal cortex. According as the output of the cortex in these cases is preponderatingly androgenic or œstrogenic, we may get precociously sexed boys, masculinised girls, women with virilism, or feminised men. The most frequent cases are of virilism in women.

Hypertrophy, or a tumour, of the suprarenal cortex in children is associated with premature sexual maturity * and in women with masculinisation and hirsutism (and also often with a basophile pituitary tumour). Many cases of masculinity (virilism) in women have been dramatically cured by removal of an adrenal tumour ; the male hair may then be removable a few days after operation.

In such cases the inner layers of the cortex were found by Vines to contain granules stainable by ponceau-fuchsin. This material is absent from normal suprarenals, except in fœtal life, up to the end of the first half. The fuchsinophile material appears sooner and persists longer in male than in female fœtuses, and is believed to indicate the presence of androgenic sex hormones. The occurrence of virilism in women seems to be due to the obtrusion of male qualities which in the normal endocrine balance of the female, are held in abeyance. The corticosteroids essential to life have little effect on the sex functions when given to intact animals ; desoxycorticosterone, however, has been shown to have a progesterone-like action, and progesterone itself is present in the cortex. Substances having actions similar to those of cortical sterols have been recovered from the urine of mares and cows.† By utilising a colour reaction with *m*-dinitrobenzene and KOH, a comprehensive estimation may be made of all the 17-ketosteroids in the urine ‡ : these include several adrenal cortical and androgenic steroids. Normal men excrete 10–15 mg. and women 6–10 mg. daily : in children prior to puberty the amounts are much smaller ; in adrenal cortical tumours the amounts of 17-ketosteroids may rise to 200 mg. daily.§

Relations of Cortex with Pituitary Anterior Lobe. After hypophysectomy the inner layers of the cortex, first the zona reticularis and then the zona fasciculata shrink and degenerate, and these changes can be prevented by the injection of suitable extracts of the anterior lobe—the so-called adrenocorticotropic hormone. Hypertrophy of the inner cortical layers can be induced by the injection of these extracts into normal animals. The influence of the cortex on the metabolism of carbohydrate, fat and protein is the most affected by the adrenocorticotropic factor, from which it may be suspected that it is the inner layers of the cortex which secrete the hormones that are concerned with the control of these aspects of metabolism. The outer, and more newly-formed cells of the zona glomerulosa may either secrete enough hormone, or a hormone of the right kind, to exercise control over the salt and water regulation of the body after hypophysectomy.

Nature of Action. Various explanations have been advanced to attempt to explain why the suprarenal cortex is essential to life, and to find in what the fundamental action of the cortical hormones consists. Apart from any theories, it is evident that they must have some action which affects processes that are quite indispensable to life ; no doubt some of the effects are secondary to this action. Opinions differ as to what the fundamental action is, and depend very much on the clarity with which results emerge.

---

* Bulloch and Sequeira. *Trans. Path. Soc., London,* 1905, **66,** 189.

† Selye and Dosne. *Lancet,* 1940, **239,** 70.

‡ Callow *et al.* *Bioch. J.,* 1938, **32,** 1312.

§ Callow and Crooke. *Lancet,* 1944, **246,** 464.

The striking excretion of sodium from the body after adrenalectomy, together with the accumulation of potassium and loss of water, have led to the theory that the fundamental action of the hormones is related to the control of the salt and water balance, and that the other effects, such as those on carbohydrate metabolism, are in some way related to this. But these effects on salts and water are chiefly due to the desoxy-hormone.

The tissue chlorides certainly play some important part in general metabolism, as may be shown by the experiment of acute chloride depletion. A dog is given a large intraperitoneal injection of 5 per cent. glucose, say 1 l. ; much of the blood chloride diffuses into this, and three hours later the fluid is withdrawn. It is then found that the metabolic rate (oxygen usage) of the animal is low, but is restored to normal by intravenous NaCl.[*] The NaCl is said to play a part in facilitating transfer of oxygen from hæmoglobin to the tissues.

Another view is that the fundamental effect is on carbohydrate metabolism, and as we have seen in Chapter XLVI, this effect is certainly quite pronounced. This effect is due to the corticosterone type of hormone. It consists in a depression of glucose usage by the tissues together with accelerated glucose formation from protein or amino-acids, and increased glycogen storage. A way in which the protein metabolism may be affected may be by an effect on liver arginase, which is increased by corticosterone.

Units. Various units of activity of the cortical principles have been proposed. Thus, the Pfiffner " dog unit " is the minimal daily dose per kg. body weight which will keep an adrenalectomised dog constant in body weight and with a constant low blood urea. If 0·3 g. kg./day of NaCl is given with the diet, the unit is equal to 0·5–1·0 g. of fresh gland, or 0·015–0·020 mg. desoxycorticosterone kg./day. If sodium salts are not administered, at least ten times as much will be needed.

The suprarenal cortex also has a high content of ascorbic acid, which is probably due to its storage there, perhaps combined with a steroid.

FUNCTIONS OF THE MEDULLA

The medulla can be destroyed by operation, or by insertion of a small tube of radium, without causing death. It seems that the functions of the medulla, if essential to life, can be more or less effectively maintained by the other chromaffine tissue found at the back of the abdomen. But there is no conclusive evidence that the chromaffine material is, in fact, essential.

Schäfer and Oliver in 1894[†] found that an aqueous extract of the suprarenal bodies, when injected into the circulation, caused a great rise of blood pressure, brought about chiefly by generalised vaso-constriction. The substance responsible for this was limited to the medulla, and later on Abel [‡] isolated an active substance to which the name of *adrenaline* [§] was given. Long afterwards *nor*-adrenaline was shown to be present too (formulæ p. 361).

Adrenaline gives a blue colour with phosphotungstic acid,[‖] or with arsenomolybdic acid ;[¶] the latter can be employed for its quantitative estimation, but it is more often assayed in biological fluids by a biological method, *e.g.* by the relaxation of a loop of isolated intestine. An even more delicate test is the relaxation of the non-pregnant rat uterus suspended in Tyrode solution containing excess of KCl (0·2 p.c.) : this can detect a concentration of 1 in 10^9 [**]

It may be distinguished from nearly related compounds by the green fluorescence, shown in ultraviolet light, when alkalised.*

The natural form is lævorotatory and is physiologically about twelve times as active as is the dextro-variety.† Both dextro- and lævo-forms have been prepared synthetically. The general chemical and physiological properties of *nor*-adrenaline resemble those of adrenaline, the physiological differences being rather quantitative than qualitative.‡

It is accepted that adrenaline and *nor*-adrenaline as prepared from the suprarenal are identical with the active hormones which these organs can release into the blood stream, and with the synthetic compounds. When we speak of a release of " adrenaline " from the suprarenals, we mean a release of both substances, but the conditions under which one or the other might preponderate are as yet uncertain.

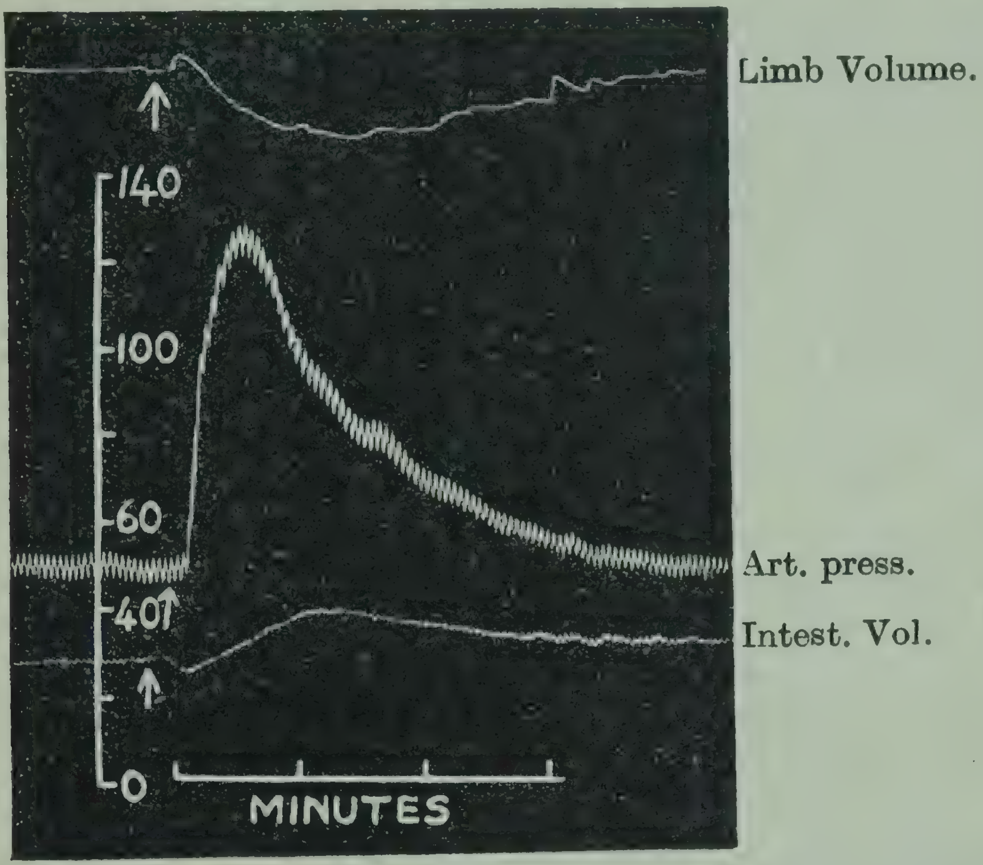

Fig. 639. Effect of Intravenous Injection of Adrenaline on Limb Volume, Arterial Pressure and Intestine Volume of Decerebrate Cat. At arrow 0·01 mg. adrenaline; passive dilatation of intestine. (G. A. Clark. *J. Physiol.*, 1930, 69, 181.)

Adrenaline, though almost inert when given by mouth, is active in minute amounts on injection into the general circulation, injection of 0·0025 mg. per kg. body weight sufficing to evoke an effect upon blood pressure. On injecting it into the circulation there is immediately a rise of blood pressure which, if the vagi are intact, is only moderate in amount, since it is accompanied by a slowing of the heart. This latter is due to an excitation of the vagus secondary to the rise of blood pressure, and is not due to direct action of the drug on the vagus centre except that it increases its reflex excitability.§ (The slowing is more evident with *nor*-adrenaline.) If the vagi be divided, the injection of adrenaline, even after destruction of the central nervous system, evokes a huge rise of pressure, which may amount to 300 mm. Hg. The most intensely constricted vessels are those of the skin; in the splanchnic area the effect is smaller, so that if the rise of pressure is large, these vessels may become passively dilated (Fig. 639).

Adrenaline injected into the circulation arouses those activities which can normally be excited by stimulation of the sympathetic system.‖ With *nor*-

adrenaline the parallel is even closer (*v.* p. 361). After adrenaline injection the liver glycogen is rapidly discharged, and hyperglycæmia and glycosuria result.* Potassium is also liberated from the liver.† The glycogen of muscle is also discharged, being converted into lactic acid.‡ Fatigue of skeletal muscle is postponed. The heat production and oxygen usage are increased.§ In the head, it causes dilatation of the pupil, secretion of saliva, and erection of the hairs. The dilatation of the pupil is much accentuated after previous removal of its sympathetic supply by excision of the superior cervical ganglion.‖ On the heart it has a strong augmentor and accelerator influence, greatly increasing its oxygen utilisation,¶ so that it beats more effectively, and empties itself more completely in systole, even against the enormously increased resistance offered by the constricted arterioles. The bronchi and bronchioles are fully relaxed ** ; respiratory movements are often temporarily inhibited (adrenaline apnœa : this is a secondary effect of the rise of arterial pressure on the carotid sinus). On the lung vessels, adrenaline has probably a slight constrictor influence. With regard to the vessels of the brain, we find the same slight constriction as in the case of excitation of the sympathetic nerves to this organ, In the abdomen, it causes complete relaxation of the musculature of the cats and the human uterus, of the stomach, and of the small and large intestines but contraction of the ileocolic sphincter, and of the rabbit's uterus. On the bladder, its effect varies according to the animal studied, but in every case is identical with that obtained by stimulating the hypogastric nerves. It has been shown that very small doses of adrenaline usually cause a definite *fall* of blood pressure in anæsthetised animals. This is probably due to relaxation of the arterioles,†† particularly in muscle,‡‡ outweighing the vasoconstrictor effect elsewhere ; *nor*-adrenaline only produces constrictor effects, hence its pressor action is more powerful than that of adrenaline. Its action on the pregnant cat's uterus is also more powerful, but otherwise its actions are generally weaker, than those of adrenaline.

The motor effects of adrenaline are usually reversed after previous injection of ergotamine, the active alkaloid of ergot, or of dibenamine. These drugs cause paralysis of all adrenergic mechanisms. Excitation of the splanchnic nerves, or injection of adrenaline, will now bring about a fall of blood pressure, due to dilatation of the vessels in the splanchnic area.§§ The substance 933 F. (piperidomethylbenzodioxane) is also an anti-sympathomimetic substance, which reverses the hypertension caused by adrenaline, though it does not paralyse adrenergic nerves.

The point of action of the adrenaline appears to be in the muscular or glandular tissues themselves, since its effects may not only be obtained after destruction of the sympathetic nerves, but even obtained (and in an exaggerated degree) after time has been allowed for the peripheral (post-ganglionic) fibres to degenerate as a result of extirpation of the corresponding ganglia. We have already dealt (p. 360) with the probability that the "adrenergic" nerves produce their effects by the liberation at their endings of some related substance, probably *nor*-adrenaline.

The splanchnic nerve is the secretory nerve to the suprarenal medulla. The fibres end without the interposition of any ganglion cells on their course,‖‖

the cells of the medulla themselves being modified sympathetic ganglion cells. Stimulation of the peripheral end of the splanchnic nerve causes a discharge of adrenaline and *nor*-adrenaline into the blood stream. This discharge accounts for the secondary rise, often accompanied by quickening of the heart, observed on a blood-pressure tracing as the result of stimulating the splanchnic nerve.* Through the splanchnic nerves, a discharge of adrenaline can be excited by many general conditions, such as anoxæmia,† pressure on the brain, puncture of the fourth ventricle,‡ administration of anæsthetics, or mental disturbances such as excitement or fright. Such a discharge is an important element in the adaptation to environmental stress, and enables the animal to react for the preservation of its life, either by offence or by flight. If one splanchnic nerve be cut before the administration of anæsthetics or the induction of a condition of irritation or fright, the suprarenal gland on the corresponding side will be found to contain two or three times as much adrenaline as the gland which has been left in connection with the central nervous system. It is stated that no such condition of exhaustion can be produced by electrical stimulation of the peripheral end of the divided splanchnic. This may be because the splanchnic fibres are not very suitably excited by faradic stimulation, and so the recuperative process in the medulla is able to keep pace with the depletion.

The splanchnic endings in the medulla are cholinergic, and small intra-arterial injections of acetyl choline into the suprarenal cause a large discharge of "adrenaline".§

Cannon and his co-workers‖ demonstrated the liberation of adrenaline from the suprarenals, by observing the acceleration of the denervated heart. Cats were used in these experiments, and the heart was denervated by removal of the stellate and other thoracic sympathetic ganglia and section of the vagi in the neck. Such animals, in states of asphyxia, fear, pain or rage showed pronounced cardiac acceleration, but if the splanchnics were divided, the effect was very slight or absent. Reflex secretion of adrenaline could also be shown in this preparation by stimulation of the central end of the sciatic nerve.

Similarly, Kellaway, using a cat with the pupil of one eye deprived of its sympathetic supply, showed that the hypersensitive denervated pupil dilates in even mild degrees of asphyxia or oxygen lack.

Tournade and Chabrol ¶ also showed that the secretion of adrenaline may be produced reflexly. Their method is to anastomose the suprarenal vein of one dog A, with the external jugular vein of a second dog B. The arterial pressure of B is recorded and the spleen of B placed in a plethysmograph. When the central end of the sciatic nerve of A was stimulated, there was a rise of blood pressure and a shrinkage of the spleen in B. By a similar technique, Heymans ** has shown that a fall of blood pressure in the arteries (but especially in the *sinus caroticus*) leads to a reflex liberation of adrenaline. The arrangement of this experiment is shown in Fig. 640. Adrenaline is liberated from the suprarenals of dog B when the carotid pressure on the left (innervated) side is lowered, but not when the carotid artery pressure on the right side is lowered (carotid sinus denervated on right side of B). When the adrenaline is liberated in B, the spleen of C (suprarenals removed) contracts.

Stewart and Rogoff,†† using other methods, claimed to have demonstrated that adrenaline is continually being passed out from the suprarenals into the blood, but it is doubtful whether in normal quietly resting animals the concentration of adrenaline in the blood exceeds 1 part in 1,000 millions, and this would produce no general effects.

When adrenaline is injected into the blood stream, the effect is only transitory—a matter of seconds for a small dose, *e.g.* 0·01 mg. for a cat. It rapidly disappears from the blood, and is taken up and protected from auto-oxidation by the tissues.‡‡ Here it seems to be inactivated in two ways, first, by an adrenaline oxidase, a variety of amine oxidase,§§ and secondly, (at all events when given by mouth) it is eliminated by conversion into an ester.* It is partly on this account that when injected into the portal vein adrenaline is relatively ineffective, since the liver is known readily to form sulphate esters with phenolic bodies.

Adrenaline is thus a typical hormone, a body of comparatively low molecular weight, having a drug-like excitatory action on specific tissues of the body, easily diffusible, and rapidly destroyed after discharging its office. There seems little doubt that we must ascribe to the chromaffine tissue the function of elaborating this substance, and it has been claimed † that living medullary tissue can convert *p*-hydroxyphenylethylamine into adrenaline.

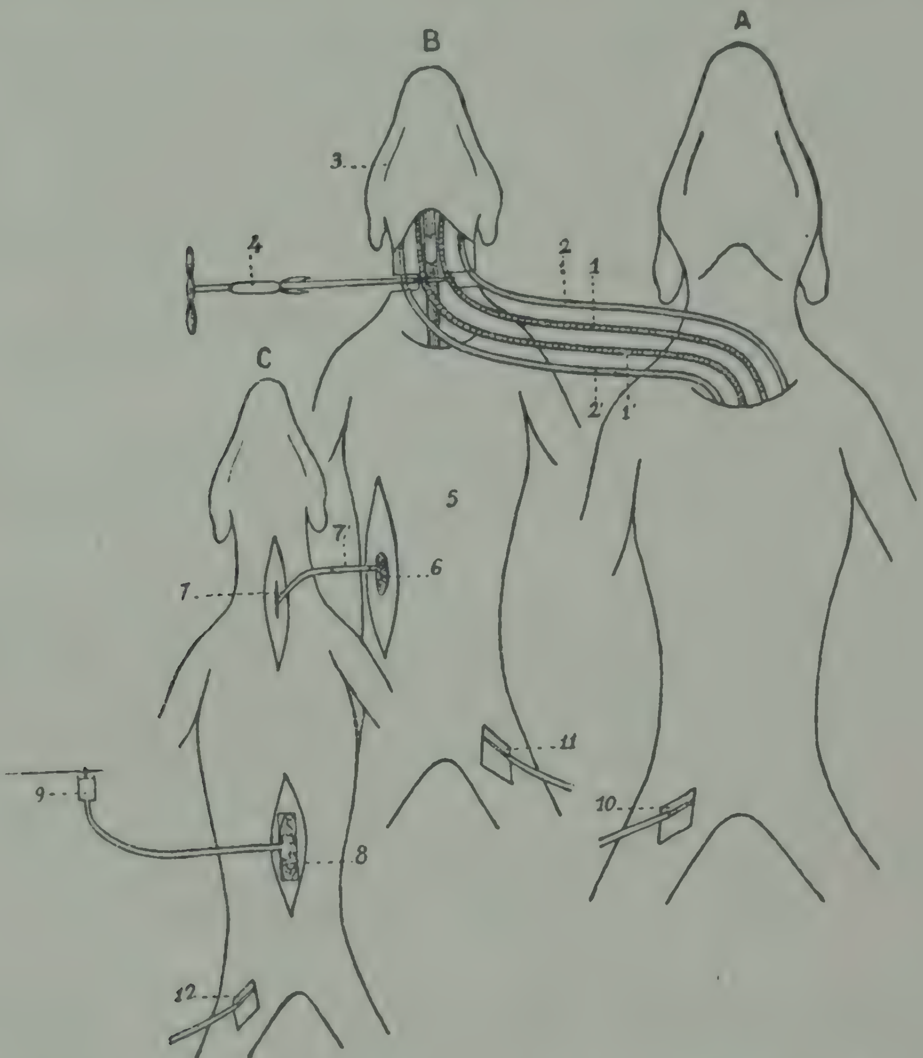

FIG. 640. Perfusion by Carotid and Jugular Anastomosis from A to Semi-isolated Head of B (right carotid sinus denervated), and from Suprarenal Vein of B to Jugular Vein of C (adrenalectomised). Spleen of C in a plethysmograph contracts when adrenaline is liberated by B, as *e.g.* when pressure in left carotid of B is lowered. Systemic pressures recorded from femoral arteries. Vagi of B divided; also all neck tissues, except spinal cord, divided by *écraseur* (4). (C. HEYMANS.)

What part adrenaline plays in the normal functions of the body has, however, been contested with no little heat. It has actions closely resembling, but not identical with, those of the normal sympathetic transmitter (*nor*-adrenaline). An important difference is that, at low concentrations, it dilates muscle vessels, whereas *nor*-adrenaline constricts. The bulk of opinion seems to be that adrenaline is very slowly poured out by the normal suprarenal, and that this output is stopped or greatly reduced by section of the splanchnic nerve supply; that the amount of adrenaline so liberated is too small to exert an effect upon the tone of the arterioles, though it might affect the tone and permeability of the capillaries; and that, in states of emotion, asphyxia, exposure to cold, etc., there is a sudden liberation of adrenaline in such amount (*e.g.* 0·004 mg./kg./min.) as suffices to produce the effects seen on injection of that substance into the blood stream. According to this view, the *emergency theory*, we should be inclined to regard the suprarenal medulla as resembling the sympathetic nervous system in being a useful adjunct in times of stress, though not essential to life.

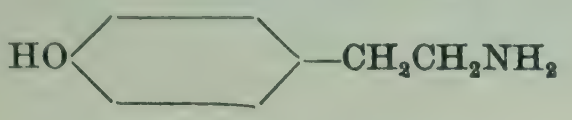
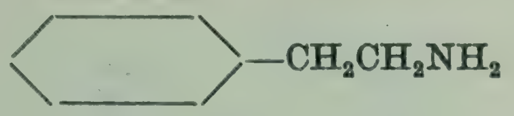
† SCHULER and WIEDEMANN. *Z. f. p. C.*, 1935, **233**, 235.

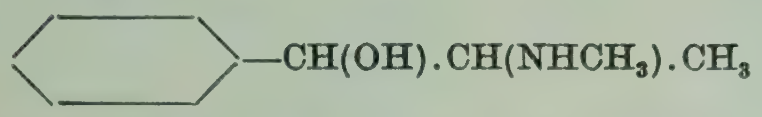
Owing to the rapid destruction of adrenaline, it produces very little effect when given by the mouth. There is, however, a whole series of substances, more or less allied to adrenaline in chemical constitution, which undergo less rapid destruction and can therefore be administered by mouth. Dale and Barger described such substances produced from amino-acids by a process of decarboxylation. Tyrosine would yield hydroxyphenylamine, and phenylalanine would give phenylethylamine. Such substances may be formed in minute quantities during the normal processes of putrefaction which occur in the alimentary canal. Another similar substance is the drug ephedrine. The constitution of these substances is shown in the following formulæ :



p-hydroxyphenylethylamine



phenylethylamine



ephedrine

Ephedrine sensitises tissues not only to adrenaline, but also to the stimulation of adrenergic nerves. This appears to be because it inhibits the enzyme, amine oxidase, by which adrenaline is destroyed.* This recalls the action of eserine in potentiating the action of acetyl choline or of cholinergic nerves.

THE THYROID

In development, the thyroid is formed by a down-growth from the floor of the pharynx. It consists of two oval bodies weighing, in man, 20 to 25 g., lying on either side of the trachea, and joined, in many animals, across the trachea by an isthmus. It is made up of an aggregation of vesicles varying in diameter from 15 to 150μ, each lined by a single layer of cubical epithelial cells, and filled with a fluid known as " colloid " (Fig. 643, A). Mitochondria are sometimes very abundant in the cells, and these and the Golgi apparatus undergo definite changes under conditions which are believed to be associated with alterations in the secretory activity of the thyroid, *e.g.* an increase when the animal is exposed to cold. The internal secretion formed by the epithelium is shed into the colloid, and probably makes its way into the blood direct, or along the lymphatic efferents of the gland. The thyroid is richly supplied with blood by three arteries, and is surrounded with a plexus of veins lying immediately under the capsule. It receives at least three times its own weight of blood per minute. The nerve supply is from the cervical sympathetic.

Diseases due to both deficient and excessive activity of the thyroid are known, and clinical observations of these first gave the clue to the functions of the thyroid.

Thyroid Deficiency. The effects of thyroid deficiency differ according to whether the deficiency is manifested in infancy or in later life.

If the atrophy of the thyroid occurs in early life, during the period of growth, *e.g.* in young children, the growth of the skeleton practically ceases. The bones of the limbs may grow in thickness but not in length. There is early synostosis of the bones of the skull, and complete cessation of development of mental powers. Children so affected are called *Cretins.* They may live for many years, but when twenty-five or thirty still present a childish appearance (Fig. 641, c). Stunted, pot-bellied and ugly, they have the intelligence of children of four or five. They often present fatty tumours above each clavicle, and similar subcutaneous tumours of fat or loose fibrous tissue are found in cases of myxœdema in the adult. The basal metabolism is low, and sugar tolerance high.

---

* Gaddum and Kwiatkowski. *J. Physiol.*, 1938, **94,** 87.

Removal of the thyroid from tadpoles causes a comparable failure of proper development, so that metamorphosis is absent or delayed.

If care be taken to spare the parathyroids at the operation, removal of the thyroid from young animals results in the same retarded development and stunting of growth as are observed in children when there is deficiency of the thyroid.

A decline of thyroid function in later life results in a somewhat different picture. In this country, attention was called to the connection of a depressed condition of metabolism known as *myxœdema* with alteration or atrophy of the thyroid. A patient affected with myxœdema presents a gradually increasing blunting of his or her mental activities ; speech is slow, cerebration delayed. With this nervous defect are associated changes in the connective tissues, the subcutaneous connective tissue becoming thickened, so that the face and hands appear swollen and puffy, looking at first sight as if œdema were present. The swelling is, however, due to newly-formed connective tissue, and not to the presence of an excess of interstitial fluid in the tissues. The patient often has a yellow waxy appearance, with a patch of colour on the cheeks. The hair falls out, the pulse is slowed, and the temperature tends to be subnormal owing to the diminution of the general metabolism of the body. Determination of the patient's basal metabolic rate shows this to be definitely (20–30 per cent.) below the normal value, as calculated from weight and height.* The intake of food and the excretion of nitrogen and of calcium are diminished. When the thyroid is extirpated in adults the result is the production of typical myxœdema.

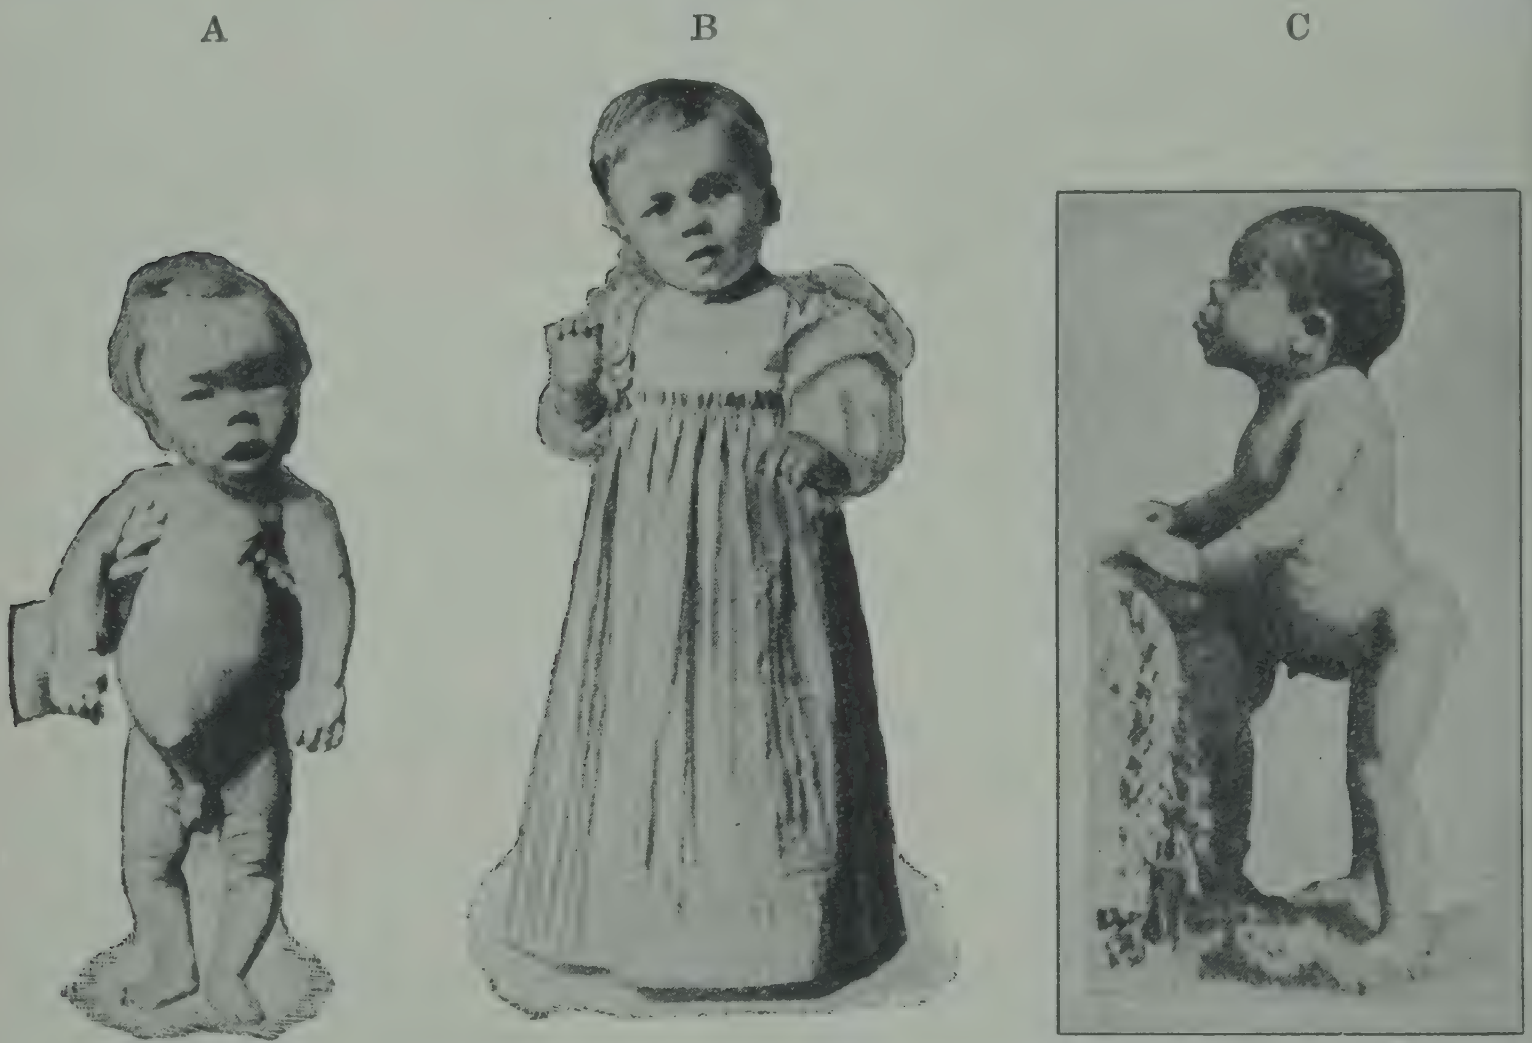

FIG. 641. A. A cretin, 23 months old. B. The same child, 34 months old, after administration of sheep's thyroids for 11 months. C. A cretin, untreated, 15 years old. (W. OSLER.)

THYROID FEEDING. Schiff first showed that the effects of extirpation of the thyroid might be prevented if, at the same time, the thyroid from another animal were transplanted into the subcutaneous tissue. On removing the transplanted thyroid, the typical symptoms of thyroid deprivation at once appeared. It was later found that it was sufficient to administer the thyroid gland, either fresh, dried, or partially cooked, by the mouth. An ugly and idiotic cretin can be converted by this means into a child of ordinary intelligence with normal powers of growth (Fig. 641, A and B). Given to myxœdematous patients, fresh or dried thyroid gland restores the basal metabolism, nitrogen output and body temperature to their normal levels, reduces the swelling of the subcutaneous tissues, causes a new growth of hair, and reinstates the patient's former condition of mental health *† (Fig. 642). It is possible that a moderate degree of thyroid inadequacy is not infrequent, and that the beneficial effects on general health, in removing excessive corpulence and in promoting the growth of hair, which are observed on administering thyroid to people in middle life, may be due to the actual reinforcement of a function which is being insufficiently discharged. Nor is the thyroid without influence on the healthy

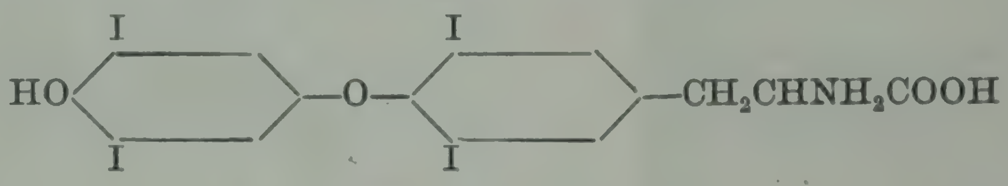
† Fox. *B.M.J.*, 1892 (ii.), 941.

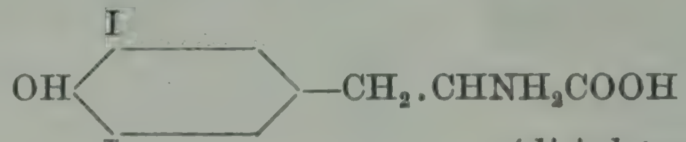
individual. When tadpoles are fed with thyroid substance, the rate of metamorphosis is greatly accelerated.* If given in large doses either to man or to animals, it quickens the pulse, even causing violent palpitation, and increases the metabolic activities of the body,† so that the appetite is increased, the glycogen store of the liver is reduced, the nitrogenous output rises above the intake, and the subcutaneous fat is diminished or disappears.

There are grounds for the belief that the thyroid plays a part in the production of the increased metabolism and rise of temperature in fevers. It may also, by liberating its secretion more rapidly, be concerned in causing the rise of metabolism which results when there is a tendency for the body temperature to be lowered ; under these conditions the blood flow through the thyroid is increased,‡ and the gland shows histological changes.

Thyroxine. The specific material of the colloid, called *thyroglobulin*, contains iodine in organic combination. Kendall, in 1914, isolated an active principle by hydrolysis of the thyroid, and gave it the name *thyroxine.* Harington and Barger § showed this to be the *l*-compound :



and prepared it synthetically. The *d*-isomer has one-sixth the activity of the natural one. About 60 per cent. of the iodine of the thyroid is present in another and simpler compound, *di-iodotyrosine:—*



(*di-iodotyrosine*)

which is physiologically much less active. Traces of mono-iodotyrosine also occur.

From two molecules of the di-iodo compound, by an oxidative reaction in which the side chain of one is removed, a molecule of thyroxine is formed. A similar reaction takes place when a tyrosine-containing protein is iodised, and by treating casein with iodine it has been shown that thyroxine can be obtained in small amounts.‖

The thyroid of an average human adult probably contains about 20 mg. of thyroxine. This substance, when administered, exhibits all the therapeutic properties of the dried gland itself. Thus 1 mg. of thyroxine definitely raises the basal metabolic rate, the maximal effect appearing after a day or two. It therefore increases the sensitivity of animals to oxygen lack. It also relieves the condition of hypothyroidism, and accelerates the metamorphosis of tadpoles. It is believed that the thyroid of the normal individual produces about 1 mg. thyroxine a day.

The thyroxine is manufactured in the thyroid itself, presumably from tyrosine, *viâ* iodotyrosine. It seems probable that the thyroxine is formed, and is stored, as part of a protein molecule, such as thyroglobulin. The gland has a remarkable affinity for inorganic iodine ; usually it stores about 2 to 5 mg. per g. of dry gland. If iodide be injected into the circulation, the greater part of it may be recovered from the thyroid within five minutes. The maximum uptake is about 10 to 20 mg./100 g. tissue.¶

Experimental evidence as to the biosynthesis of thyroxine has been obtained by the use of radioactive iodine (^{131}I). An injection of radioactive iodide is given to an animal, and within a few hours the iodine is found to have been concentrated in the thyroid. At first it is present as iodide : then some of it is found in the di-iodotyrosine fraction : later still, increasing quantities are in the form of thyroxine. Thus, in the sheep, the following amounts were found, as percentages of the total radioactive dose * :—

Time.	As Di-iodotyrosine.	As Thyroxine.
2 hours	2–10 per cent.	0·1–1·0 per cent.
48 ,,	20–30 ,,	2·0–3·5 ,,

A similar demonstration has been effected with slices of surviving thyroid tissue : if the tissue is minced, there is no formation of thyroxine, nor is there if the tissue oxidations are inhibited by the addition of cyanide.† The essential reaction in the biosynthesis is probably an oxidation, whereby iodine is formed from iodide : the iodine converts tyrosine to di-iodotyrosine and this, while still in peptide combination, passes on to thyroxine spontaneously.

It is possible that the power of formation of thyroxine is not absolutely specific to the thyroid, since evidence of its formation in *small* amount has been obtained in the liver and muscle of thyroidectomised rats dosed with radioactive iodine. In the normal animal, however, the activity of the thyroid doubtless far outweighs that of the other tissues, which thus get but slight access to available iodine.

Although thyroxine produces effects so similar to those of the gland itself, the evidence that thyroxine, as such, is eliminated by the thyroid, or circulates in the blood is equivocal. Normal blood, however, does contain small amounts of iodine, about 3 μg. per 100 c.c., and this may be increased from two- to five-fold in exophthalmic goitre. By the intravenous injection of iodine, the iodine content of the blood is temporarily raised, but falls to normal in an hour or two, most rapidly in hyperthyroid subjects and most slowly in the hypothyroid ones.‡ The delay which elapses between the administration of thyroxine, and the production of physiological effects, has often been interpreted to mean that the relatively simple molecule of that substance needs to be built up into some more elaborate molecule before it can be effective. The active material of the thyroid is probably a globulin, of which thyroxine forms one of the constituents, and from which the active ingredient, thyroxine, may be liberated into the blood stream.

Thyroxine produces no effects when added to isolated tissues, although tissues taken from animals previously dosed with the active principles show an increased rate of oxygen usage. Thyroglobulin does cause an increase in the oxygen usage of isolated tissues,§ from which it was inferred that the delay in the action of thyroxine is due to the time needed for its conversion into thyroglobulin.

What causes release into the blood of the active constituent of the thyroid, whatever it may be, is not known. Some are in favour of a nervous influence, *viâ* the cervical sympathetic ‖ ; others regard the release as dependent on the presence in the blood of the thyrotropic pituitary hormone.

Iodine Lack. If iodine be entirely absent from the drinking water and food, the thyroid undergoes enlargement ; this is most clearly seen if the deprivation occurs during ante-natal life by reason of the mother before and during pregnancy having been fed on foods lacking in iodine. The resulting enlarged thyroid of the offspring has the structure of a parenchymatous hyperplastic goitre. The glandular tissue is increased in amount and the colloid reduced or absent (Fig. 643 B). If the lack of iodine is continued after birth the gland undergoes further hyperplasia. Early administration of small amounts of iodine in the form of iodide restores the gland to its normal size and structure, but if given later on in life complete restoration is unlikely, the gland instead undergoing further enlargement and showing on histological examination (Fig. 643, D) large irregular vesicles distended with colloid—the "colloid goitre." * Very large doses, however, may be more effective. Of common foods, fish is richest in iodine. Absence of iodine from the soil and water seems to be the cause of the great prevalence of goitre in certain inland districts, especially in Switzerland and in parts of the United States. It has been shown by Marine and others that this endemic goitre can be practically eliminated from these districts by the occasional administration of minute doses of iodine or iodides to the entire population (as by addition to the water supply or to the table salt).

A. B.

C. D.

FIG. 643. Illustrating the Influence of Iodine Lack on Thyroid Structure. A = thyroid of puppy on diet which included cod-liver oil (containing iodine)—normal structure. B = thyroid of puppy on same diet except that it contained peanut oil (no iodine)—hyperplasia. C = human thyroid; simple colloid goitre. D = simple colloid goitre in dog's thyroid: the dog was iodine-deficient for 10 months, after which KI was given daily for 8 months (15μ g. I. daily.) (E. MELLANBY. "Nutrition and Disease." Oliver and Boyd, 1934.)

Hyperthyroidism. The symptoms caused by excessive doses of thyroid gland are strikingly similar to those occurring in the disease known as *exophthalmic goitre* (Fig. 644), where there is a true hypertrophy of the gland associated with increased basal metabolic rate, a body temperature tending to be above the normal, cardiac palpitation, exophthalmos or proptosis (bulging of the eyes), wasting, great restlessness, occasional glycosuria, and muscular weakness. Requirements of vitamins A, B and C are increased, because of the raised general metabolism. The iodine content of the blood is usually raised, while the thyroid itself contains less iodine than normally. Its structure is of the hyperplastic type, and this is possibly a result of its low iodine content. Administration of iodine causes a transitory return of the structure towards the normal, with some reduction in the symptoms, but these become worse later on, especially if the iodine is discontinued.

---

* E. MELLANBY. Nutrition and Disease. (1934: Oliver and Boyd.)

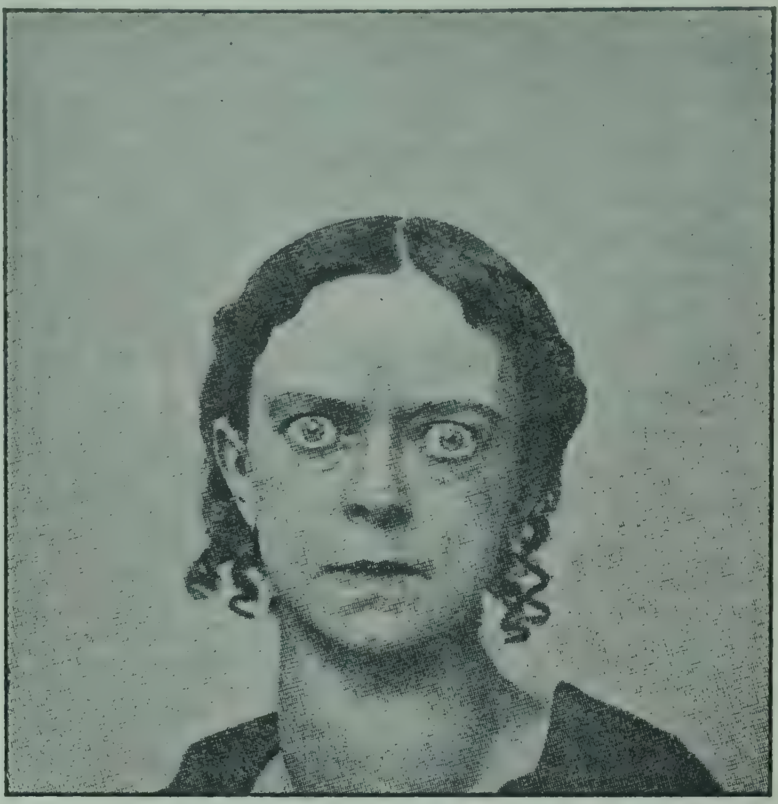

FIG. 644. Exophthalmic Goitre. (After PARSONS.)

In these cases, removal of part of the hypertrophied gland often removes the symptoms and restores the patient to health. In some cases, however, the condition recurs. If the whole gland is removed, it is necessary to administer daily doses of dried gland for the rest of the patient's life, in order to prevent the development of myxœdema.

One view of the condition is that it is due to a failure of the gland to retain the thyroxine which it makes. This is attributed to a hormone present in the anterior lobe of the pituitary body.

Thyrotropic Hormone. As will be shown later, the pituitary anterior lobe is closely related to the activity of the thyroid. Extracts of the anterior pituitary can be prepared which, on injection, cause hypertrophy and hyperactivity of the thyroid, and even exophthalmos. Indeed, exophthalmos is believed to be directly due to the presence of the thyrotropic hormone and not to excess of thyroxine. Injection of such extracts causes increase in basal metabolism, hyperplastic change of structure in the thyroid, and increase of blood iodine.*

Thyroid and Vitamins. The condition of hyperthyroidism, or the administration of thyroid, or of thyroxine, increases the requirement of vitamin B_1, lack of which has been demonstrated in the tissues. This is because the B_1 requirement varies with the calorie output, which thyroxine raises. If adequate amounts of the vitamin are given, the loss of weight accompanying thyroid administration is lessened.† The effects of vitamins A ‡ and C is similar, as regards loss of weight.

Goitrogenic Substances. Administration of certain compounds by mouth leads to enlargement of the thyroid, with histological changes similar to those seen in parenchymatous goitre. Such substances include seeds of *Brassica*, KCNS, thiourea, thiouracil, allylthiourea, *p*-aminobenzoic acid, and sulphaguanidine. Administration of 0·1 per cent. thiouracil in the drinking water of rats, for example, soon produces goitres, and reduces the B.M.R. This substance has been used clinically, with striking results, in the treatment of hyperthyroidism.

† PETERS and ROSSITER. *Bioch. J.*, 1939, **33,** 1140.

‡ LOGARAS and DRUMMOND. *Bioch. J.*, 1938, **32,** 964.

The effect of the thiouracil is to depress the synthesis of thyroxine in the thyroid, probably by opposing the oxidative conversion of iodide to iodine: it does not abolish the effects of a dose of thyroxine: KCNS on the other hand inhibits the uptake of iodine by the thyroid.*

The B.M.R. of rats is also lowered by daily dosage of 1–7-dimethylxanthine (paraxanthine), about 10 μ.g./100 g. body weight. The substance, which is of widespread occurrence, appears to antagonise the effects of thyroxine.†

THE PARATHYROIDS

The parathyroids, discovered by Sandström in 1880,‡ are four oval bodies, which, in man, together weigh about 140 mg., situated, two on each side, on the border of the thyroid gland or actually embedded in its substance. One of each pair is developed from the 3rd, and one from the 4th branchial pouch. In histological appearance, they consist of solid masses of columns of epithelial cells, most of which are pale and hyaline, but a few of which are oxyphil, surrounded with connective tissue and richly supplied with blood sinusoids (Fig. 645). In some animals, *e.g.* in the dog, they are embedded in the thyroid. In others, such as the rabbit, they lie outside the gland, and it is easy to avoid them in the exision of the thyroid. Accessory parathyroid tissue is also frequently found in the thymus and along the aortic arch. To this varying distribution of the parathyroids is due the discrepant early results of extirpation of the thyroid in carnivora and herbivora respectively. The parathyroids have often been inadvertently removed in man, with fatal results, in the operation of thyroidectomy, prior to a knowledge of their importance.

In spite of their close anatomical association with the thyroid, the parathyroids have a function entirely distinct from that gland. Whereas removal of the thyroid produces simply a condition of myxœdema, or retardation of growth in the young animal, removal of the parathyroids is followed by nervous disturbances and *tetany*, which rapidly prove fatal, especially in young animals.§ The motor nerves become inordinately excitable to galvanic currents. In man, tetany consists in a tendency for muscles, especially of the forearms, to undergo painful spasms. There is flexion of the metacarpo-phalangeal joints, the interphalangeal joints being extended, and thumb and little finger are drawn towards the palm. Wrist and elbow may be flexed and forearm slightly pronated. The carpal spasm may be precipitated by pressure on the upper arm with a sphygmomanometer armlet (Trousseau sign). The condition is always found to be accompanied by a diminution of the calcium content and increase of P content of the blood,‖ the former falling from the normal figure of about 10 mg. Ca per 100 c.c. serum to between 4 and 7 mg. The excretion of calcium and of phosphate is reduced. In chronic cases of hypoparathyroidism defects of skin. hair and nails occur, and cataract of the lens is encountered.

§ Gley. *C. R. Soc. Biol.*, 1897, **4**, 18.

‖ MacCallum and Voegtlin. *J. Exp. Med.*, 1909, **11**, 118.

The symptoms are found to be temporarily relieved by administration of calcium lactate, either by the mouth or subcutaneously, and are aggravated by a meat diet. The condition of tetany after parathyroidectomy may be relieved by subcutaneous implantation of a normal gland.

Collip * discovered that, by extraction of fresh parathyroid glands with 5 per cent. hydrochloric acid and then precipitating the proteins by neutralisation, a fluid is obtained which contains the hormone of the parathyroids in a very potent form. One or two injections per day of this extract serves to ward off indefinitely the symptoms of tetany in parathyroidectomised dogs, or to cure such symptoms when they have already supervened, either in dogs or in human beings suffering from tetany due to parathyroid insufficiency. The parathyroids are thus the seat of formation of a hormone which regulates calcium metabolism through a specific control of blood calcium concentration.

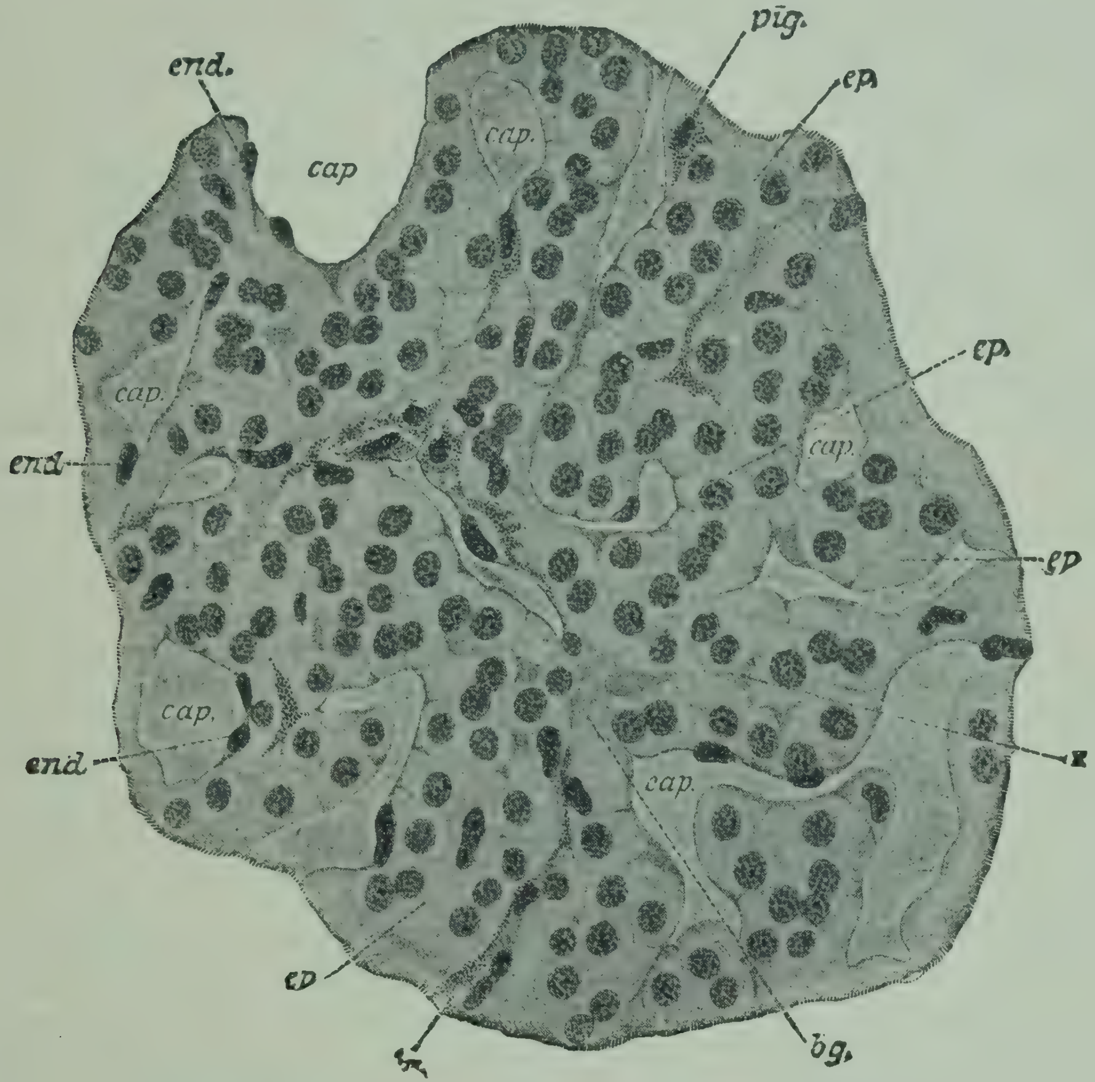

FIG. 645. Section of Parathyroid. (KOHN.)

ep.	Secreting epithelium.	*cap.*	Sinus-like capillaries.
pig.	Cells containing pigment.	*end.*	Endothelial cells.

The active principle is a protein,† and is destroyed by pepsin, so that it is ineffective when given by the mouth.

When the extract is administered to normal dogs there is, after a lag of three to four hours, a steady rise in the calcium content of the serum, which reaches a maximum in five to nine hours, and then returns at the same rate to normal. The blood phosphorus is lowered as the calcium rises, except when large doses are given. Excretion of calcium and phosphorus are increased. When several successive injections are made, there is a summation of effect, and the calcium value of the serum may rise to 15 or 20 milligrammes per 100 c.c. When the figure of 15 is passed, the dog shows definite symptoms of "hypercalcæmia." The animals lose appetite, become weak, there is diarrhœa and vomiting and rise of blood urea, followed by collapse and death. The impairment of the circulation is associated with great loss of plasma, and increase in the viscosity of the blood. Prolonged overdosage may lead to the formation of renal calculi, which consist of calcium phosphate, and to calcifications of various tissues.

Parathyroid extracts ("parathormone") are standardised by administration to dogs and determination of the increase in serum calcium in a given time. The unit is defined as 1/500th of the amount required to produce in a dog of 20 kg. weight an increase of 5 mg./100 c.c. in serum calcium in fifteen hours.* The most potent dry preparations contain about 12 units per mg. In man 100 units per day will raise a low blood calcium by 50 per cent., but when the blood calcium is normal even 500 units may only cause a small rise.

Calcium of Blood and Bone. The action of the parathyroid hormone is closely connected with the complex and largely unsolved problems of calcium metabolism. Of the normal serum content of calcium of about 10 mg./100 c.c., probably less than half is present in the ionizable form, the remainder being in the form of non-diffusible and unionised complexes of uncertain nature. The ratio between these two forms seems to depend on the *pH*, the protein, the phosphate, and probably other things. Thus, if phosphate is added to the blood, either *in vitro* or *in vivo*, there is a conversion of Ca ions into a physiologically inert and colloidal form, as calcium phosphate.† In the body this colloidal calcium phosphate is phagocytosed by macrophages of the liver and spleen, and so removed from circulation.‡ The excitability of the neuro-muscular mechanisms appears to depend chiefly on the content of ionizable calcium present, and the causation of tetany by rise of *pH* (as by overbreathing) may similarly be ascribed to reduction of the ionic calcium of the blood and tissues.

The principal store of calcium is in the bones. The nature of the mineral basis of bone is still a matter for dispute; it contains calcium phosphate and carbonate, or hydroxide, in some close chemical or physico-chemical union, and appears to be of constant composition.§ The relations of $Ca^{\cdot\cdot}$ and PO_4''' ions to calcium metabolism have been discussed briefly on p. 817, and it was there stated that the calcification of bone is probably dependent upon the liberation of phosphate from organic combination owing to the action of the enzyme phosphatase, which is present in the bone. In this and in many other ways the metabolism of calcium and of phosphate are closely related.

Under the influence of calcium lack, or of the action of the parathyroid hormone, calcium is removed from the bones, especially from the trabeculæ of the cancellous bone. The excretion of calcium and of phosphate in the urine is increased. In lead poisoning, lead is deposited with calcium in the bone, and may remain there for long periods if the calcium is not mobilised; if a dose of parathyroid hormone is given, however, the lead is released with the calcium,‖ and excreted. If a period of rest is now given, the calcium is replaced in the bone, and, on giving a second dose of parathyroid, calcium without lead is excreted. It seems that the parathyroid acts by stimulating the formation of new osteoclasts, which exert their solvent action on the calcium salts of the bone. At a later stage of overdosage, however, a reaction may occur, and the animal becomes relatively immune: in this stage osteoblasts are increased and new bone formed rapidly.¶ It has also been thought that the action of vitamin D may be due to a stimulant action on the parathyroid, but the evidence for this is not free from objections. The whole subject is complex, and the reader is referred to the reference articles for a fuller discussion.

Hyper- and Hypo-parathyroidism. Occasionally cases of parathyroid adenomata occur, and show all symptoms of hyper-parathyroidism—high Ca and low P in the serum, increased Ca and P excretion, softening or fibrocystic disease of the bones, and often renal phosphatic calculi. Removal of the tumour, which may weigh several grammes, cures the condition. The converse state of hypoparathyroidism, accompanied by low blood Ca, high P, reduced Ca and P excretion, and signs of tetany, may occur spontaneously, or after surgical operations on the thyroid.

THE PITUITARY BODY (Hypophysis)

In the pituitary body, which weighs about 0·5 g. in man, we have four important structures, the *anterior lobe, posterior lobe, pars intermedia,* and the *pars tuberalis.*** It consists of two main parts, anterior and posterior, which have separate modes of origin. An outgrowth from the buccal cavity in the embryo meets a hollow extension of the anterior cerebral vesicle. The buccal ectoderm gives rise to the anterior lobe and pars intermedia of the pituitary, while the neural epiblast becomes developed into the posterior lobe (Fig. 646). In some animals, the posterior lobe remains hollow and retains its primitive connection with the third ventricle of the brain, but in man it becomes entirely solid.

** Herring. *Q. J. Exp. Physiol.*, 1908, **1**, 121, 161, 261; 1914, **8**, 245, 267.

The anterior lobe in the adult, which comprises pars tuberalis, pars intermedia, and pars distalis, consists of nests of epithelial cells, many of which, the chromophobe cells, are only stained with difficulty, while some (the α-cells) are filled with acidophile and others (the β-cells) with basophile granules. The chromophobe cells are parent cells from which the two types of chromophile cells are formed. In man there are normally about 50 per cent. chromophobe, forty of α- and ten of β-cells.

Striking changes in the histology of the anterior lobe occur under certain conditions. For example, after castration the basophile cells are increased: in pregnancy, cells called pregnancy cells appear; they are finely granular acidophile cells, derived from chromophobe cells; after thyroidectomy there is diminution in the acidophiles and vacuolation of basophiles; in hyperthyroidism the acidophiles increase; œstrone injections lead to increase, and then to degeneration of the basophiles, later the acidophiles are increased.

The anterior lobe is separated from the posterior lobe by a cleft, which is the remains of the original hollow outgrowth from the buccal cavity. The anterior lobe and pars tuberalis are highly vascular, the other parts only poorly supplied with vessels. The epithelial tissue immediately adjoining the cleft probably belongs to the *pars intermedia* and differs from that constituting the anterior lobe. Its cells, which present but few granules, are arranged in islets, separated by an intervening tissue continuous with the main mass of the posterior lobe. Many of the islets are hollow and enclose a colloid material. The amount of colloid material increases in animals which have undergone extirpation of the thyroid gland.

b.	Third ventricle.	*f.*	Epithelial cleft.
c.	Pars tuberalis.	*g.*	Pars intermedia.
d.	Epithelial investment of posterior lobe.	*h.*	Posterior lobe.

The colloid material of the anterior lobe has been traced by Herring into the stalk and is believed to contain active materials which may ultimately find their way into the third ventricle. An interesting vascular arrangement has been described * under the name hypophysio-portal circulation. In this, arterial twigs supply the median eminence of the posterior pituitary, the efferent vessels from which then form wide sinusoids in the pars distalis of the anterior lobe. The anterior lobe appears to have no effector nerves, such few nerve fibres as it has being chiefly related to the blood vessels.† It has been suggested that its activities are controlled by humoral means, perhaps by way of the hypophysio-portal system.

The *posterior lobe* includes the median eminence of the tubular cinereum, the infundibular stem, and the infundibular process. The last-named part is composed of neuroglial tissue and spindle-shaped cells called *pituicytes.*‡ It is also abundantly supplied with nerve fibres, many of which terminate in structures that appear to be sensory receptors, and it has been suggested that these endings may "constitute a 'chemo-receptive' or 'presso-receptive' apparatus devoted to the reception of stimuli which enable the hypothalamic centres to control the metabolic and hormonal functions of the body."[*] The posterior pituitary receives sympathetic post-ganglionic nerve fibres; their cell stations are in the superior cervical ganglion. It is perhaps of importance that there are nervous connections (the supraoptico-hypophyseal, paraventriculo-hypophyseal, and the tubero-hypophyseal tracts, Fig. 656) between the hypothalamus and the pituitary. These are efferent tracts which can be traced to the posterior lobe.

† RASMUSSEN. *Endocrin.*, 1938, **23**, 263.

‡ BUCY. *J. Comp. Neurol.*, 1930, **50**, 505.

The *pars tuberalis* surrounds the infundibular stalk, and spreads out on the base of the brain in the neighbourhood of the tuber cinereum. The interest of the pars tuberalis is due to the fact that it has been found that many of the results attributed to removal of the pituitary body can be obtained by merely injuring the hypothalamic region; these results are polyuria, glycosuria, loss of heat regulation, and early death.[†] An important feature of the results is atrophy of the posterior lobe.

The two lobes, anterior and posterior, certainly have entirely different functions. The *pars intermedia* is closely adherent to the posterior lobe, and its functions have not been entirely dissociated from those of the latter.

THE ANTERIOR LOBE

Extracts of the anterior lobe of the pituitary certainly contain at least six different hormone-like substances, and though it cannot be definitely asserted that these same substances are passed into the blood stream, they are provisionally assumed to be. They are named as shown below :—

Metabolic Hormones	(1)	(*)	Growth and diabetogenic hormone.
	(2)		Thyrotropic hormone.
	(3)	(*)	Adrenocorticotropic hormone (ACTH).
Gonadotropic Hormones	(4)		Follicle-stimulating hormone (FSH).
	(5)	(*)	Interstitial-cell-stimulating hormone (ICSH).
	(6)	(*)	Lactogenic hormone.

All these anterior pituitary hormones are proteins. Those marked * have been separated in the pure crystalline state. (1) and (6) are only slightly soluble in water, the others are freely soluble. The proteins are of two types, (1) (3) and (6) being simple proteins, and (2) (4) and (5) being glyco-proteins, containing mannose and hexoseamine. The proteins show species specificity in some cases.

Since these hormones have the property of stimulating other endocrine organs, it is evident that the anterior pituitary could, by releasing them, exercise profound influences over the whole body, and that the description of the anterior pituitary as the master gland of the endocrine system is correct cannot be doubted.

Effects of Extirpation. The effects of extirpation of the whole pituitary (hypophysectomy) are mainly due to the removal of the anterior lobe. Extirpation of this lobe, by abruptly removing the source of all the anterior pituitary hormones, as would be expected, produces extensive and complex results. In clinical cases of pituitary hypofunction in which different factors may be affected to different extents, and in which, accordingly, the symptoms are very variable, effects identical with those seen on experimental extirpation are not to be anticipated, and in fact are rarely, if ever, encountered. Our fundamental clues have, however, been gleaned from clinical observation, and confirmed and supplemented by properly controlled laboratory experiments on the lower animals.

The pituitary body is not essential to life, but its extirpation is followed by profound changes.[‡] Growth is arrested sooner or later, there is loss o

muscle tone, the reproductive organs fail to mature, or else atrophy, there is atrophy of the thyroid, suprarenal and probably other endocrine organs and profound metabolic changes. There is a high sugar tolerance, a reduction in the hyperglycæmic action of adrenaline, and the post-absorptive blood sugar content is lowered. Protein metabolism in fasting is at first increased and later diminished: there is often abundant deposition of adipose tissue. This latter is, however, stated to be due rather to incidental injury to the hypothalamic region than to the removal of the pituitary itself.

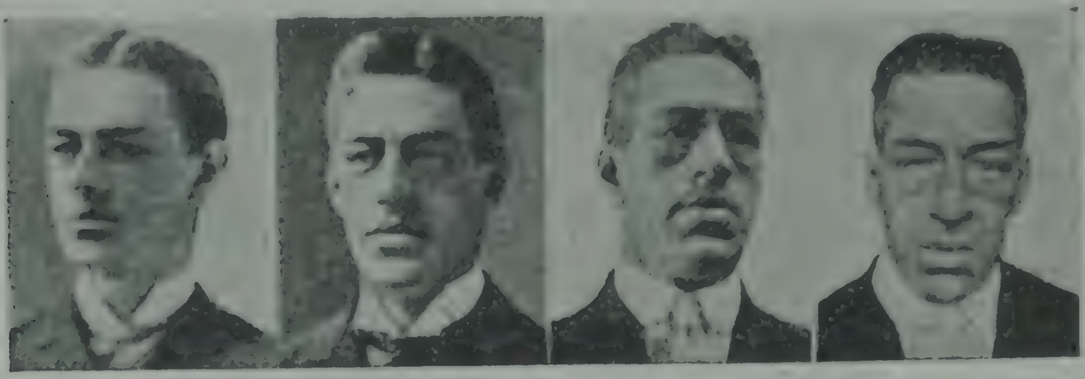

FIG. 649. A Case of Acromegaly. I., aged 24, before onset of the disease. II., aged 29. III., aged 37. IV., aged 42, with pronounced acromegaly. (After CUSHING. "The Pituitary Body and its Disorders." Lippincott, 1912.)

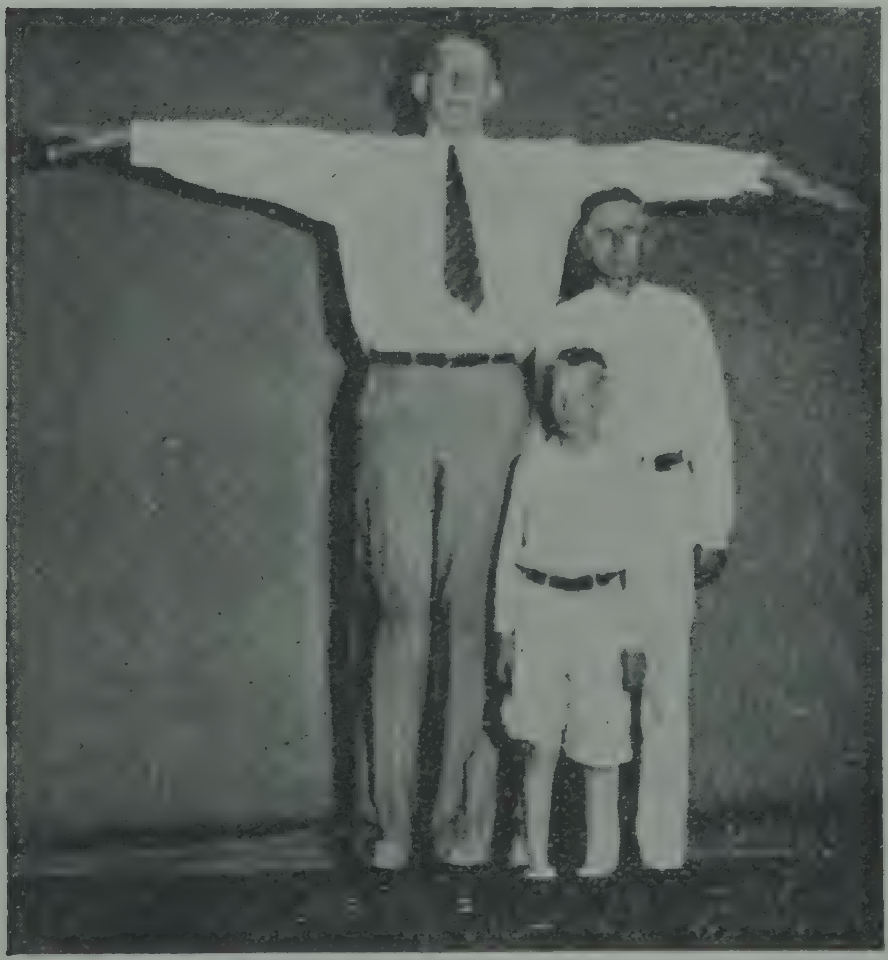

FIG. 650. Giant, aged 13½, beside a 9-year-old Brother, and his Father, who is 5 ft. 11 in. in height. (After BEHIEMS and BARR. *Endocrinology*, 1932, **16**, 125.)

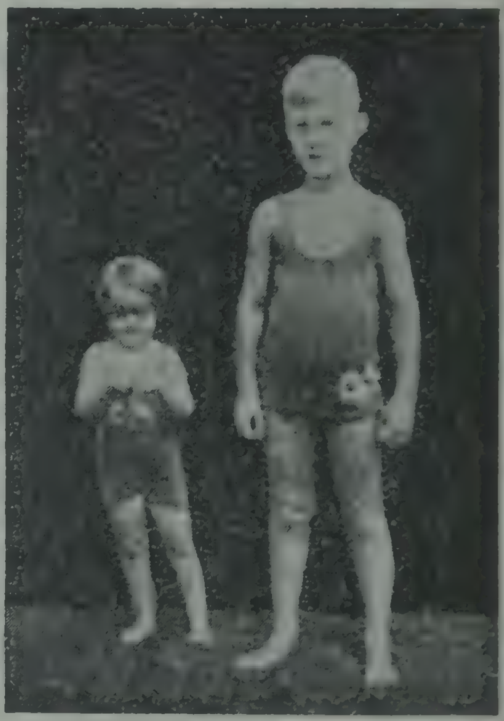

FIG. 651. Female Pituitary Dwarf aged 9½ compared with a Normal Boy of the same age. (After ENGELBACH. *Endocrinology*, 1932, **16**, 11.)

In the human subject, generalised hypofunction of the anterior lobe is found in Simmond's disease (Fig. 647); there is lowered metabolism, cachexia, loss of sexual function and premature senility. In the disease called progeria, which is also probably of pituitary origin (Fig. 648), the senescence is very dramatic. Atrophy of the anterior lobe is found at autopsy.

It is interesting to note that there is a reciprocal influence between the anterior pituitary and the various organs which it can affect. Thus, pregnancy, or extirpation of the gonads, thyroid or suprarenals causes definite histological changes to occur in the anterior lobe of the pituitary body.

(1) The Growth Hormone.* The first clue to the functions of the anterior pituitary body was furnished by the observations of Marie † that the disease called *acromegaly* is associated with pituitary tumour, and it is now known that the tumours consist of the eosinophile cells. In this disease certain parts of the skeleton, particularly of the lower jaw, hands and feet, take on renewed growth in adult life (Fig. 649). Various other symptoms not directly related to the increase in the production of growth hormone are also often present. Thus there may be limitation of the field of vision, leading to blindness; this begins in the temporal fields owing to pressure of the tumour on the optic nerve fibres from the nasal parts of the retinæ. The condition is relieved by surgical removal of the tumour. There is also not infrequently a lowered sugar tolerance or even diabetes.

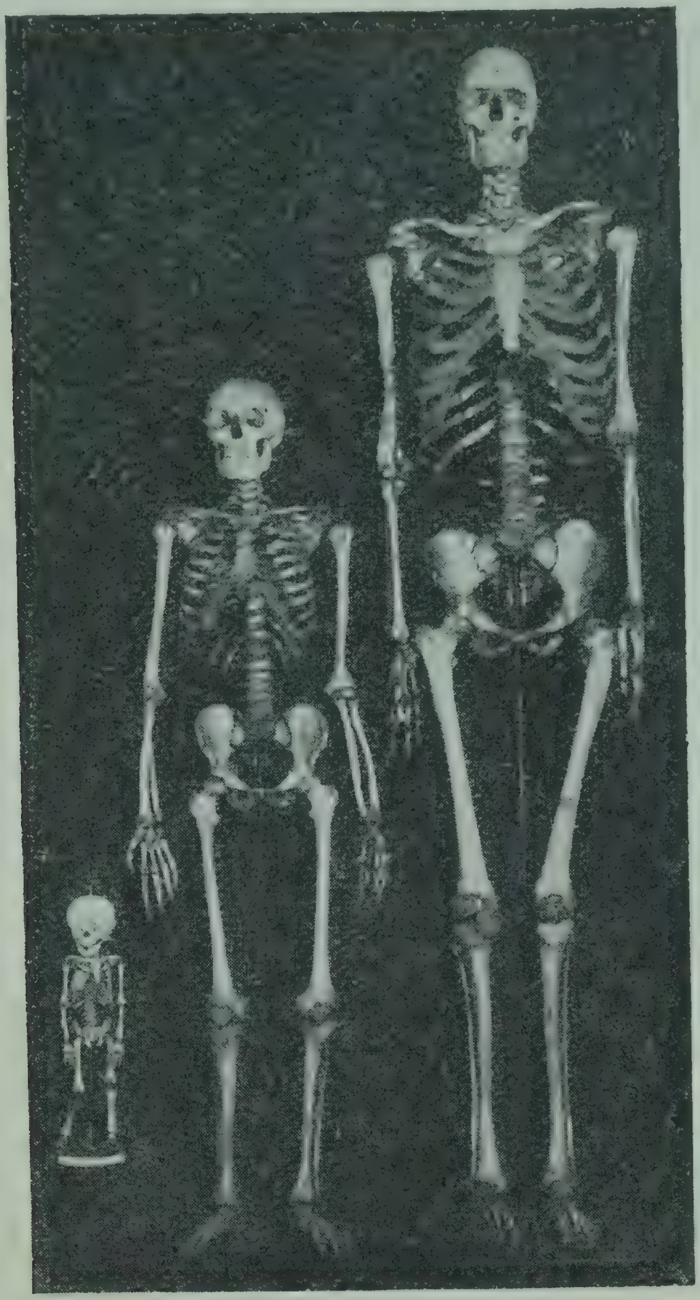

Fig. 652. Skeletons of Dwarf, Normal Man and Giant. *Dwarf*, Caroline Crachami (Cat. No. 4175·1), height 50·3 cm. (19·8 in.), pituitary fossa width 8 mm. *Normal Man* (Cat. No. 33·1), height 169·8 cm. (5 ft. 6·9 in.), pituitary fossa width 15 mm. *Giant*, O'Brien ♂ (Cat. No. 3865·1), height 231·1 cm. (7 ft. 7 in.), pituitary fossa width 22 mm. (By courtesy of Dr. H. J. Beattie, Royal College of Surgeons of England.)

Gigantism and Dwarfism. When the disease occurs during the period of active growth, the limbs and trunk bones also grow to an abnormal size resulting in a condition of "*gigantism*" (Figs. 650, 652). In such giants, X-ray examination usually shows the presence of an abnormally large pituitary fossa, and there seems little doubt that this condition is due to an over-action by which the growth hormone is produced at an abnormally high rate.

Reduced activity of the eosinophile cells is associated with the converse condition of "*dwarfism*" (Figs. 651, 652), though the condition is usually complicated by the results of deficiency in other pituitary hormones besides the growth factor. In the form known as the *Lorain-Levy* type there is a state of sexual infantilism; the dwarfs are of childish stature and proportions, though of normal intelligence; in girls, menstruation is delayed or absent. Dwarfism of the Lorain-Levy type is said to be associated with chromophobe adenomata, the depression of the hormone production being then ascribed to the pressure which results.

* H. M. Evans. *J. Amer. Med. Assoc.*, 1935, **104**, 1232.

† Marie. *Rev. Med.*, 1886, 298; *Brain*, **12**, 59.

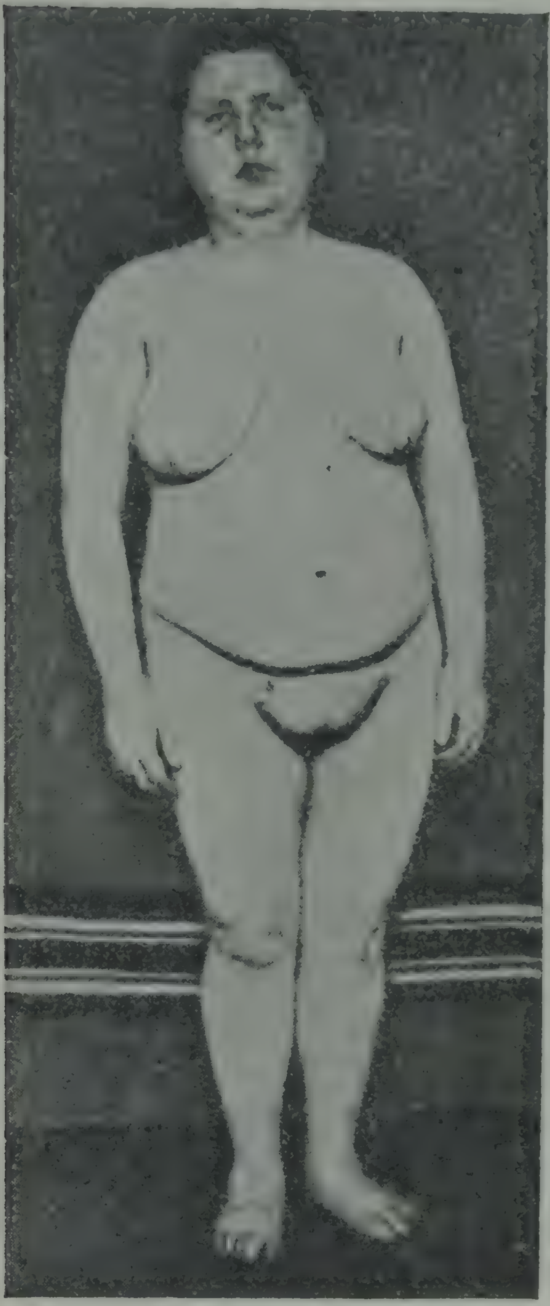

Fig. 653. Fröhlich's Syndrome. (From Deusch. *Deutsch. Zts. f. Nervenheilkunde*, 1925, **86–87**, 117.)

In the *Fröhlich-syndrome* (Fig. 653) there is adiposity and great apathy, in addition to infantilism, and sexual development is conspicuously delayed in males. When the condition arises in adult life, the conspicuous features are fatness and loss of sex functions. It is usually due to a congenital tumour of the hypophyseal duct and is of complex symptomatology.

Dwarfism may also be produced experimentally in animals by removal of the anterior lobe of the pituitary body when young. These hypophysectomised animals, of course, also show results of deprivation of other pituitary hormones, just as do some of the human cases of pituitary hypofunction. Thus some are sexually infantile (lack of gonadotropic hormone), and these retain infantile appearance and proportions. Others, in which only growth is in abeyance, have normal adult proportions. The administration of growth hormone extracts to human dwarf children has resulted in resumption of growth.*

Experimental gigantism (*e.g.* rats 50 per cent. above the normal size, and of twice the normal weight) has been produced in animals by the injection of partially purified growth hormone, prepared from extracts of the anterior lobe † (Fig. 654). The hormone can be separated in pure crystalline form.‡ Skeletal growth, checked by hypophysectomy, is restarted by the hormone, and is especially noticeable in the epiphyseal cartilages. Feeding of amphibian larvæ with fresh anterior pituitary results in accelerated metamorphosis. The growth hormone also has an effect on protein metabolism, which consists of an increased laying down of protein in muscles and a diminution of protein breakdown. Appetite is improved, but even when the food given is not increased, growth is still accelerated. Muscular tone and power are augmented by the hormone. The growth hormone may be inactivated in pituitary extracts by adding small amounts of tricresol.

It now seems certain that the growth hormone is identical with the *diabetogenic hormone* mentioned on p. 971. It has been observed that glucosuria, or even diabetes, may be associated with acromegaly, while in the Fröhlich syndrome there is increased carbohydrate tolerance; it has been shown that hyperglycæmia and glycosuria may be produced after an interval of some days by the injection of extracts of the anterior lobe. When the pituitary is extirpated, on the other hand, the animals become very sensitive to insulin and even tend to develop hypoglycæmic symptoms if not liberally fed.

† H. M. Evans and Simpson. *Amer. J. Physiol.*, 1931, **98**, 511; Bülbring. *Q. J. Pharm., Pharmacol.*, 1938, **11**, 26.

‡ Li *et al.* *J. Biol. Chem.*, 1945, **159**, 353.

Whether the hormone administration results in growth or in diabetes is robably dependent upon the age of the animal and on the extent to which the slet tissue can respond by producing more insulin : if it can, then growth occurs, f not, diabetes ; in young individuals the former effect is the more likely.*

It seems certain that some cases of spontaneous hypoglycæmia are due to hypofunction of the anterior pituitary,† and on the other hand, it is possible that certain clinical cases of diabetes may be due to hypertrophy of the anterior lobe ; the mode of action of the principle is uncertain (*v.* p. 974).

Although distinct from the thyrotropic hormone, the growth hormone is potentiated by the latter ; both lower the blood amino-acids, while thyrotropin lowers blood urea. The growth hormone reduces the activity of liver arginase, but the relation of this to the diminished protein metabolism is uncertain, because hypophysectomy also reduces liver arginase. Probably *in vivo* there is collaboration between growth, thyrotropic and adrenocorticotropic hormones in stimulation of growth. As explained above, the presence of an adequate supply of insulin is essential, as otherwise the growth hormone has a diabetogenic action.

(2) **Thyrotropic Hormone.**‡ Extirpation of the pituitary body leads to an involution of the thyroid, accompanied by reduction in the height of its epithelial cells, reduction of about 30 per cent. in the basal metabolic rate, and a reduced nitrogen excretion. The result is due to the removal of a hormone, the thyrotropic hormone, which exerts a stimulating effect on the thyroid. This effect probably consists in part in the facilitation of the release of thyroxine from the thyroid into the blood, since after hypophysectomy the thyroid, though smaller, contains more thyroxine than normal. Conversely, thyroidectomy results in enlargement of the pituitary body. It has been suggested that myxœdema and cretinism may be primarily due to pituitary hypofunction, the thyroid being affected secondarily. The hormone can be prepared reasonably free from active impurities,§ and when injected leads in a few days to an increase up to + 35 p.c. in basal metabolic rate, accompanied by evidence of increased formation of thyroxine and by thyroid hyperplasia‖ with increased height of its epithelial cells ; it also produces exophthalmos.¶ Assay of the hormone is made by estimating the effect of five daily doses on the weights of the thyroids of immature female guinea-pigs (200 g.) ; the weight increases from 30 mg. to anything up to 100 mg., according to the dose.** The maximal effect on metabolism is reached after one or two weeks of daily injections, and thereafter dies down, and returns to the normal, or even falls below it. The reduction appears to be due to the presence, in the serum of the injected animals, of an anti-body, due to the antigenic action of the protein, usually from a different species, of which the hormone consists, or with which it is associated.

The hormone produces no effects on thyroidectomised animals. Thyrotropic hormone is excreted in the urine, and may be recognised there after thyroidectomy; this may be due to increased production or to failure of fixation by the thyroid.

(3) **Adrenocorticotropic Hormones.**[*] After hypophysectomy there is considerable atrophy of the inner layers of the suprarenal cortex, which can be reversed by injection of anterior pituitary extracts, and which has its counterpart in the clinic in the small suprarenals seen in pituitary dwarfism. The loss of muscle tone following hypophysectomy is probably due to adrenal cortical atrophy, since it is restored by administrations of cortex extracts. A reciprocal connection is also indicated by the fact that after adrenalectomy and in Addison's disease, there is a reduction in the number of basophile cells in the anterior pituitary.

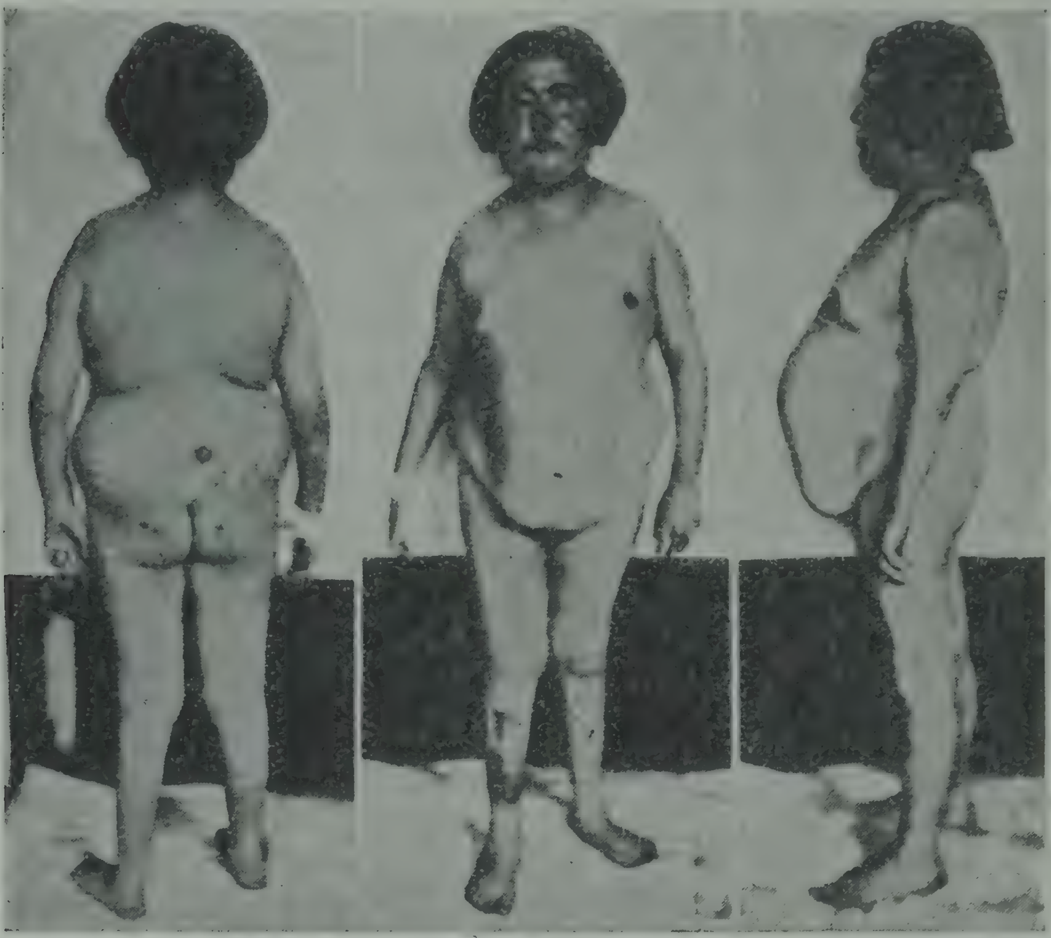

FIG. 655. Case of pituitary basophilism. Note the dark-coloured face and adiposity. (From CUSHING, *Bull. Johns Hopk. Hosp.*, 1931, **49–50,** 137.)

A pure protein, free from other pituitary hormones, has been prepared.[†] The extracts improve the resistance of rats to exposure to cold, but this effect is not obtained if the rats are previously adrenalectomised. Hypertrophy of the suprarenal cortex can be obtained by the injection of such extracts, and cortical hyperplasia is not infrequently seen in acromegaly. Cushing showed that in certain cortical adrenal tumours, associated with painful adiposity and reproductive disturbances, with hirsuties in females, there is frequently a basophile adenoma of the pituitary [‡] (Fig. 655).

Since it has been shown that the suprarenal cortex has important effects on the metabolism of carbohydrate, fat and protein, caution must always be exercised in concluding that metabolic effects of pituitary extracts are directly attributable to the action of pituitary metabolic hormones (*see* below) and not to indirect effects of the adrenocorticotropic hormone. An effect on protein metabolism is probably of this nature. Hypophysectomy lowers liver arginase, while corticosterone increases it in normal, hypophysectomised or adrenalectomised rats; the adrenocorticotropic hormone also increases liver arginase.[§]

(4) and (5) **The Gonadotropic Hormones.** It was discovered by Smith and Engle, and by Zondek and Aschheim in 1927, that the subcutaneous mplantation of fresh anterior pituitary gland into young animals led to precocious sexual development, as a result of which the gonads not only matured early, but also, in consequence of their maturation, produced other hormones having important effects on the secondary sex characters and on the sex cycle. These hormones will be referred to in more detail in Chapter LII.

(6) **The Lactogenic Hormone.**[*] Various other factors, to be dealt with later (Ch. LIII), are responsible for the initial growth and development of the mammary glands during pregnancy, but these effects do not culminate in secretion of milk. Once the growth of the glands has reached a suitable stage, however, secretion can be initiated and maintained by a hormone formed in the anterior pituitary. The name "*prolactin*" has been given to this hormone, which can be separated from the other pituitary constituents, and shown to be independent of them. Pure prolactin is a crystalline protein,[†] rich in sulphur, and of potency of 30 I.U. per mg.[‡]

It is assayed by its effect in causing a growth in the crop-gland of pigeons. The international unit of prolactin has been defined as the specific activity contained in 0·1 mg. of a standard preparation.

FAT METABOLISM. The presence of a hormone affecting fat metabolism was first indicated by the work of Burn and Ling,[§] who injected NaOH extracts of anterior pituitary into rats fed on butter. The injections caused considerable increase in the excretion of acetone bodies. It has since been shown that there is also an increase in the ketone bodies, particularly the β-hydroxybutyric acid, of the blood. The name "*ketogenic hormone*" has accordingly been given to the responsible principle. One of its effects seems to be an increase in glycogen storage in the liver; another is the production of fatty livers in fasting guinea-pigs—an effect which lipocaic can prevent.[||] It acts on thyroidectomised animals and appears to be distinct from the other pituitary hormones. It may be identical with a factor causing increased metabolic rate and fall of R. Q.[¶] It is probable that the close resemblance to clinical diabetes which results from dosage with the anterior pituitary is usually due to the combined actions of the carbohydrate and ketogenic hormones.

THE POSTERIOR LOBE OR NEUROHYPOPHYSIS

Extracts made from the neural lobe and neural stalk of the pituitary cause a rise of blood pressure when injected intravenously,[**] and this observation formed the starting point for investigations of the active principles of the posterior lobe, with its attached parts.[††]

The physiological effects which can be produced by injection of pituitary "posterior lobe" extracts ("pituitrin") containing all the hormones (and also histamine as an impurity) are as follows:

(1) Rise of arterial blood pressure (*pressor* action) with cardiac slowing, when large doses are injected intravenously into the anæsthetised animal. A second dose soon after the first produces a fall of pressure. Most arterioles are constricted. Injected subcutaneously (0·5 c.c.) in man, there is no rise of blood pressure, but intense pallor due to cutaneous vaso-constriction. The cardiac output may be diminished and the coronary vessels are constricted. According to Krogh, a certain content of pituitrin in the circulating blood is essential for the maintenance of the normal tone of the capillaries in the frog.

[††] GEILING. *J. Amer. Med. Assoc.*, 1935, **104**, 738.

(2) Contraction of plain muscle generally. Administration of pituitar extract to a lactating animal leads to sudden expulsion of milk, due to contraction of the plain muscle in the walls of the milk sinuses. There is als contraction of the plain muscle of the alimentary canal. The production o contraction of plain muscle of the uterus is called the *oxytocic* action.

(3) Expansion of the melanophores (pigment cells) of the frog's skin (Hogber and Winton), so that the skin looks darker in colour. (Especially by extract of the pars intermedia.)

(4) *Diuretic Effect.* When urine of high osmotic pressure is being secreted injection of pituitary extracts often causes diuresis, with increased excretion o Cl' and reduced excretion of PO_4'''. Also, in anæsthetised animals, a brie diuresis follows the injection of large doses : this is due to the rise of bloo pressure.

(5) *Anti-Diuretic Effect.* When urine of low osmotic pressure is being produced, pituitary injections have the opposite effect on water excretion though Cl' excretion is increased. Thus, if injected into a normal man wh has received a large draught of water (1 l.) pituitrin delays for four or five hour the excretion of the water by the kidneys, so that it accumulates for a tim in the plasma and in the tissue fluid in equilibrium with it. Ultimately a pathological condition, water poisoning, may develop owing to excessive retention of water. The effect appears to be due to an acceleration of water reabsorption in the kidney tubules. It also increases the excretion of certain ions, *e.g.* Cl, as has been shown with the heart-lung-kidney preparation (p. 1013) The principle causing this water retention is much more abundant in mammalian than in other pituitaries * and is absent from the pars intermedia. The condition of diabetes insipidus, however brought about, may be relieved temporarily b the subcutaneous injection of a watery extract of the posterior lobe.

(6) Hyperglycæmia, glycosuria, lowered sugar tolerance, loss of liver glycogen, and an action antagonising that of subcutaneously injected insulin.

There is also a rise in the fat of the liver, and a decrease in basal metaboli rate. To what extent these effects are due to a specific hormone or to hormones from the anterior lobe is uncertain.

The best known actions are the pressor effect, the anti-diuretic effect, and the "oxytocic" action on uterine muscle. For all these purposes pituitrin in subcutaneous injection, is employed clinically.

It had long been disputed whether these actions are to be attributed to a single active principle, or whether more than one such hormone is concerned as was claimed by Dudley. Kamm and others † seemed to have settled the discussion in favour of the latter, and the separated oxytocic and presso principles ("*pitocin*" and "*pitressin*") can now be obtained on the market. The cardiovascular and anti-diuretic effects, and the contraction of most of the plain muscle of the body are due to the pitressin fraction. The contraction of the uterus and the diuretic effect ‡ are specific effects of the oxytocin, but the human uterus is not always equally sensitive to its action ; in the early stages of pregnancy it is ineffective, but as pregnancy advances the sensitiveness increases and reaches a maximum at parturition ; after delivery the uterus is again insensitive for some time. More recently, the idea of a single polyvalent active substance, which is a protein, has been revived.§ The smaller molecules of pitocin and pitressin which are separable from extracts are, on this view, split off by decomposition of the protein molecule.

The melanophore-expanding principle is a separate substance, derived from the pars intermedia.

The unit of pressor activity is that of 0·1 c.c. of a standard pituitary

(posterior lobe B.P.) extract. Milliunits are commonly employed in standardising, the tests being made on spinal cats.

The international unit of oxytocin is the activity of 0·5 mg. of standard dried posterior lobe, as tested on an excised guinea-pig's uterus under standard conditions.* The oxytocic principle has been concentrated by adsorption methods † and an activity of 225 units per milligramme reached; this gives a powerful contraction of the uterus in a concentration of 1 in 550 millions.

Functions of the Posterior Lobe. There now seems to be little doubt that the posterior lobe has as its main function the control of the water balance of the body, by regulation of the secretion of urine. This may be effected by an appropriate interplay between the anti-diuretic properties of the pitressin fraction and the diuretic effects of the oxytocin fraction. If so, we have yet to learn how these antagonising factors are severally released. As a subsidiary function, it is regarded also as playing some part in the conduct of parturition. The pressor action is probably incidental, and is only seen when relatively large amounts of the pitressin fraction are injected.

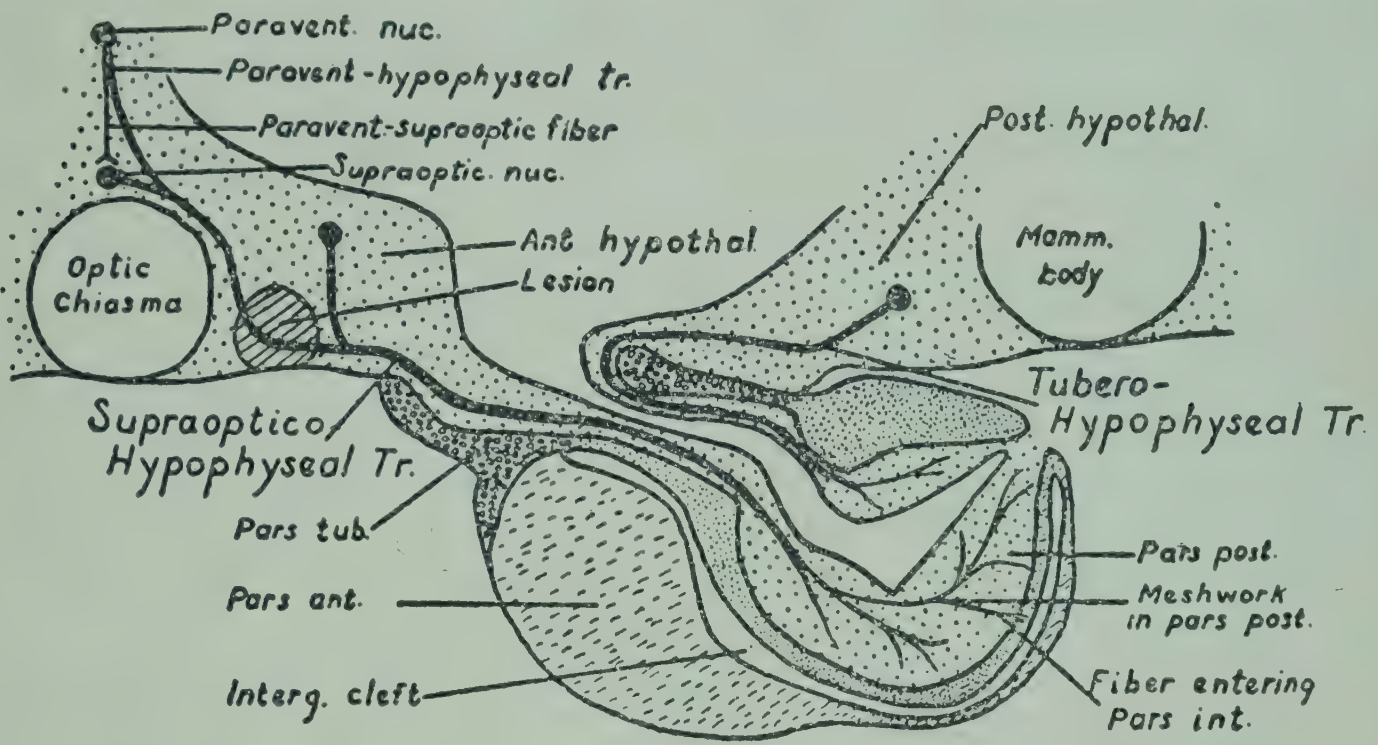

FIG. 656. Diagram of Medial Saggital Section of Hypothalamic Region of Cat showing Nervous Connections of Posterior Lobe of Pituitary Body. Bilateral Damage to the shaded area marked "lesion" causes Diabetes Insipidus. (RANSON, Harvey Lecture, 1936–37.)

DIABETES INSIPIDUS. In some disorders of the pituitary body or hypothalamus, diabetes insipidus occurs. This is a state in which large volumes, 10 to 30 l. daily, of dilute urine are passed; the urine shows no other abnormality than an excess of water; the large water output causes intense thirst and necessitates the drinking of large volumes of water. Injection of pituitary extract causes a large reduction in the urine flow, accompanied by a fall in glomerular filtration rate and in renal blood flow (*v.* p. 1014), and an increased glomerular filtration fraction.‡ In experimental animals, diabetes insipidus can be produced in one of two ways, viz. by extirpation of the pars nervosa, or by bilateral section of the supraopticohypophyseal tract (Fig. 656).

When the tract is divided, polyuria occurs at once, lasts for about five days, and returns to stay permanently from about the twelfth day. It is then found that the supraoptic nuclei have degenerated and the pars nervosa has atrophied, and contains no pituicytes, and little or no diuretic or other active principle. This suggests that the posterior lobe is dependent for its function, and indeed for its existence, on the innervation which it receives by this tract.

---

* BURN. Methods of Biological Assay, 1928. (Oxford: Med. Publ.)

† GULLAND and NEWTON. *Bioch. J.*, 1932, **26**, 337.

‡ WINER. *Arch. Int. Med.*, 1942, **70**, 61.

When the posterior lobe, *i.e.* the pars nervosa, together with the median eminence and infundibular stem is extirpated, diabetes insipidus also follows, provided that no other damage is done, and that the extirpation is complete. But *complete hypophysectomy does not produce this result*, though if an animal is completely hypophysectomised and then has anterior lobe tissue grafted under the skin, the polyuria occurs and lasts as long as the graft survives. It is therefore evident that in order to produce the state of diabetes insipidus the presence of the anterior lobe is as important as the total absence of functional pars nervosa, and it is immaterial whether the latter is made ineffective by actual removal, or by withdrawal of its nerve supply followed by atrophy. The condition is temporarily cured by the injection of small doses of pitressin.

The suppression of the diuresis by removal of the anterior lobe has its counterpart in the fact that the injection of anterior lobe extracts into normal animals often causes polyuria. This is possibly due to the general effects on metabolism, and on other endocrine organs, among which the suprarenal and thyroid must be counted.

Thyroid extracts also exert a diuretic action, and after thyroidectomy the urine formation is reduced.

WATER REGULATION. When a large volume of water is drunk there is a lag in time between the occurrence of dilution of the blood and the onset of diuresis, and it has been supposed by Verney that this is due to the time taken for the anti-diuretic principle, present to begin with in the blood, to be appropriately diminished. For there is evidence that when the water of the body is reduced, there is a secretion of anti-diuretic substance into the blood; because such substances can be recovered from the urine of thirsting animals, except when they have been previously hypophysectomised,* or when their supraopticohypophyseal tracts have been severed.†

The hormones of the pituitary posterior lobe are probably set free in response to a raised osmotic pressure of the plasma (p. 1014), but there are results which suggest that it may also be reflex. When the central end of the divided vagus nerve was stimulated, in the isolated perfused dog's head, an anti-diuretic principle could be demonstrated in the venous blood : pressor and oxytocic substance were also set free into the blood by afferent vagus stimulation. None of these substances was found in the blood from a hypophysectomised head under similar conditions.‡ The afferent arc of this reflex was traced to the supraoptic region, and the efferent arc is no doubt the supraopticohypophyseal tract.§ As a result of afferent vagal stimulation the pituicytes are found to undergo histological changes, such as a loss of granules, so that these cells may probably be regarded as the ones which secrete the hormones of the posterior lobe.||

FUNCTION IN PARTURITION. As will be shown in a later chapter, the oxytocin of the posterior lobe may play a part in determining the onset of parturition. This is thought to be due to the fact that the uterus towards the end of pregnancy becomes increasingly sensitive to the contracting effect of oxytocin, and also possibly to the fact that at the onset of labour, there is an increased liberation of oxytocin into the blood stream. There is good evidence that after hypophysectomy delivery may be difficult.

THE THYMUS

The Thymus in man grows rapidly up to the second year of life and then less rapidly; involution begins at about the fifteenth year and in later adult life only traces remain. The involution is delayed by castration and hastened by sexual activity, malnutrition and pregnancy. In certain cases of arrested development, or of general weakness in young people, the thymus has been found to be persistent. The Hassal's corpuscles, found in the medullary part, have not had any function assigned to them. Removal of the thymus appears to have no constant effect. The injection of extracts, administration by the mouth, or grafting of thymus tissue have in most instances given no regular and outstanding results.

It has been suggested that the thymus produces a hormone the effect of which is to depress neuromuscular conduction, and thymic tumours are, in fact, found in some cases of myasthenia gravis,* the underlying cause of which is a loss of neuromuscular conduction.

DOROTHY H. ANDERSEN (1932). The Relationship between the Thymus and Reproduction. *Physiol. Rev.*, **12**, 1.

OTHER ENDOCRINE ORGANS

The internal secretions of the *pancreas* and of the *gonads* are dealt with elsewhere (Chapters XLVI and LII).

The *Pineal Gland* has so far not been proved to have any endocrine function.

CORRELATION OF ENDOCRINE ACTIONS

The functions of the individual organs of the body are integrated in two ways—by the action of the nervous system and by the action of hormones, and in the conservation of the constancy of the internal environment (homoiostasis) in its many different aspects, sometimes one and sometimes both means of correlation are brought into play. For example, the sugar content of the blood is kept approximately constant as a result of the action of hormones, such as insulin, adrenaline, the hormones of the suprarenal cortex, anterior pituitary and thyroid, and of the central nervous system acting through its effects on the liver, suprarenal medulla and pancreatic islets. It seems almost self-evident, in such a case, that each of these factors must not only be able to influence the blood sugar level, but must also in its turn be influenced by it, and /or by all the other factors that play a part: if this were not so, we should have not correlation, but metabolic chaos.

The rate at which insulin is secreted by the pancreas is not affected by altering the total amount of pancreas within reasonable limits, *e.g.* by partial excision or by the in-grafting of as many as three extra glands, but only by the amount of sugar in the blood which reaches it.

The most remarkable examples of the inter-connections between endocrine organs are found in those instances in which the anterior pituitary plays a part, and of which we have already met with some examples. For instance, the anterior pituitary produces thyrotropic hormone, which controls the growth and activity of the thyroid, while the thyroid hormone also exercises an influence on the size and activity of the anterior pituitary. But the interaction does not stop at a mutual one between two endocrine functions, but may echo widely throughout the whole endocrine system. Thus, thyroidectomy leads to enlargement, with hypofunction, of the anterior pituitary: this results in deficient formation of gonadotropic hormones and so to depression of sexual functions, atrophy of sex organs, loss of secondary sex characters, and so on. It is also probable that the anterior pituitary is subject to indirect nervous influence by means of which further correlations of function are effected.

---

* MCEACHERN. *Medicine,* 1943, **22**, 1.; SCHWEITZER. *Exp. Med. Surg.*, 1947, **5**, 168.

A little reflection will show that the permutations and combinations of actions between the different hormones must have almost limitless possibilities, and it has in fact, as well as in fancy, been possible to postulate more than one endocrine "House that Jack Built."

Various types of functional association between the endocrine organs have been found, *e.g.* :—

(1) An organ, *e.g.* the anterior pituitary, may produce a hormone which has the effect of maintaining or stimulating another endocrine organ, *e.g.* the gonads.

(2) The hormone of one organ, *e.g.* the gonads, may moderate and reduce the activity of another, *e.g.* of the gonadotropic function of the anterior pituitary.

(3) Some hormones sensitise tissues to the action of other hormones, *e.g.* thyroxine sensitises to the action of adrenaline.

(4) Two hormones, *e.g.* that of the ovary and that of the corpus luteum, may sometimes work to reinforce each other, and in other ways may be antagonistic.

In order to establish an effect of one endocrine organ, A, on another one, B, it should be shown that (1), extirpation of B produces at least as great a hypofunction as extirpation of A, and (2) the effects of extirpation of B cannot be counteracted by implantation or injection of A.

It should be noted that although hyperfunction is seen under pathological conditions in which adenomata of the endocrine glands are formed, it is not possible to produce such results of hormone excess by the grafting of additional endocrine tissue into a normal animal. This is because a hormone usually exerts a controlling action on the growth or activity of the gland which produces it. Thus, by giving large doses of thyroid, a state of hypofunction of the thyroid, with eventual atrophy of the gland may be produced. It is for similar reasons that a graft of an endocrine organ does not take well if by doing so the animal would then be provided with an excess of it, but takes best when the organ in question is deficient in amount of activity, or has been previously excised. In other words, an endocrine organ will not grow where it is not needed. When a graft is made into a normal animal it does not lead, even immediately, to liberation of excess of the hormone; thus if the thyroid and parathyroids are grafted in by blood-vessel suture into a parathyroidectomised dog, the blood calcium rises to normal in a few hours, and stays there; but if the graft is made into a normal dog there is no alteration in the blood calcium. This means that, as in other known instances, it is the level of a particular constituent in the blood which regulates the action of the endocrine organs in releasing their secretions.

Among the more important of the functional associations between endocrine organs the following may be mentioned :—

ANTERIOR PITUITARY AND GONADS. The anterior pituitary, by its gonadotropic hormone, maintains the structure and functions of the gonads, as will be explained in a later chapter, and as a result of the normal functioning of the gonads the sexual organs and secondary sex characters are also maintained in normal condition. Reciprocally, the gonads, by their hormones, restrain the activity of the gonadotropic functions of the pituitary.

Caution is needed, however, in the interpretation of some of these results. What has actually been shown is that, say, after administration of the gonad hormones, such as the œstrogens, the substance of the anterior pituitary will be found, when implanted into an immature animal, to be less potent than it usually is in provoking precocious sexual activity. This has, as stated, been interpreted as indicating that when the gonads are actively producing their hormones, these react on the anterior pituitary in such a way as to check the production of more of the gonadotropic hormone there. But histological studies of the pituitary suggest that it is, in fact, secreting *more* actively and that the absence of the gonadotropic hormone may be due, not to slackening of secretion, but to exhaustion of the secretory reserves.

A similar criticism applies to many of the statements regarding inter-relations between endocrine organs.

ANTERIOR PITUITARY AND THYROID. By its thyrotropic hormone the anterior pituitary controls the growth and activity of the thyroid, and the thyroid, reciprocally, restrains the rate of formation of the pituitary thyrotropic hormone. After thyroidectomy the anterior pituitary hypertrophies, the basophiles increasing, and the gonadotropic, thyrotropic and lactogenic hormones diminishing.

ANTERIOR PITUITARY AND SUPRARENAL. The effect of the adrenocorticotropic pituitary hormone has already been discussed. A reverse action of the suprarenal on the pituitary is doubtful, though in Addison's disease there is a diminution in the basophiles.

ANTERIOR PITUITARY AND PARATHYROID. There is some doubt of the existence of relationship between these two glands.

ANTERIOR PITUITARY AND PANCREATIC ISLETS. We have mentioned the probable relationship between the growth hormone and the islet tissue, but it is not known what *rôle* this plays in normal life and growth.

THYROID AND GONADS. Although there is no doubt that alterations in thyroid activity affect the gonads and all that depends on them, it is not quite clear to what extent the relationship is an indirect one in which the anterior pituitary is concerned. Generally speaking, thyroidectomy causes hypofunction of the gonads (but also of the anterior pituitary), a condition which is rectified by the administration of thyroid. In normal animals small doses of thyroid stimulate the gonads to increased functional activity, but large doses depress sex functions. Castration causes in some species a state of hypofunction of the thyroid, while the ovarian follicular hormone may cause hyperthyroid activity.

SUPRARENAL AND GONADS. The important effect of the suprarenal on the sex functions has already been mentioned, and is not surprising in view of the fact that cortical hormones include some of the sex hormones, and in all cases are chemically closely related to them. Tumours of the cortex, with overaction of the cortical layers produce the remarkable cases of virilism with hirsutism in women ; surgical removal causes a complete cure. In some cases the anterior pituitary is perhaps the prime offender, as in pituitary basophilism, in which, as a secondary effect, the suprarenal cortex is involved.

Nervous Control of Endocrine Organs. The endocrine organs exert their effects on other organs, including other endocrine organs, through the blood stream, and for the most part are not under the close control of the central nervous system. The ideas of hormonal and nervous control are, however, closer to one another now than in the past, for, as we have seen, the transference of nervous action is probably effected by the agency of chemical transmitters, and this may be viewed as a kind of local endocrine activity.

The suprarenal medulla is certainly under the control of the nervous system, and is reflexly excited to activity by a variety of afferent stimuli, the efferent path being by way of twigs from the splanchnic nerves. Likewise the neurohypophysis can be stimulated electrically, either directly, or *viâ* the nucleus supraopticus, to produce antidiuretic and oxytocic hormones.* The reflex discharge of antidiuretic and oxytocic substances into the blood by vagus stimulation, already mentioned, is similar proof that the posterior pituitary is under the control of the nervous system.

---

* HARRIS. *Phil. Trans.*, 1947, **232B,** 385 ; *J. Physiol.*, 1948, **107,** 412, 430.

The islet tissue of the pancreas is another instance of nervous control, for although the secretion of insulin is mainly controlled by the blood sugar level, acting directly on the islets, there is probably a second line of action, perhaps reserved for emergencies, in which the vagi act as secretory nerves to the islet tissue.

Other instances are less definite, but in some respects the anterior pituitary provides an example. In some mammals, such as the rabbit, the maturation and discharge of ova does not occur until about twelve hours after copulation has taken place. It does not occur even then if the pituitary is extirpated within half an hour of coitus,* but can be produced at any time by the injection of an extract of the anterior pituitary, or by electrical stimulation of the tuber cinereum, though not of the anterior pituitary itself. It is inferred from these facts that the influence of the nervous system is indirect, that a humoral transmitter is liberated in the tuber cinereum, transferred to the sinusoids of the anterior hypophysis *viâ* the hypophysio-portal circulation, and stimulates this to release the hormones,† among which are the F.S.H. and I.C.S.H. The formation, and perhaps also the release, of other tropic hormones is probably effected in a similar way, so that the control of the nervous system over the thyroid and adrenal cortex is indirect. Discharge of adrenocortical hormone can also be effected indirectly through adrenaline liberation mediated *viâ* the splanchnic nerve.

B. REPRODUCTION

CHAPTER LI

THE FORMATION OF GERM CELLS

In multicellular organisms, the cells which conjugate to form a new cell, capable of developing into an individual, are of two kinds. One, which has generally a certain amount of reserve material stored up in its cytoplasm, is the female element and is called the *ovum*. The other cell, which consists of little more than nuclear material, is the male element and is called the *spermatozoon*. Both kinds of cells are derived from the germinal epithelium which can sometimes be

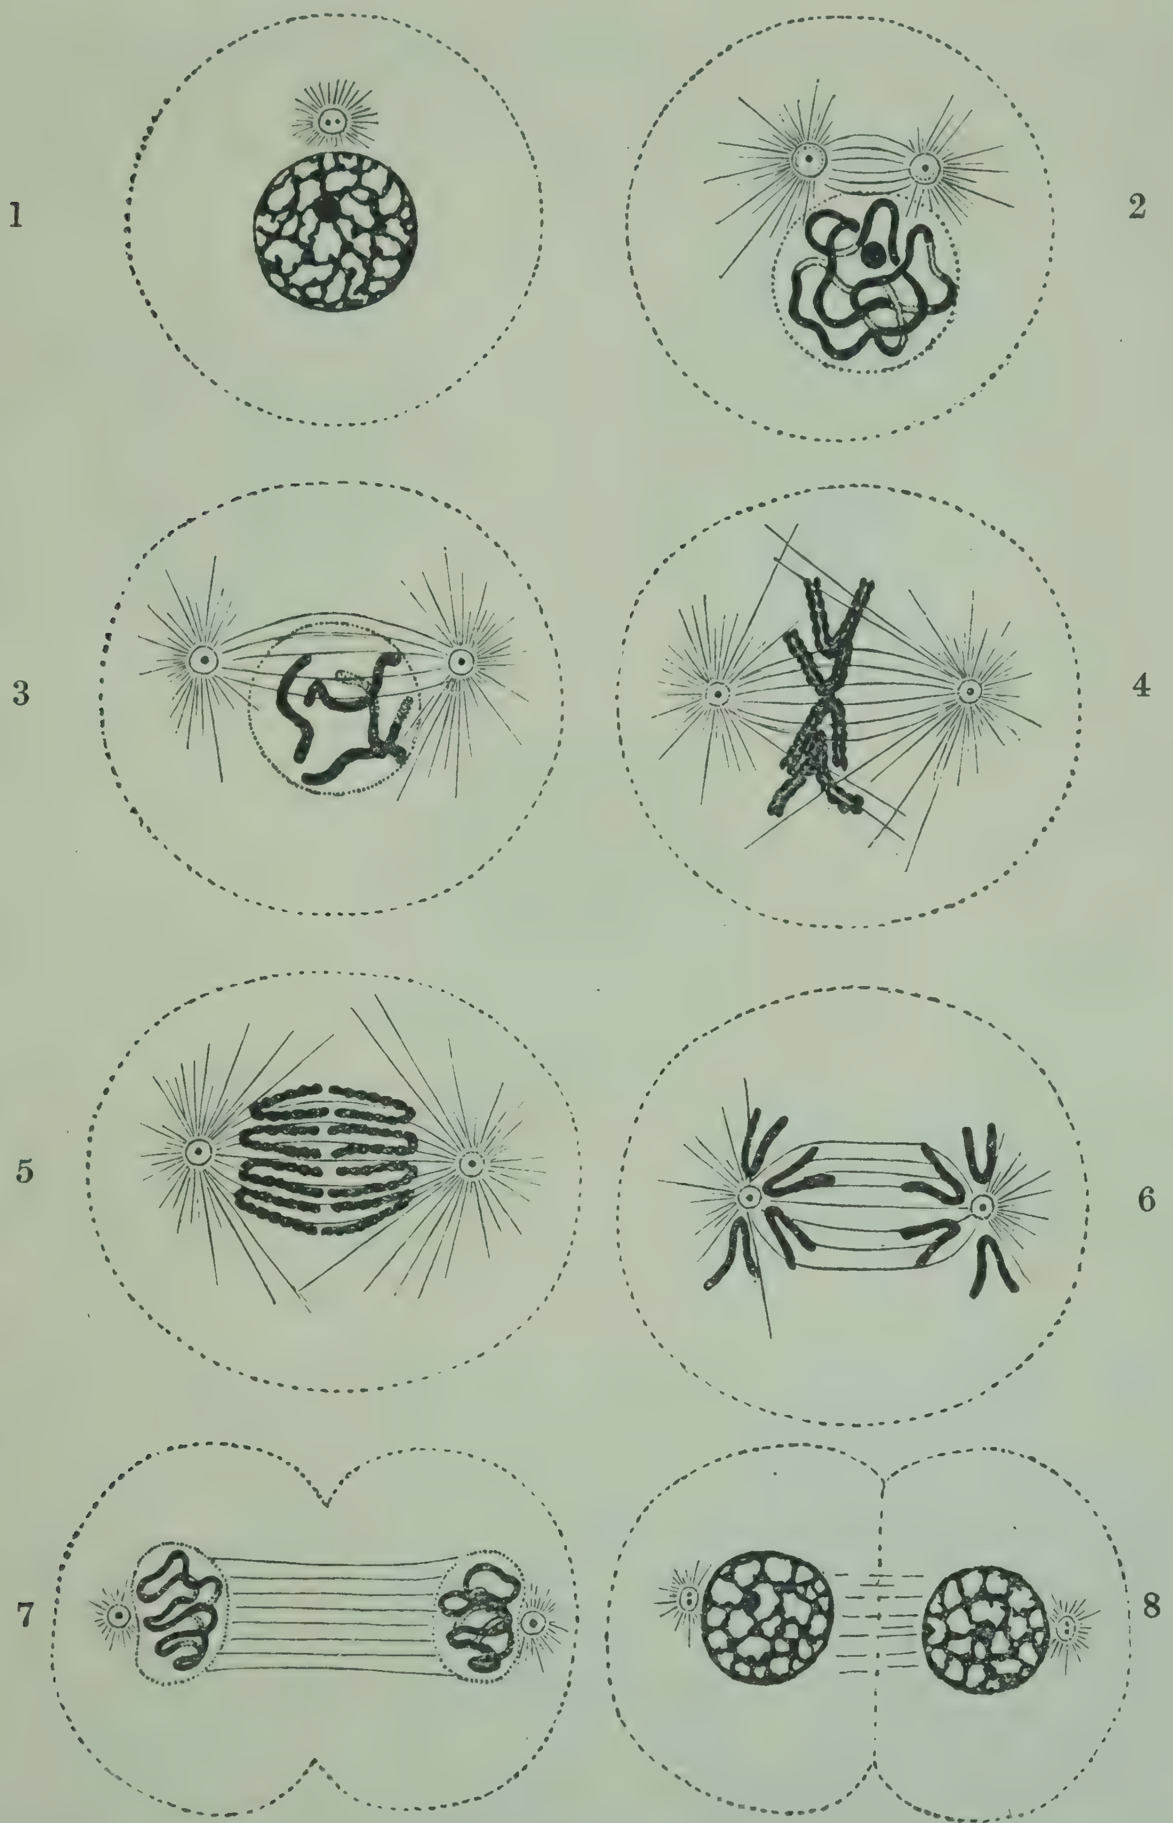

Fig. 657. Diagram showing the Changes which occur in the Centrosomes and Nucleus of a Cell in the Process of Mitotic Division. (Schäfer.)

The nucleus is supposed to have four chromosomes.

traced directly back to the first divisions of the fertilised egg. The use of the reserve material in the ovum is to serve as food for the developing individual. The ripe ovum and spermatozoon cannot be regarded as complete cells, but rather as half-cells. Before their union, or conjugation, both male and female germ cells undergo certain important changes which further differentiate them from the somatic cells of the individual. The essential differences between a ripe germ cell and a somatic cell can be best seen by a study of the nuclear changes which precede their formation.

Mitotic Division. In division, the nuclei of all somatic cells, undergo a series of changes which are similar throughout both animal and vegetable kingdoms (Fig. 657), and result in the production of qualitatively identical daughter nuclei.

The nucleus of the resting cell in its vegetative condition is generally separated from the cytoplasm by a nuclear membrane, and contains irregular masses of chromatin. In the cytoplasm of most animal cells may be seen a small particle known as the centrosome. When division is about to take place, the clumps of chromatin arrange themselves into a filament which forms a continuous skein, the "spireme stage." This then breaks up into a number of segments, often V-shaped, the chromatin filaments or *chromosomes*. Each of the filaments, in large nuclei, may often be seen to be composed of rows of granules. While this change has been occurring, the nuclear membrane in most cases disappears, and the centrosome outside the nucleus divides into two parts which travel to opposite ends of the nucleus. Round each centrosome, the cytoplasm is modified and presents a radiate appearance, the *aster*, while joining the two centrosomes is a spindle of fine fibres, the *achromatic spindle*. The V-shaped segments of chromatin arrange themselves in a circle at the equator of the spindle midway between the two centrosomes. Each of the loops then *splits longitudinally*, and each half travels towards one or other of the centrosomes, thus forming two daughter nuclei. The half-loops then join to form a skein, and may return to the condition of a resting nucleus. The entire process, as seen in tissue cultures, takes about two or three hours, though probably about twelve hours elapse between the commencement of division in a cell and the beginning of renewed division in the daughter cells. These different phases in division are presented by all somatic cells, and have received the following names:

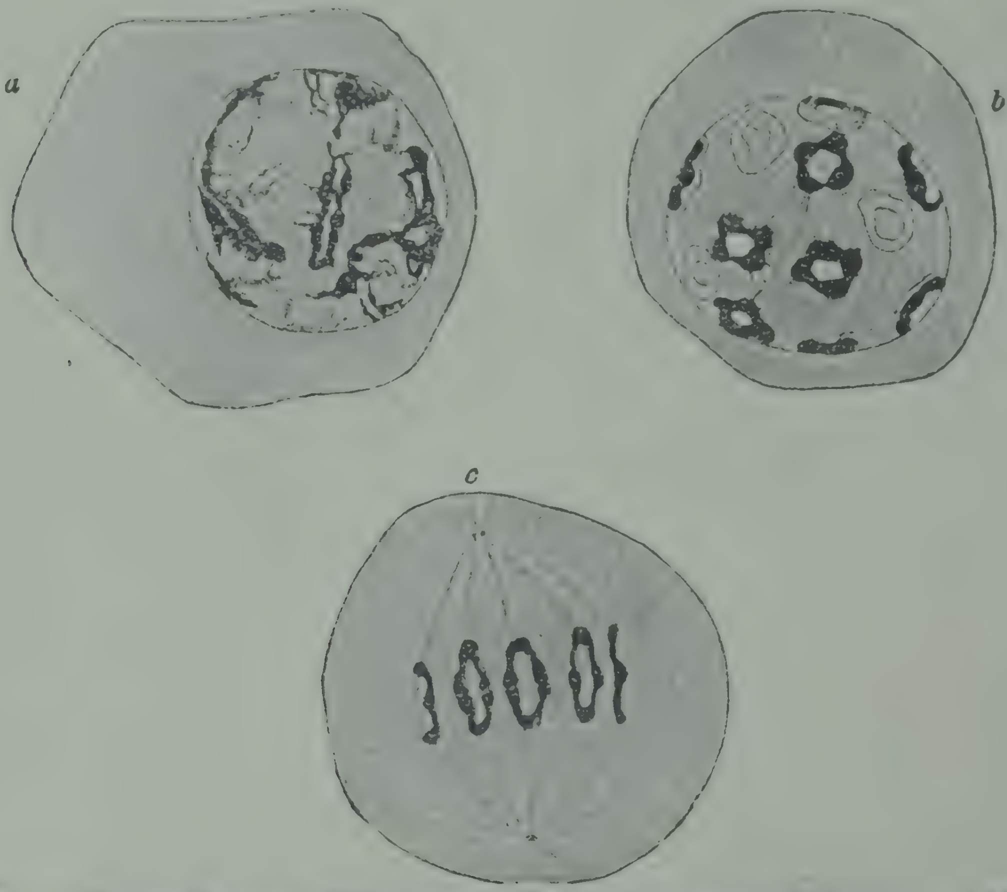

Fig. 658. Three Stages of Meiosis in Spermatocyte of Triton. (Moore.)

a. Germinal condition of chromosomes.
b. Gemini arranged in quadrate loops or tetrads.
c. Separation of tetrads into the duplex chromosomes of the daughter nuclei.

(1) *Prophase* (the formation of the spireme and of the achromatic spindle, and the breaking up of the spireme into chromatin loops or chromosomes). This phase occupies from ten to thirty minutes.

(2) *Metaphase* (the splitting of the chromosomes). This takes from two to twelve minutes.

By the action of the alkaloid colchicine the division of cells is arrested at the metaphase. This is an advantage when we wish to confirm the occurrence or increase of cell division, because after a few hours a decisive number of cells in metaphase will have accumulated.

(3) *Anaphase* (the travelling of each half-chromosome to the extremity of the spindle), which occupies about three to five minutes.

(4) *Telophase* (the retrogressive changes, leading to the conversion of the chromatin filaments into an ordinary resting nucleus, which are accompanied or preceded by a division of the cytoplasm across the equatorial part of the spindle). The latter part of the process takes about three to twelve minutes, but the retrogressive changes take from thirty minutes to two hours.

When the spireme has broken up into separate chromosomes, it is possible to count them, and it is found that the number present in any cell (*diploid number*) is constant for the species. The chromosomes are not all alike in appearance or in potentialities, but are present in pairs that are alike. Thus, every human somatic cell has 48 chromosomes, *i.e.* 24 pairs of chromosomes in its nucleus.* Identical numbers are found in types so far apart as the ox, the guinea-pig, and the onion. In the mouse, the salamander, and the lily the number is 24. Other types, such as the crustacean Artemia, are said to have as many as 168 chromosomes, the much-investigated fruit-fly, *Drosophila melanogaster*, has eight, while in Ascaris the cells contain only two to four chromosomes. There is usually an even number of chromosomes, the chromosomes of each pair being similar in size and shape. On division, each chromosome gives rise to daughter-chromosomes of exactly similar shape and size. The somatic type of cell division, called *mitosis*, seems to be adapted to ensuring an equal qualitative as well as quantitative distribution of the nuclear chromatin among the daughter cells resulting from the division of any cell. As we have seen in an earlier chapter, the nucleus, by its interaction with the cytoplasm, determines the processes of assimilation and growth of the whole cell. For the preservation

of type in cell division it is therefore essential that the nuclei of the daughter cells shall be identical in all respects with the nucleus of the mother cell.

Reduction Division. Sexual reproduction involves the conjugation of two cells, male and female, with union of their nuclei. If each of these nuclei consisted of the normal number of chromosomes, the fertilised egg cell would contain double the number characteristic of the species, and since these chromosomes would divide by splitting, the number of chromosomes in each cell would be doubled with each generation. This doubling is obviated by the fact that in the formation of the germ cells, the ovum and spermatozoon nuclei undergo a special type of division, which leads to the reduction of the chromosomes in the sexually mature cell to one-half of the number characteristic of the species. This mode of cell division is often called "reduction division," or "meiosis" (Figs. 658 and 659).

We may take as an example the development of spermatozoa. The mother cells of the spermatozoa, the *primary spermatocytes*, divide twice, giving rise to four daughter cells, the *spermatids*, each of which develops into a functional spermatozoon. In the nuclear changes preparatory to the first division, the pairs of similar chromosomes become fused together (synapsis). At the first, or reduction division, the members of each pair, instead of being split longitudinally, are merely separated again, so that each of the resulting cells receives one member of each pair and hence contains what is called the *haploid* number which is only half the somatic (or diploid) number of chromosomes. At the second division, these are split in the usual way, so that the ripe germ cells also contain the haploid number of chromosomes, *e.g.* 24 in man. The distribution of the paired chromosomes between the daughter cells at reduction provides the possibility of qualitative difference between them, since the chromosome which goes to each daughter cell represents one of the two which form a pair in cells of the somatic type. If we indicate four normal chromosomes as *a*, *b*, *c*, *d*, of which *a* and *b* form one pair and *c* and *d* form the other, in ordinary somatic division each daughter cell would also contain chromosomes which may be represented as *a*1, *b*1, *c*1, *d*1, and *a*2, *b*2, *c*2, *d*2. But on reduction one daughter cell receives *a* and *c*, while the other daughter cell receives *b* and *d* in the usual way. Exactly similar changes take place when there are larger numbers of chromosomes, one member of each pair of somatic chromosomes finding its way into the ripe spermatozoon (Figs. 658 and 659).

The mitochondria and Golgi apparatus can be traced throughout all the stages of spermatogenesis, and are approximately shared out in the cell divisions. In the formation of the spermatozoa from the spermatids, well-marked changes occur in the cytoplasmic inclusions. The tail of the spermatozoon arises in association with one of the centrioles. In the mature spermatozoon the head is derived from the nucleus of the spermatid ; the acrosome, which forms a cup of variable shape according to species, is formed in association with the Golgi apparatus, in a manner somewhat similar to that of the formation of granules in gland cells. The middle piece is of cytoplasmic origin and composed largely of mitochrondria in spiral formation.

In the ovum, during maturation, analogous changes take place. Two successive cell divisions occur as in the formation of spermatozoa, but the daughter cells are of very unequal size. In the first or reduction division, the chromosome pairs separate as in the spermatocytes, so that each of the daughter cells contains the haploid number of chromosomes, and, as in the male, each of them represents one of a pair of similar chromosomes present in the somatic cells. The larger of the two resulting cells, which retains most of the cytoplasm, is still called the ovum, while the smaller one is spoken of as the " first polar body " or " first polocyte." The ovum now divides again and throws off a second polar body, the division being of the usual homotypical variety. The first polar body also divides, so that, from the original ovum, four cells are produced, one of which retains the greater part of the cytoplasm, while the others are extruded, and degenerate (Figs. 659 and 661). The only difference, therefore, between the formation of ovum and spermatozoon is that in the former case three of the cells formed by the division of the primitive ovum are abortive, whereas in the spermatozoon all four daughter cells produced from the spermatocyte remain functional. Since the nuclei of the mature ovum and spermatozoon contain only the haploid number of chromosomes, they are sometimes spoken of as *pro-nuclei*.

In oögenesis, the mitochondria increase in numbers and are evenly distributed in the cytoplasm of the ripe cell. The Golgi apparatus similarly becomes spread out, and in some cases yolk is formed in association with it ; in the mammal, however, it merely spreads out, usually near the periphery.

Fertilisation. When the spermatozoon enters the ovum, two results normally ensue. First the egg is *activated, i.e.* provoked to cell-division. Second, *syngamy*, or the fusion of male and female pro-nuclei occurs. The essential features of fertilisation are best studied in lower invertebrates, such as ascaris or echinoderms. In the latter, fertilisation takes place in the sea-water, into which both ova and spermatozoa are extruded. The ovum of the echinoderm consists of a naked mass of protoplasm. Of the countless hordes of spermatozoa which may be in the neighbourhood of a given ovum, only one, as a rule, enters.

As soon as the spermatozoon has entered the ovum, a tough membrane is rapidly formed round the latter, so preventing the entrance of any further spermatozoa. The head of the spermatozoon enters the egg, while the tail atrophies and disappears. The head of the spermatozoon enlarges and assumes the character of a nucleus, the dense mass of chromatin breaking up first into a thread and then into the characteristic haploid number of chromosomes (Fig. 662). The egg now contains two pro-nuclei, exactly similar in appearance, one derived from the male and the other belonging to the egg itself. The two pro-nuclei approach one another and join. In many cases, there is an apparent fusion of the substance of the two nuclei. In others, the chromatin filaments of male and female simply lie side by side, forming a complete nucleus with the diploid number of chromosomes. The fate of the remainder of the spermatozoon is uncertain: it has been suggested that the acrosome plays some essential physico-chemical part in fertilisation, but there are no indications of what this may be. In some rare cases, the mitochondria of the spermatozoon have been seen to enter the cytoplasm of the ovum and mingle with those already there. In the series of divisions which precede the formation of the female pro-nucleus, the centrosome of the ovum generally disappears, whereas in the formation of the spermatozoon, the centrosome persists and forms the middle part of the spermatozoon. In many cases, the centrosomes divide in the spermatozoon itself, so that this contains two centrosomes, when it enters the egg. These two centrosomes then become the centres of attraction spheres. They diverge,

A. Second polar globule just formed; the head of the spermatozoon is becoming a reticular nucleus (♂), which shows two chromosomes; just above it, its archoplasm is shown: the egg nucleus (♀) also shows two chromosomes. B. Both pro-nuclei reticular and enlarged; a double centrosome (*a*) is visible in the archoplasm. C. The chromatin is now filamentous; the centrosomes are separating. D. The chromosomes are more distinct and shortened; the nuclear membranes have disappeared; the attraction spheres are distinct. E. Mingling and splitting of the four chromosomes (*c*); the achromatic spindle is fully formed. F. Separation (towards the poles of the spindle) of the halves of the split chromosomes, and commencing division of the cytoplasm. Each of the daughter-cells now has four chromosomes; two from the ovum, two from the spermatozoon.

and between them is formed an achromatic spindle, along the equator of which the chromatin filaments of male and female pro-nuclei arrange themselves. It is doubtful, however, how far the centrosome can be regarded as a permanent cell structure.

Fertilisation is, in some species, rapidly followed by an enormous increase in the oxygen consumption of the egg, and by cell division. The egg is said to have been activated. Each of the chromosomes splits longitudinally, half going to each of the daughter cells, and this process is repeated throughout the succeeding divisions which result in the formation of the new individual. Thus, every cell of the offspring's body contains a nucleus of which exactly one half is paternal and the other maternal in origin.

Parthenogenesis. The impetus to division is normally given by the entry of the spermatozoon itself. The strong impetus to cell division given by the process of fertilisation has naturally aroused much curiosity as to its intimate character. It might be thought that, for cell division to commence, syngamy, *i.e.* the completion of the normal number of chromosomes, is essential. As against this may be adduced the fact that, in certain conditions division takes place, and an embryo is formed, without fertilisation, *i.e. parthenogenesis* occurs. The female pro-nucleus may, under certain conditions of environment or nutrition, start dividing and give rise to an embryo, each cell of which contains only the haploid number of chromosomes. In other cases of parthenogenesis, only one polar body is extruded, or the second polar body joins again with the female pro-nucleus. In these cases, the ovum contains a nucleus, with a diploid number of chromosomes, which divides and produces an individual also consisting of diploids as though resulting from the union of ovum and spermatozoon.

In unfertilised echinoderm eggs, various artificial modes of treatment will lead to the appearance of attraction spheres in the cytoplasm, and even to division of the non-fertilised egg. By the addition of mild cytolytic agents to the medium in which the eggs are contained, Loeb succeeded in imitating the changes which normally need the entrance of a spermatozoon for their occurrence. On immersing the eggs in a weak solution of lactic acid, a membrane is formed. The eggs are then placed in concentrated sea-water for a short time, and then removed to ordinary sea-water. Division rapidly occurs, with the production of an apparently normal larva. This artificial "fertilisation" is called *artificial parthenogenesis.** Loeb suggested that the activation by the spermatozoon is essentially due to a destructive action, which may be chemical in nature, on the cortical layer of the ovum, and that the spermatozoon brings with it enzymes or other chemical substances, which excite the egg nucleus and cytoplasm in the same way as the chemical measures adopted for this artificial induction of segmentation.

Mechanical damage to the outer part of the ovum may also lead to parthenogenetic development, as for instance of the unfertilised frog's egg, when punctured with a needle.

The two functions of the spermatozoon in fertilisation, viz., activation of the ovum, and syngamy, can be separated, and thus shown to be distinct. If frog spermatozoa are treated with very large doses of X-rays and then added to unfertilised eggs, these are penetrated and activated, but syngamy fails : the result is the production of morphologically uniform haploid embryos, which are in fact parthenogenetic.†

In mammals, parthenogenesis is less easy to demonstrate, but rabbit spermatozoa treated with ultra-violet light were able to activate eggs without syngamy, and cleavages resulted.‡ Rabbit ova can be activated by cooling, or by treatment with the spermatozoa of other species : segmentation occurs,

CHAPTER LII

REPRODUCTION IN MAMMALS

Hormonal Influences on the Reproductive Organs. Even within the mammalia the phenomena of reproduction show the greatest variations from species to species. Some species breed only at certain seasons of the year, others at any season. There are innumerable anatomical distinctions peculiar to species. The number of offspring produced also shows a species variation, and so do many details of the reproductive process. In the action of the hormones concerned, however, there is a good deal of common ground, and many of the observed differences between species may be traced to different quantitative or different time relations in the production of the essential hormones.

In the development and functioning of the reproductive apparatus the principal part is played by the hormones produced in the pituitary anterior lobe and in the reproductive organs themselves.

Puberty * is the transition stage on the way to full sexual maturity. The onset of puberty is due to the action of the gonadotropic hormones which now begin to be formed in the anterior lobe of the pituitary body, and which provoke the changes in the gonads which culminate in maturation of the germ cells, *i.e.* ripe spermatozoa and ova produced in the testis and ovary respectively. A further example of endocrine influence is found in the effects exerted by the hormones of the gonads themselves upon the other parts of the reproductive apparatus and upon the body generally. Thus, castration (orchidectomy). *i.e.* removal of the testes, or spaying (oöphorectomy or ovariectomy), *i.e*, removal of the ovaries, if carried out before the time of puberty, prevents the development of the secondary sexual characters, which normally occurs at this epoch.

In the human species, this period is marked, or preceded, in the male by increased growth of the skeleton, by growth of the larynx, leading to a lowering in pitch of the voice, by the growth of hair on the face and pubes, by development of the external genitalia, and by the emergence of sexual desire. The chief sign of puberty (the menarche) in the female consists in the periodic changes in the uterus, which in the human subject and the apes give rise to menstruation, *i.e.* a flow of blood and mucus from the genital organs, lasting three to five days and repeated about every four weeks. There is also enlargement of the breasts, attended by some growth of the mammary glands and by a moulding of the whole form, making it more fit for the bearing of children. The various secondary sex characters are largely the consequences of the action on the body of divers hormones which now begin to be produced in the maturing gonads. Menstruation persists, except during pregnancy and early lactation, so long as the ovary is functional. The activity of the ovary comes to an end between the forty-fifth and fiftieth year (" the climacteric," " menopause," or " change of life "). With the cessation of its activity, menstruation also stops, and the uterus undergoes atrophy. Castration after puberty, though not causing any change in the skeleton, which has already assumed its permanent form, brings about retrogressive changes in the other genital organs, analogous to those occurring in the female at the climacteric.

In animals, the series of changes known as the *œstrous cycle*, one phase of which includes the phenomena of " coming on heat," is in certain respects analogous with the menstrual cycle in the human female, and, like this, depends on the normal activity of the ovary. It is permanently abolished by extirpation of the ovaries, but may be reinduced by implantation in the peritoneum of an ovary from another animal of the same species or by injection of the appropriate ovarian hormone. This fact shows that the changes in the uterus responsible for "heat," as well as for menstruation, are independent of any nervous connections between the ovaries and the rest of the body, and must therefore be brought about by the circulation in the blood of hormones produced in the ovaries. According to some authors, the essential structures for the production of these genital hormones are the "interstitial cells" found in both the testes and ovaries of various animals. These interstitial cells are not, however, universally present.

---

* Jung. *Illinois Med. J.*, 1941, **80,** No. 6.

The chemical correlations between the ovaries and the other organs concerned in reproduction are perhaps best shown in the changes which attend *pregnancy*. This is accompanied by a great development, first of the mucous membrane, and later on of the muscular wall, of the uterus. The mucous membrane thickens, and so forms a bed for the developing fertilised ovum. With this growth of the uterus, there is a corresponding growth of the other parts of the genital tract, *e.g.* the vagina. At the same time, rapid changes take place in the mammary glands. These changes may be studied experimentally in the rabbit, in which gestation lasts about thirty days. In a virgin rabbit of a year old, it is difficult, with the naked eye, to see any trace of the mammary gland, which consists entirely of ducts lined with a single layer of flattened epithelial cells. Four or five days after fertilisation, when it is still impossible with the naked eye to discover any embryos in the swollen uterine horns, on reflecting the skin from the abdomen each mammary gland appears as a circular pink area, about 3 cm. in diameter. On section, the gland consists of ducts which are in an active state of proliferation. By the ninth day, the whole abdomen is covered with a thin layer of glandular tissue; by the twenty-fifth day, this tissue is ½ cm. in thickness and consists for the greater part of secreting alveoli. At full term, the alveoli contain ready-formed milk.

This hypertrophy of the mammary glands during pregnancy occurs after complete division of all possible nervous paths between the glands and the ovaries or uterus. If two animals are united like Siamese twins (parabiosis), and so have blood in common, and one becomes pregnant, the mammary glands of both develop and form milk. Ancel and Bouin first brought forward evidence that the corpus luteum is intimately concerned with the growth of the mammary glands, and may indeed cause a certain degree of hypertrophy of these glands in the entire absence of any product of conception within the uterus. As first shown by Heape, discharge of an ovum and formation of a corpus luteum occur in the rabbit only as a result of copulation. The same effect may sometimes be produced by artificial rupture of a ripe follicle, whereupon there is a development of the mammary glands. If no impregnation has taken place (*e.g.* if the buck has been sterilised by ligature of the vas deferens), the glands develop for fourteen days and then begin to atrophy. This period corresponds to the period of active growth of the corpus luteum. The limited growth of the glands which occurs at puberty must be connected with the growth of ripe ova or with the growth of the corpus luteum.

There are also definite relationships between the activity of the sexual organs and that of certain other endocrine organs. Thus, castration at an early age leads to persistence of the thymus gland, which normally atrophies just before the sexual organs commence their functional activity. The existence of a connection between the thyroid and the ovaries has been a popular belief for 2,000 years. In many individuals, the thyroid is perceptibly enlarged at each menstrual period. On the other hand, extirpation of the thyroid before puberty, brings about, among the other signs of cretinism, failure of development of the ovaries, so that puberty is partially or completely delayed. Hypertrophy of the pituitary body in pregnancy and in menstruation, and enlargement and increase of oxyphile cells in its anterior lobe after castration, as well as the inhibited development of the external genitalia in hypo-pituitarism, and many facts derived from laboratory experiments illustrate the fundamental relation between the pituitary body and the sex glands. There are also close relations with the suprarenal cortex, as shown, for example, in the sexual precocity associated with tumours of that tissue.

THE FEMALE REPRODUCTIVE ORGANS

The essential organ of reproduction in the female is the ovary, the seat of production of the ova. The accessory organs in the mammal include the oviducts or Fallopian tubes, the uterus, in which the fertilised ovum is retained during the period of pregnancy and in which it develops, the vagina, which is adapted for the reception of the penis in the act of copulation, and the external genitalia.

ov. Ovum.
ch. Theca.
dp. Discus proligerus.
gr. Membrana granulosa.
lq.f. Liquor folliculi.

Among the accessory organs we may also reckon the mammary glands, which undergo a special development during pregnancy, and serve for the nourishment of the young individual during the first period of extra-uterine life.

Ovulation. The discharge at certain periods, into the peritoneal cavity, of a ripe ovum, is called ovulation. It only occurs during the sex life. At the time of its occurrence an electrical potential difference is detectable between the cervix or vaginal epithelium and the surface of the body,* but the significance of this is not known.

---

* Burr *et al.* *Yale J. Biol. Med.*, 1937, **10,** 155.

At birth the ovary consists of a stroma of spindle-shaped cells, and is covered by a layer of cubical epithelium (the germinal epithelium) continuous with the mesothelium lining the general peritoneal cavity. Embedded in the stroma, but especially numerous just underneath the epithelium, are a vast number of "primordial follicles". These are formed, during fœtal life, by downgrowths of the germinal epithelium. They may perhaps also be formed continuously throughout the whole sexual life,* in a similar manner, though this is not the current belief. Of the cells produced in this way from the germinal epithelium, some undergo enlargement to form the primordial ova, while the others are arranged in single layers of flattened nucleated cells, the "follicular epithelium," as a sort of capsule to each ovum. Of the primordial follicles, about 70,000 are to be found in the ovary of the newborn child, and during the woman's life some 500 of these follow their full course and become ripe ova. The remainder are destroyed. During the first twelve to fourteen years of life, although some primordial follicles are already developing into well-formed Graafian follicles, with growth of the ova, these do not attain maturity, but retrogress and form "atretic" follicles.

The maturation of the ova, with their containing Graafian follicles, first occurs with the onset of puberty. The first stage in the growth of the follicle is a proliferation of the follicular epithelium, the cells of which become cubical and are arranged in several layers round the ovum. At one point in the mass of cells surrounding the ovum, a cavity appears, filled with fluid, the *liquor folliculi*. The epithelium thus becomes separated into two parts, viz. the *membrana granulosa*, several layers thick, lining the whole follicle, and the *discus proligerus*, a mass of cells attached to one side of the follicle, in which is embedded the ovum (Fig. 663). Round the growing follicle, the stroma assumes a concentric arrangement and forms a capsule, of which the internal layer consists chiefly of spindle-shaped cells richly supplied with blood vessels—the *theca interna*—while the outer layer—the *theca externa*—is made up of a tough fibrous tissue. With the growth of the follicle, the ovum also becomes larger and surrounds itself with a distinct membrane, known as the *zona pellucida*. This membrane presents a fine radial striation, which is supposed to indicate the existence of canals, through which the ovum may obtain sustenance from the surrounding cells of the follicular epithelium. The nucleus also becomes larger, and forms the *germinal vesicle*, containing a well-marked nucleolus—*the germinal spot*. The mature Graafian follicle projects from the surface of the ovary as a transparent vesicle about the size of a pea. (Its diameter is about 15 mm. in the human.) In the process of growth, the ovum has increased from a diameter of 25μ to 200μ. Before the ovum can undergo fertilisation, the double division of the nucleus, or germinal vesicle, has to take place, which leads to the formation and extrusion of the three polar bodies. This process probably occurs just before or just after the discharge of the ovum from the ovary.

With increasing size of the Graafian follicle, the membrane covering it becomes progressively thinner and more vascular, and the ovum moves towards its outer surface. At certain periods, or under certain conditions, the membrane ruptures, and the liquor folliculi, with the ovum, is discharged into the peritoneal cavity, the ovum being, at first, still surrounded by an adherent mass of the cells of the discus proligerus. In some animals, this process of *ovulation* occurs at definite periods of the year. In others, such as the ferret † and rabbit,‡ the occurrence of ovulation depends upon coitus taking place during the period of sexual activity. It is probable that, in the human female, ovulation normally occurs alternately in each of the two ovaries, once every four weeks during the thirty-five years of sexual life. Menstrual cycles not accompanied by ovulation are quite frequent, however, and probably one-fourth of cases of sterility are due to the regular occurrence of such *anovulatory cycles.* A vast number of the Graafian follicles, after developing to a certain extent, undergo regressive changes, both during childhood and during adult life. The cellular elements degenerate, phagocytes wander into the follicle and attack the degenerating ovum, so that finally the follicle is replaced by connective tissue, without the formation of any corpus luteum.

---

* Evans and Swezy. *Mem. Univ. Calif.*, 1932, **9**, 119.

† Marshall. *Q.J.M.S.*, 1904, 48.

‡ Heape. *Proc. Roy. Soc.*, 1905, **76**, **B**. 260.

The ovum, when set free, is directed into the open end of the Fallopian tube by the current set up by the cilia with which the epithelium is furnished. One factor favouring entrance of the ovum into the Fallopian tube has been said to be a movement of the fimbriated ends of the tube towards the ovary. There may be other directive forces besides this, for, when the ovary on one side is removed, and the Fallopian tube on the other side closed, pregnancy, though less likely to occur, is far from infrequent. According to Corner, the passage of the ovum along the Fallopian tube occupies three days.

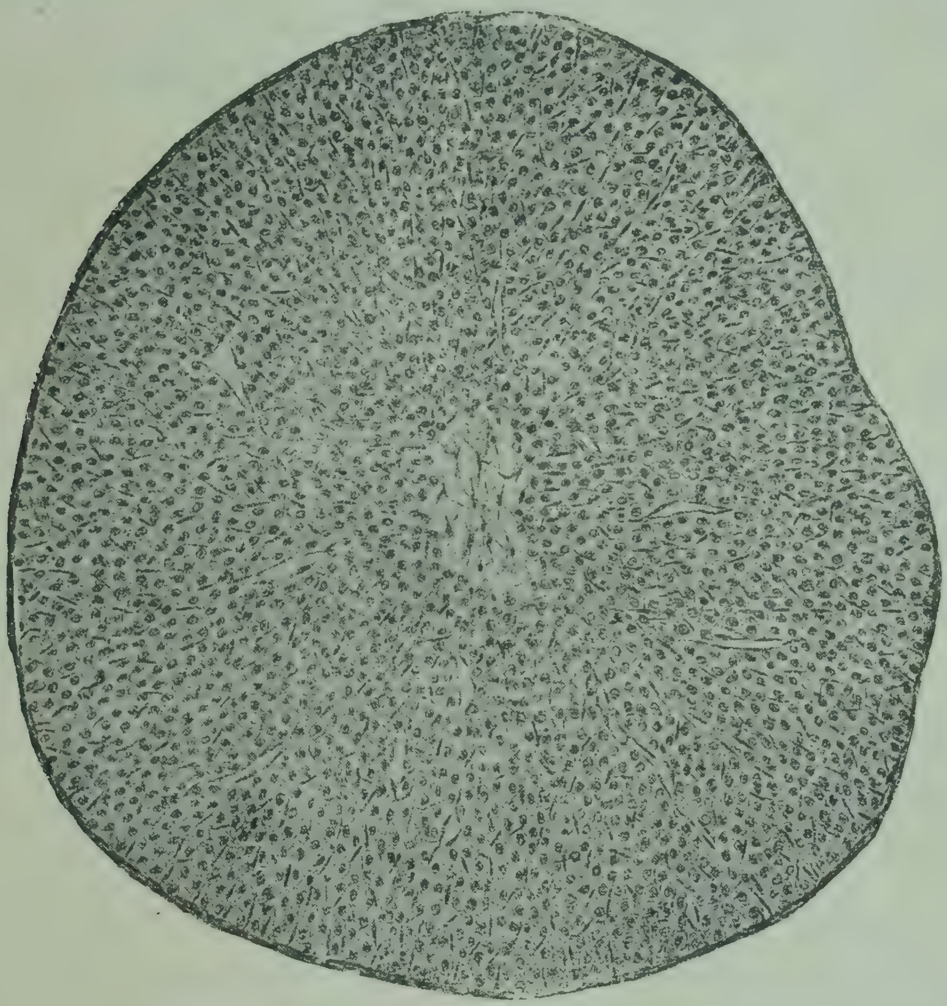

Fig. 664. Fully Developed Corpus Luteum of the Mouse. (Sobotta.)

After the discharge of the ovum, the remaining portions of the follicle undergo a characteristic series of changes, which results in the production of the *corpus luteum.* Immediately after the rupture, the cells of the membrana granulosa rapidly increase in size, a few of them undergoing mitotic division, so that a dense mass of cells is formed, nearly filling the original follicle. At the same time, the cells of the internal theca proliferate at the periphery, and the cells thus formed also grow in among the cells filling the Graafian follicle. The luteal cells finally attain a size four or five times that of the cells of the membrana granulosa in the mature follicle. Blood vessels grow from the external theca towards the centre of the follicle. The corpus luteum (Fig. 664) attains its greatest size in the non-pregnant human about the nineteenth day of the menstrual cycle, at which stage it has a grey colour: it then gradually undergoes regressive changes. The cells within the follicle then undergo fatty degeneration and present a yellow colour, due to a lipochrome known as *lutein.* If, however, the ovum, which has been discharged, undergoes fertilisation, and pregnancy results, the corpus luteum continues to grow for a considerable time and attains its largest size at about the third month, though it persists, often in an apparently degenerating condition, until after the end of pregnancy.

The big corpus luteum found in pregnancy is often spoken of as the "true" corpus luteum, and is distinguished from the *corpus luteum spurium* of menstruation, or of ovulation without fertilisation. There is no essential difference, other than that of size, between these two kinds of corpora lutea.

The Œstrous Cycle. The sexual activity of females shows recurrent changes, which vary in detail according to species, the whole cycle being known as the œstrous cycle (Heape, Marshall). In some animals, known as monœstrous, such as the bitch, there is only one œstrous period in each sexual season, of which the bitch has two a year, and between the seasons a period of quiescence, or anœstrus, is found. In others, *e.g.* mare, pig, rat and mouse, there are several heat or œstrous periods in the season, and these are separated by short resting intervals called diœstrus. In the pig, there is, at intervals of three weeks, an œstrous period lasting three days. In the human subject the alternations of rest and activity are less clearly defined. The phases of the œstrous cycle may be classified as follows :—

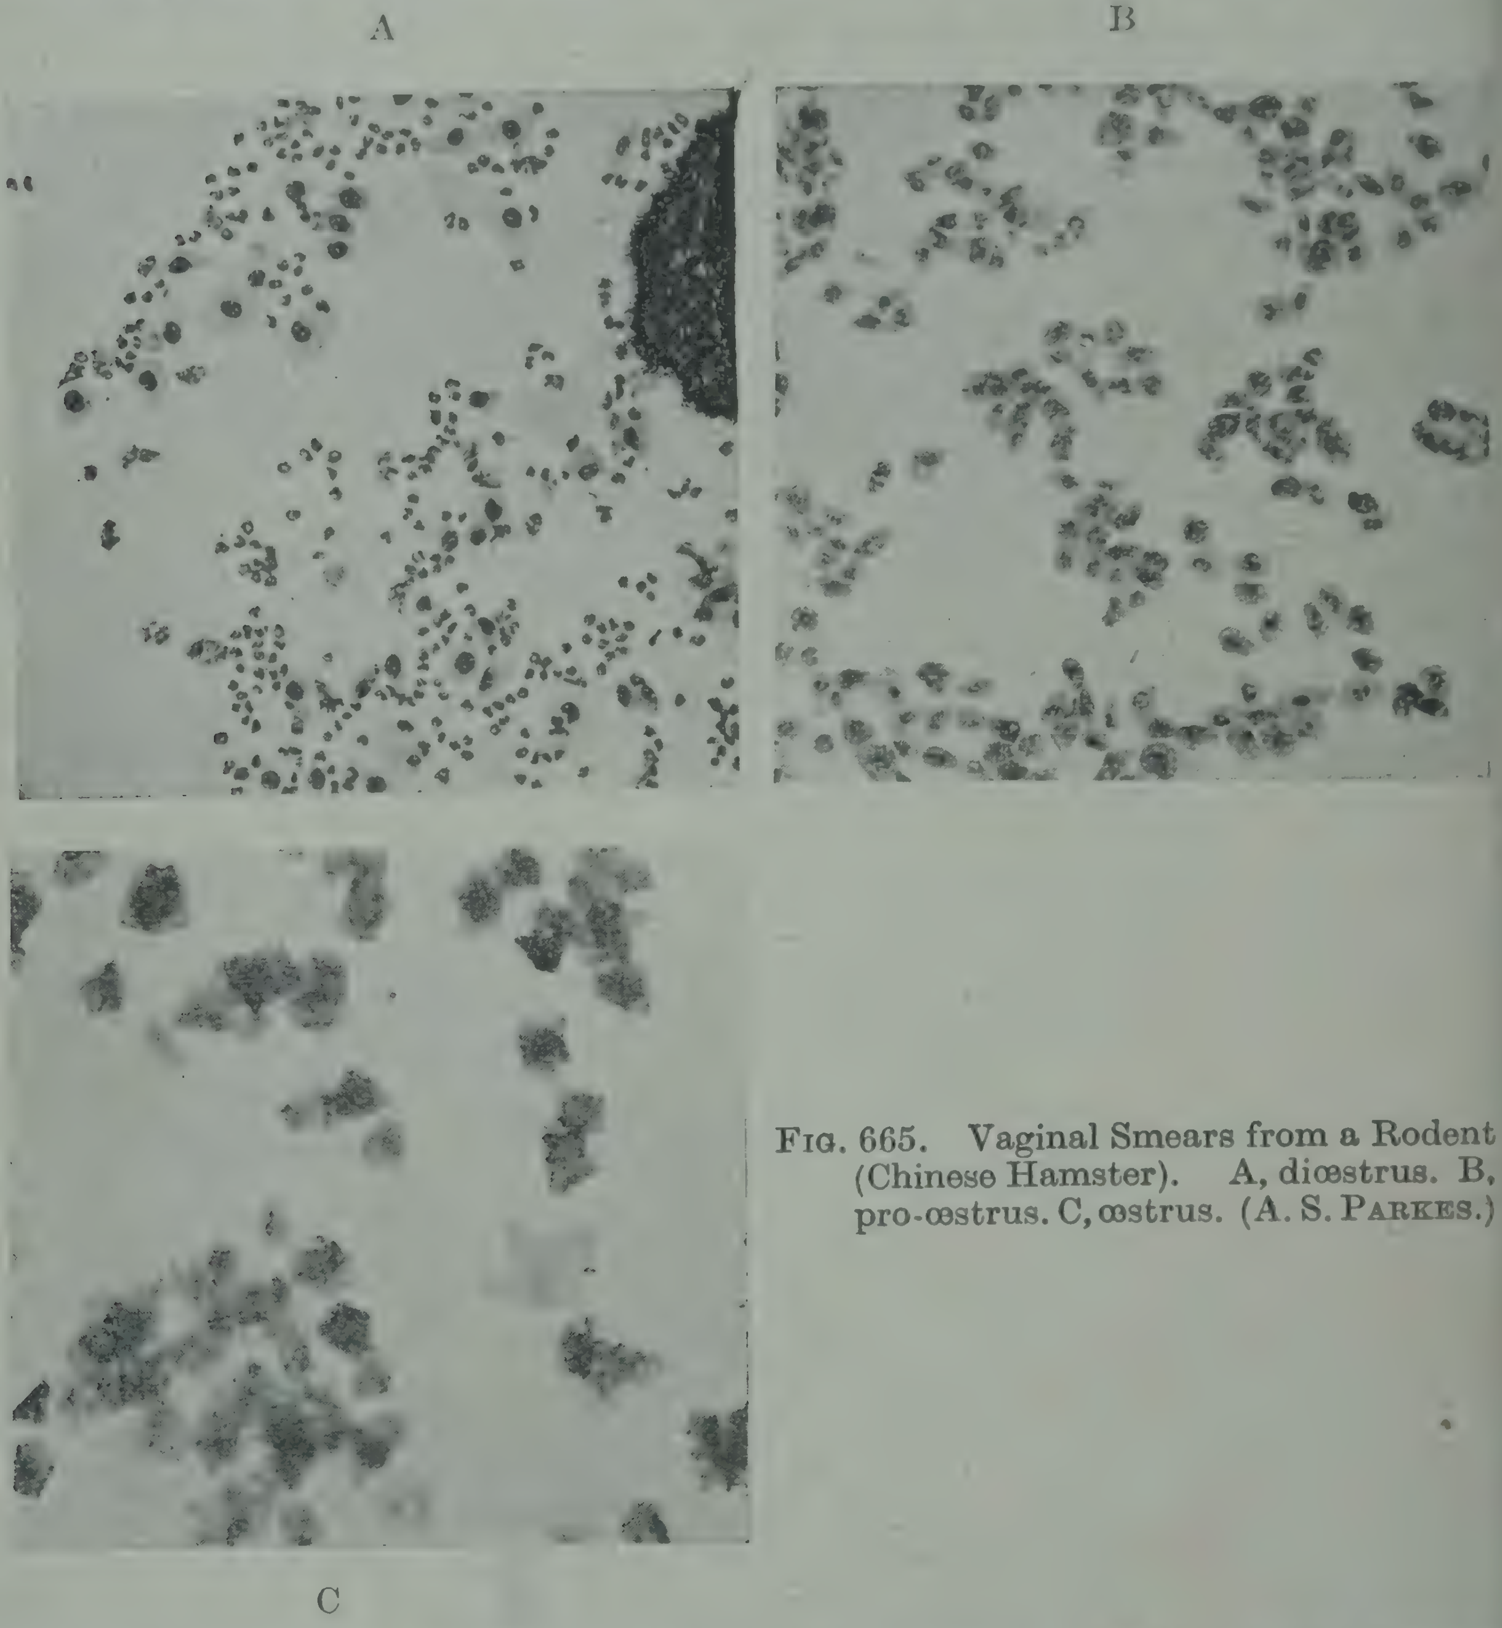

FIG. 665. Vaginal Smears from a Rodent (Chinese Hamster). A, diœstrus. B, pro-œstrus. C, œstrus. (A. S. PARKES.)

(1) Pro-œstrus, the preparatory phase.

(2) Œstrus, the period of "heat", during which alone, in most animals, copulation is permitted.

(3) Metœstrus, or luteal phase.

(4) Diœstrus (or anœstrus), or sexual rest.

These periodic modifications of sexual activity are accompanied by changes in the generative organs, in general metabolism and activity (œstrus being accompanied by increase of general activity), as well as in the behaviour towards the male, and these have been extensively studied during the last few decades.

The recurrent changes in the generative organs are normally associated with ovarian changes (follicular ripening and corpus luteum formation) ; they affect the external genitalia, the vagina, uterus, and often (especially during metœstrus) the mammary glands, and these changes are closely related to the normal sexual life in any given species. It is simplest to regard the œstrous cycle as made up of a basic *follicular phase*, consisting of a short diœstrus, a pro-œstrus and an œstrous period, with a short transition phase of met- or post-œstrus : and such a basic cycle is well seen in the unmated mouse. In most other animals, and in the mated mouse, the cycle is further modified by a *luteal phase*, due to the greater development of the corpus luteum, which, in the unmated mouse, is small and transient. As the luteal phase is connected with the functions of the corpus luteum, and may be regarded as a phase superadded to the basic follicular stage, and showing a good deal of species variability, we shall consider it later.

During pro-œstrus, growth of the follicle occurs, and at œstrus, in most animals, maturation and ovulation follow, though in some, such as the rabbit, this normally only happens if and when copulation takes place.

The study of the œstrous cycle has been greatly facilitated by the discovery, made by Stockard and Papanicolaou,* that the vaginal lining of some mammals undergoes characteristic histological changes during each phase.

In the rat and mouse, for example, in pro-œstrus the epithelial layers increase in number and in thickness, and then in œstrus the superficial cells lose their nuclei, become keratinised (cornification) and desquamate. Afterwards a transitory infiltration with leucocytes leads on to a return of the epithelium to a resting state, with few layers. Hence, by microscopical examination of vaginal smears at regular intervals, the state of the cycle at any time can be determined.

These changes, as seen in the smear, are briefly as follows (Fig. 665). In the pro-œstrous period there are nucleated epithelial cells only ; during œstrus the vagina is cornified, during metœstrus leucocytes appear in the smear, during diœstrus there are leucocytes and nucleated epithelial cells. The whole cycle in the unmated mouse takes about five days (Parkes), occupied approximately as follows : Pro-œstrus, eighteen hours ; œstrus, forty-two hours ; metœstrus, twelve hours ; diœstrus, two and a half to three days.

In the stages of pro-œstrus and œstrus the uterus becomes enlarged and congested and filled with fluid, which may be blood-stained. Its contractions become slow, large and strong, as contrasted with the feeble but frequent contractions in diœstrus or anœstrus.

The Causation of Œstrus. If both ovaries are removed the œstrous cycle ceases, either at once or after one more period. The œstrous cycle also ceases during pregnancy, and in some animals during lactation. It is not the maturation of the Graafian follicles that is the prime mover in bringing about the condition of œstrus, since Parkes has shown that in mice the œstrous cycle persists as in the normal animal after the total obliteration of the follicular system by exposure to X-rays, either before, or at any time after, birth.† It is clear, therefore, that although the presence of the ovary is essential, the presence of the ripening follicles is not. According to many investigators the essential source of the phenomena is the theca interna of follicles of all sizes. This is further borne out by the observation that in those cases where there was one last œstrous period following double oöphorectomy, the follicles of the ovaries removed had not yet reached maturity. This shows that, instead of ovulation being the cause of œstrus, they must both have some common cause, and there is clear proof that this is the gonadotropic anterior pituitary hormone.

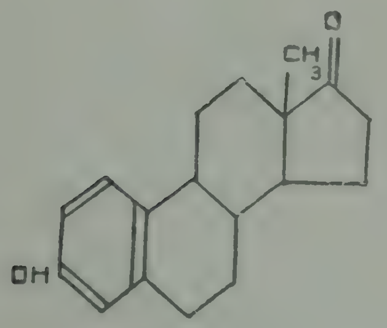
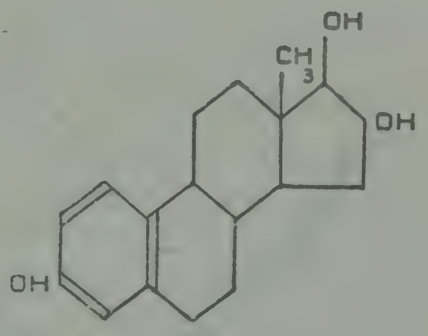
Œstrogens. It was clearly shown in 1923 by Allen and Doisy[*] that an œstrus-producing substance was present in the liquor folliculi. This, on injection into oöphorectomised mice, brought on the state of œstrus. Substances having this action are now called *œstrogens* or *œstrogenic substances.* An œstrogenic substance can be extracted from the solid parts of the ovary, from the placenta, from the urine of both men and women, but in larger amount from the urine of women at about the time of ovulation, and in still larger quantity from the urine of pregnant females. The substance is almost insoluble in water, but forms soluble alkali salts. When emulsified with water and administered subcutaneously to oöphorectomised mice, œstrus is induced in the course of the second day. Œstrogens are recognised, and extracts containing them are standardised, by the use of this method.[†] A mouse unit is the amount of a substance required to cause cornification in ten out of twenty oöphorectomised mice (but some 200 such units are needed to induce "heat"). Another test is that based on the increase in weight of the uterus of an immature mouse.

The discovery by Aschheim and Zondek (1927) that large amounts of œstrogen were present in the urine of pregnant women soon led to the isolation of one of them in a pure crystalline form. This was achieved almost simultaneously by Doisy,[‡] Butenandt,[§] and Laqueur,[‖] in 1929–30. The substance isolated proved later to be a hydroxyketone of the formula $C_{18}H_{22}O_2$.[¶] Shortly afterwards Marrian (1930)[**] isolated a second crystalline active substance which was a trihydroxy-substance. They are now called *œstrone* and *œstriol* respectively,[††] and can be separately estimated, when present together, by a colorimetric method.[‡‡] Both compounds are present in the urine of normal women (100 to 600 units daily), and of men (20 to 100 units), but are present in large amount (150,000 to 500,000 units per day) in pregnancy urine in a combined form (as glucuronides) of low œstrogenic power, from which the free and active compounds are liberated by hydrolysis with acid. Œstrone has the higher activity when tested on adult ovariectomised mice, about twice that of the trihydroxy compound. Œstriol is the more active in the induction of precocious œstrus in immature animals. A third œstrogen is present in ovarian tissue, and is called *œstradiol* ; it is the most active of them all, about six times the potency of œstrone. Which of the three compounds is the one actually elaborated by the ovary is not at present clear, though it has been supposed to be œstradiol, which is converted to the more soluble œstriol for elimination in the urine. The international units of œstrous activity are those of 0·1 μg. of œstrone or œstradiol monobenzoate (1 mouse unit = 0·1μg. of œstrone).

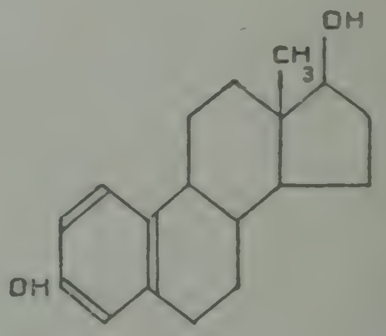
Further work indicated the following formulæ for these substances :—



ŒSTRONE



ŒSTRIOL



ŒSTRADIOL

[¶] At various times the names "*folliculin*," "*menformon*," "*theelin*" and the "*a-hormone*" have been proposed for what is probably the same hormone.

[**] Marrian. *Bioch. J.*, 1930, **24**, 1021 ; *et al.*, 1931, **26**, 25 ; 1932, **26**, 1233.

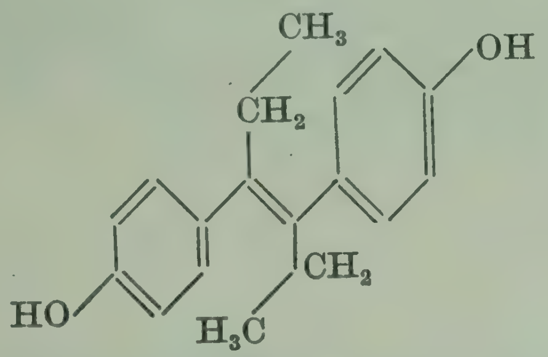
[††] Doisy has suggested the names "*theelin*" and "*theelol*" for these compounds.

[‡‡] Cohen and Marrian. *Bioch. J.*, 1934, **28**, 1603.

They are thus sterols, and closely related to some other reproductive hormones: *e.g.* progesterone and testosterone, and to adrenal cortical hormones.

They are not species-specific. Œstrone when added to the isolated guinea-pig uterus reduces the effect of oxytocin, so that smaller contractions result from it: in the pregnant uterus also it modifies the powerful contractions produced by oxytocin, retarding their rhythm and facilitating relaxation between the contractions.*

These œstrogens can be administered by subcutaneous injection in dilute alcohol, or in oil, or by implanting the solid beneath the skin. They are much less effective by mouth. The three ovarian compounds do not complete the list of naturally occurring œstrogens, for others are found in some species, *e.g.* equiline and some other sterols in the pregnant mare's urine. Also numerous synthetic substances have œstrogenic properties; some of these are sterols and some are quite unrelated, *e.g.* the most powerful is dihydroxy-diethyl stilbene (or diethyl-stilbœstrol)† which is more potent than œstradiol, though not chemically very similar.



4 : 4′-dihydroxy-α : β-diethylstilbene. "STILBŒSTROL".

The occurrence of œstrus in animals deprived of follicles by exposure to X-rays suggests that the hormone is normally produced in the stroma of the ovary. As regards its high concentration in the placenta, it is evident that, owing to the size of this organ, the placenta contains far more œstrogen than both ovaries; it has been suggested that the placenta takes up the hormones from the blood, and so protects the fœtus from their effects, but it seems more probable that they are formed in the placenta itself. Much of it is excreted in the urine of the mother.

The main effect of the injection of an adequate dose of œstrogen into the oöphorectomised female is the onset of the uterine and vaginal changes characteristic of œstrus, and also enlargement of the mammary glands. The uterus enlarges, becomes hyperæmic, and, it is stated, shows more powerful rhythmic contractions. The mammary glands (even in the male) show extension and branching of the ducts, but not of the secreting parts (Fig. 667). Large doses will check an already established lactation. Injection of œstrogen does not cause follicular maturation. The production of the hormone and ovulation, though due to a common stimulus, and normally coincident, are mutually independent.

The fate and interconversions of the œstrogens in the body are little understood.

INFLUENCE OF ANTERIOR PITUITARY. If, as indicated above, the ripening of Graafian follicles is not the cause of the presence of œstrogens, how are we to explain the periodicity of œstrus, or the occurrence at puberty of the first œstrous cycle? The work of Smith and Engle,‡ and Zondek and Aschheim § gives support to the view that the advent of puberty, as well as the rhythmicity of the œstrus phenomena, including the periodic ovulation, are part of an endocrine phenomenon, in which the anterior pituitary plays a determining *rôle*. This is effected by the gonadotropic hormones, which have since been obtained in a state of partial separation from the other pituitary hormones. Injection of suspensions of the anterior lobe of the pituitary body into adult females is followed by immediate maturation of large numbers of ova, and formation of multiple corpora lutea, or, if pregnancy follows, by the formation of abnormally large numbers of fœtuses. Injected into immature animals, the suspension brings about precocious follicle ripening and œstrus, after a latent period of about three days, *i.e.* a day longer than is required for the effect of an injection of œstrogen to manifest itself. Injection into oöphorectomised animals produces no results, which makes it evident that the effects which are produced are due to an inductive action on the ovary. In partially oöphorectomised animals, however, the hypertrophy of the remaining ovarian tissue is greatly accelerated by administration of the anterior pituitary substance. Extirpation of the pituitary body leads to atrophy of the gonads and accessory organs or, in immature animals, to failure of maturity changes.

The pituitary is capable of stimulation by nerve impulses reaching it from the hypothalamus, *viâ* the stalk.* Fee and Parkes † showed that, in rabbits, removal of the pituitary prevents the normal ovulation following copulation.

---

* BROOKS. *Amer. J. Physiol.*, 1938, **121**, 157.
† FEE and PARKES. *J. Physiol.*, 1929, **67**, 383.

Animals that have an anœstrous season in winter, *e.g.*, ferrets, can be brought into œstrus by prolonged exposure to light. This response to light cannot be brought about in hypophysectomised animals * and is impaired by section of the optic nerves. It is therefore concluded that the awakening of the gonads is brought about by stimulation of the anterior pituitary from the retina. In this reflex, the visual cortex and superior colliculi appear not to be involved, and the path seems to be either to the ventral nucleus of the lateral geniculate body, or to the subthalamus by way of the accessory optic tracts. But how the impulses then reach the anterior lobe is doubtful; it may be *viâ* the hypothalamus,† or it may be humorally conveyed (p. 1094).

There appear to be two "gonadotropic" principles formed in the anterior pituitary (Fig. 666): one, a water-soluble substance, called the *follicle-stimulating hormone* (F.S.H.), stimulating follicular maturation, and one, insoluble in water, called the *interstitial cell-stimulating hormone* (I.C.S.H.), or *luteinising hormone* (L.H.), provoking premature luteinisation ‡; these two hormones are normally excreted in small amounts in the urine. After oöphorectomy, or in states of hypo-functioning ovaries, such as at the menopause, a follicle-stimulating hormone is present in the urine in increased amount. Since in those cases the pituitary body has an increased content of the hormone and also contains numbers of large basophile cells, it is supposed that the F.S.H. is formed in the basophile cells.

Relation of the Corpus Luteum to the cycle. The basal ovarian cycle is modified to a variable extent by the presence of the corpus luteum. This structure has functions specifically connected with pregnancy, apart from which condition its effects are only incidental. These effects are responsible for the *luteal phase* of the œstrous cycle. Thus, effects due to the corpus luteum in the unmated mouse are small, in correspondence with the insignificant development of the corpora formed after ovulation. After mating with sterile (vasectomised) males, the corpora persist for a longer period and attain a greater development; the period of the cycle is then lengthened to about twelve days, during which time the uterus is much enlarged and vascularised, and there is pronounced growth of the mammary glands. This condition is called *pseudo-pregnancy*, and is seen as a normal sequel to the œstrous period in the bitch and other species where the corpora lutea of ovulation persist for a much longer time, irrespective of whether sterile copulation has occurred or not. In the bitch, the uterus is enlarged, with the endometrium thickened and vascularised, and there is enlargement of the mammary glands: as the condition passes off there is breakdown of the endometrium, with hæmorrhage.

In normal pregnancy in all species, where the corpora lutea maintain a still greater development, the œstrous cycle is suspended and all the above phenomena are accentuated. Consideration of this and other facts indicates that the corpus luteum produces a hormone having the following functions:—

(1) Inhibition of œstrus and of ovulation.

(2) Growth and sensitisation of the uterus.

(3) Maintenance of pregnancy by improvement of the nutrition of the uterus.

(4) Enlargement of the mammary glands during pregnancy and pseudo-pregnancy. Also, other special phenomena accompanying pregnancy, *e.g.* the remarkable relaxation of the pelvic ligaments which occurs in the guinea-pig, the mucification of the vaginal mucosa in the rat, modification of the endometrium in the rabbit, etc., etc.

Whether all these effects are to be attributed to the production, in the corpus luteum, of a single hormone, or of more than one, is as yet uncertain.

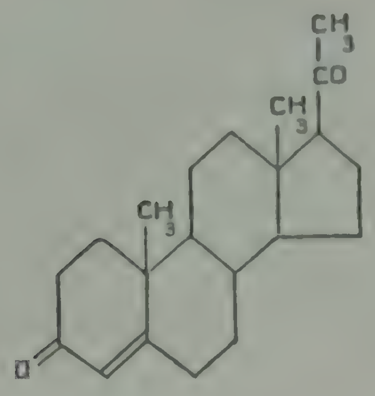
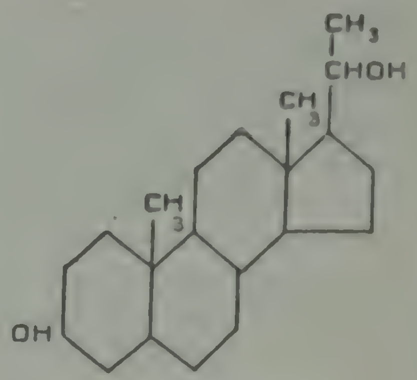
One substance has been isolated and identified with certainty.* Its structure is shown below :—



PROGESTERONE



PREGNANDIOL

and it has received the name *progesterone.* If progesterone is administered, it is converted into *pregnandiol*, the glucuronate of which is excreted in the urine.

The inhibition of œstrus and of ovulation which is effected by the agency of the corpus luteum can be shown in a variety of ways. Thus, in the cow the removal of the corpora lutea of ovulation hastens the onset of the next cycle † : conversely, if luteal formation is augmented, as H. M. Evans found to happen after injection of alkaline extracts of anterior pituitary, there is cessation of the

œstrous cycles, together with other changes characteristic of pseudo-pregnancy.

Progesterone appears from the work of Frænkel to be essential for the preparation (sensitisation) of the endometrium for the attachment of the fertilised ovum, at the initiation of pregnancy. It was shown by Loeb that, in the guinea-pig, when corpora lutea were present, mechanical irritation of the uterine mucosa, *e.g.* by a stitch passed through the uterus, led to local accumulation of decidual cells, which represented the attempted formation of a placenta ; but after removal of the corpora lutea, this response vanished. Progesterone facilitates these progestational reactions in rabbits which have been oöphorectomised during œstrus, or which, after oöphorectomy, have received preliminary injections of an œstrogen, but otherwise does not cause them in oöphorectomised rabbits. This means that the uterine response is the result of the joint action of an œstrogen and progesterone.

Other actions of progesterone are an abolition of spontaneous contractions of the uterus, and, when œstrone is also given, a considerable growth of the mammary gland (Fig. 667) with extension of the actual secreting alveoli.

Even after the placenta has been fully formed, however, the corpus luteum appears to be essential for the continuance of pregnancy, and removal of the corpora, or of the entire ovary, is followed in many species by abortion. But if progesterone is administered, oöphorectomy does not terminate pregnancy.

Menstruation. Puberty in the girl is marked by the onset of menstruation. This is a flow of blood and mucus from the uterus, recurring about every 28 ± 3 days and lasting each time from four to eight days ; it is an outcome of a modified œstrous cycle, and occurs in all the Old World primates. In some, including man, the only outward indication is the periodic bleeding ; in others, *e.g.* macaques, baboons, there are areas of skin which become highly coloured during certain phases of the cycle, or at other times if œstrogen is injected.* In normal women, except during pregnancy and lactation, menstrual periods recur at regular intervals until the age of the menopause (45–50) is reached.

Before the first menstrual period, other signs of approaching sexual maturity are usually observed and are attributed to the elaboration, by the ovary, of an internal secretion. These include rapid growth, with changes in the skeleton, leading to the typically feminine pelvis, a development of the genitalia and mammary glands, and the appearance of secondary sex characters, such as the growth of hair on the pubes. At the same time, there is development of the mental characteristics typical of the sex. At the menopause there is some loss of feminine characteristics, and a degree of psychological upset dependent on the suddenness of the change. The amount of blood lost at each menstrual period varies between 10 and 200 grammes. The flow is intermittent, and dependent on uterine contractions ; the blood is not coagulable and contains an anti-coagulant substance. Some toxic substance of unknown nature is said to be present in the sweat during menstruation. During the " period " there are often disturbances of other functions, and a general disinclination for exertion.

CHANGES IN THE UTERUS. In describing the menstrual cycle, it is customary to number the days from the commencement of one flow to the commencement of the next.

During the first (or follicular) half of the cycle, the reproductive system is under the influence of œstrogens formed in the ripening follicles : during the second (or luteal) half under that of both œstrogen and progesterone.

The histological changes† are briefly as follows : at the first day after menstruation the mucosa, or endometrium, is 1 mm. thick and the glands are short simple tubules, between which are fusiform stroma cells. This may be called the *basal zone*. Preparation for menstruation begins at once, and the *phase of regeneration* occupies till the fourth day. It consists in the appearance of a new superficial layer of epithelium, covering up the bare stroma, and about 0·5 mm. thick. Then follows the *phase of proliferation* up to the fifteenth day; in this the superficial layer reaches about 3·5 mm. in thickness, with nuclear division in the gland cells, growth and secretion of the tubules and swelling of stroma cells. The enlargement and secretory activity of gland tubules increases until the twenty-eighth day (*phase of secretion*), when the œdema of the stroma becomes localised to the middle zone of the endometrium, and the capillaries become dilated. From the twentieth to the twenty-eighth day, the progestational changes become more apparent: the superficial zone, with close-packed stroma cells, closely resembles the compact layer of the decidua, while the middle zone, with dilated glands and œdematous stroma, resembles the spongy layer. The total endometrium is now about 6 mm. thick. When the flow begins, the *phase of desquamation* (twenty-eighth to second days), these two outer zones become disorganised, infiltrated with leucocytes and phagocytes, and ultimately are shed, with some bleeding, leaving the basal zone containing the lower ends of the glands, with the stroma bare. After the flow the epithelium from these glands grows over the bare stroma to form a lining (one to four days) and the next cycle has begun (Figs. 668, 669).

Similar histological changes have been seen to occur in small pieces of surviving monkey's endometrium transplated into the anterior chamber of the eye.[*] After preliminary vasoconstriction, subepithelial hæmorrhages occurred and small papillæ formed on the free surface. These ruptured and bled for about half an hour, after which new papillæ formed and ruptured. Desquamation began locally after the first day.

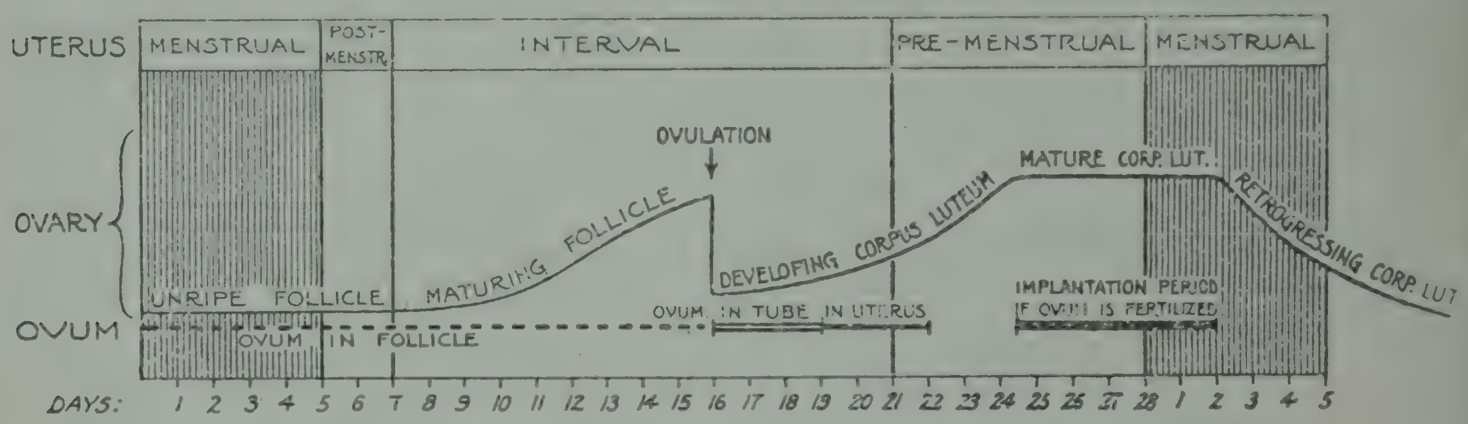

Fig. 668. Course of Events in the Human Menstrual Cycle. (G. W. Corner.)

Rhythmic contractions can be recorded at all stages by suitable small balloons passed into the non-pregnant human uterus.[†] In the first half of the cycle they are small and frequent; in the latter half, stronger but less regular. During menstruation strong waves occur at intervals of two to three minutes (Figs. 670, 671). Vasopressin causes spasmodic contraction of the uterus at all stages of the cycle, but oxytocin has no action at all on the non-pregnant uterus,[†] nor in early pregnancy.[‡]

Changes in the Vagina. The vaginal epithelium and secretions undergo a typical cycle of changes during the menstrual cycle, and these changes can be produced after ovariectomy by administration of œstrogens and progesterone. They are recognised by examination of vaginal smears.[§]

The Causation of Menstruation.[‖] There is no doubt that menstruation normally depends on rhythmical activity of the ovary, in discharging œstrogens and progesterone at appropriate times. This in its turn depends on the output of gonadotropic (follicle-stimulating) hormone from the anterior pituitary. Its onset coincides with the first production of ripe ova in the ovary and it ceases, with the cessation of ovulation, at the menopause. In cases where the ovaries have been removed before puberty, menstruation never occurs. Removal of both ovaries during the reproductive years of life is a serious operation, since it brings about a premature menopause.

Despite its cyclic character the menstrual rhythm cannot be spoken of as "œstrus." The female may experience desire at any period of the cycle, and though coitus may be refused during menstruation itself, or for some time after, this is on æsthetic grounds rather than from absence of desire. Evidence as to the relation of ovulation to menstruation rests chiefly on observations made on the ovaries in abdominal operations (Shaw *) and by Corner, Hartman, and others, on menstruation in monkeys. These tend to show that the whole cycle may be roughly divided into a "follicular" (œstrogen) phase leading up to ovulation, *i.e.* the first fourteen to sixteen days, and a "luteal" (progesterone) phase for the remainder. It seems probable that the ripening and discharge of the ova in the human ovary usually occur about the thirteenth to seventeenth day of the menstrual cycle. At the time of ovulation there are changes in body temperature and, in some women, a characteristic pain ("mittelschmertz") at rupture of the follicle. Live human ova have been found in the Fallopian tubes on the fourteenth day of the cycle,† and the most fertile period for copulation lies in the four or five days before and after mid-cycle. Œstrogen excretion also rises to a peak (600 units daily) at about mid-cycle. In the baboon, the lively colour of the sexual skin, due to processes accompany-

† ALLEN *et al.* *Contrib. to Embryol.*, 1930 (No. 414), **22**, 45.

ing the maturation of the ovum, abruptly subsides at about the mid-point of the cycle and begins to appear again shortly after the onset of menstruation. It can be produced artificially by injection of an œstrogen. During the follicular phase, and as a result of the effect of œstrogen, there is growth of the endometrial glands. According to Frænkel, after ovulation, which normally takes place once in each menstrual cycle, the corpus luteum at once begins to develop and attains maturity in about five days, *i.e.* about the twenty-first day. It persists in this state until the commencement of the menstrual flow, when it usually abruptly degenerates; in any case, it is already undergoing degeneration by the end of the flow. The excretory derivative of progesterone, pregnandiol glucuronidate, is found in the urine from the middle of the cycle (forty-eight hours after ovulation) until just before menstruation begins.* If progesterone is administered to a normal woman she excretes about 45 per cent. of the progesterone in this form. Males also excrete it after dosage with progesterone; the conversion is thus not a specialised metabolic event. In anovulatory cycles no pregnandiol glucuronidate is excreted.

Coincident with the growth of the corpus luteum and the presence of progesterone in the blood, the uterine glands undergo rapid growth and the mucosa undergoes changes preparatory to receiving a fertilised ovum. This, the progestational stage, thus corresponds to the pseudo-pregnancy stage of the lower mammals. If impregnation occurs, the embryo becomes embedded in the thickened membrane, and this continues to grow and to form the placenta, which involves the opening of maternal blood-vessels into large intervillous spaces.

Several theories regarding the significance of menstruation have been advanced. These need not be discussed here, but according to the most popular one it may be regarded as a bid for pregnancy. If this fails to occur, the ovum is lost, the corpus luteum undergoes retrogression, and, possibly in consequence of this, the hypertrophied mucosa breaks down, the *débris* being discharged, together with extravasated blood, as the menstrual fluid. In conformity with this, excision of the corpora lutea at once precipitates a menstrual flow.

It would seem that two, if not three, factors are concerned in the causation of normal menstruational changes, of which the menstrual flow is the final stage. For the proper growth changes in the endometrium, œstrogen and progesterone appear to be essential; for the causation of the menstrual flow, withdrawal or reduction in both hormones is probably necessary.† First, there is the follicular phase in which the uterus and the endometrial glands enlarge and become highly vascular. This, the proliferative phase, can be imitated in oöphorectomised monkeys by the injection of large doses of œstrogen. Stoppage or great reduction of the dose of œstrogen leads to a menstrual flow in about a week. Secondly, there is the luteal phase, in which the endometrium undergoes the characteristic changes. This phase can be imitated in spayed monkeys by following up the œstrogen injections by injections of progesterone, beginning at the fourteenth day, when the œstrogen dose is reduced. Lastly, there appears to be a phase which is responsible for the actual necrosis of the prepared endometrium; this may be imitated, in the experiment quoted above, by stopping the progesterone after ten days, *i.e.* at the twenty-fourth day, as a result of which bleeding begins about the twenty-eighth day.

A difficulty which cannot be ignored in all theories of menstruation is the unquestionable fact that normal menstruation without ovulation or corpus luteum formation often occurs in apes, and sometimes in women. In this case we might assume that there have been no progestational changes in the endometrium, and that menstruation is due merely to cessation of œstrogen production.

† Parkes. *B.M.J.*, 1931 (ii.), 559.

The probable course of events in the human menstrual cycle is summarised in the diagram on p. 1116 (Fig. 668). The changes in the endometrium and in the ovary are shown diagrammatically in Fig. 669.

The Menopause. At the menopause, ovarian function ceases. The condition normally appears more or less gradually, and the symptoms vary in severity, but it may be artificially induced by surgical removal of both ovaries, or by destruction of the ovaries by deep X-ray or radium treatment, and then the symptoms are more severe.

Cessation of menstruation may be sudden, or may be preceded by irregularity. The breasts, uterus and external genitalia atrophy and sexual desire ultimately wanes. These phenomena are to be attributed to the reduction or loss of ovarian hormones. Aspects of virilism may become apparent, such as growth of hair on the face, and an alteration of the features, and these have been said to be due to overaction of the suprarenal cortex. The anterior pituitary may become overactive too, as shown by an increase in follicle-stimulating hormone in the urine, or even by signs of incipient acromegaly. The thyroid activity is lessened, and definite hypothyroid symptoms are often encountered.

Changes in the circulation, such as hot flushes or palpitation are common. Perhaps most striking, though most often concealed, are mental and emotional instability, which may be long-lasting, or even go on to clear-cut insanity.

THE MALE REPRODUCTIVE ORGANS

In all the higher animals, we may divide the male reproductive organs into the essential organs, which form the germ cells, the spermatozoa, and the accessory organs, which have as their office the facilitation of the access of the spermatozoa to the ova (fertilisation). We also have to consider male secondary sexual characters, *e.g.*, the comb of the fowl, the horns of the stag, and, in man, the body build and stance, the deep voice, and the specialised distribution of hair on face, chest and pubic region.

The essential sexual organ of the male is the testis. This is made up of a collection of convoluted tubules, the seminal tubules, which are contained in a number of compartments separated by fibrous septa. The tubules present few or no branches, each one being about 500 mm. long. Several tubules unite to form a straight tubule, which leads by a series of communicating spaces, the rete testis, into the vasa efferentia (Fig. 672). These join to form the duct of the epididymis, coiled into a mass lying at the back of the testis. The epididymis is composed of the convolutions of this single duct, which is about 20 feet long. From the lower end of the epididymis, the vas deferens, a tube with thick muscular walls, leads by the abdominal ring to the base of the bladder, where it opens into the beginning of the urethra in its prostatic part. Just before it joins the urethra as the ejaculatory duct, each vas deferens is joined by a diverticulum, the seminal vesicle, which lies along, and is attached to, the base of the bladder. The seminal vesicles are lined by columnar epithelium, and have plain muscle in their walls. They contain a glairy liquid which may, but which usually does not, contain some spermatozoa. The prostate, which surrounds the first part of the male urethra, is divided into lobules by septa of unstriated muscle-fibres, enclosing numerous wide branched racemo-

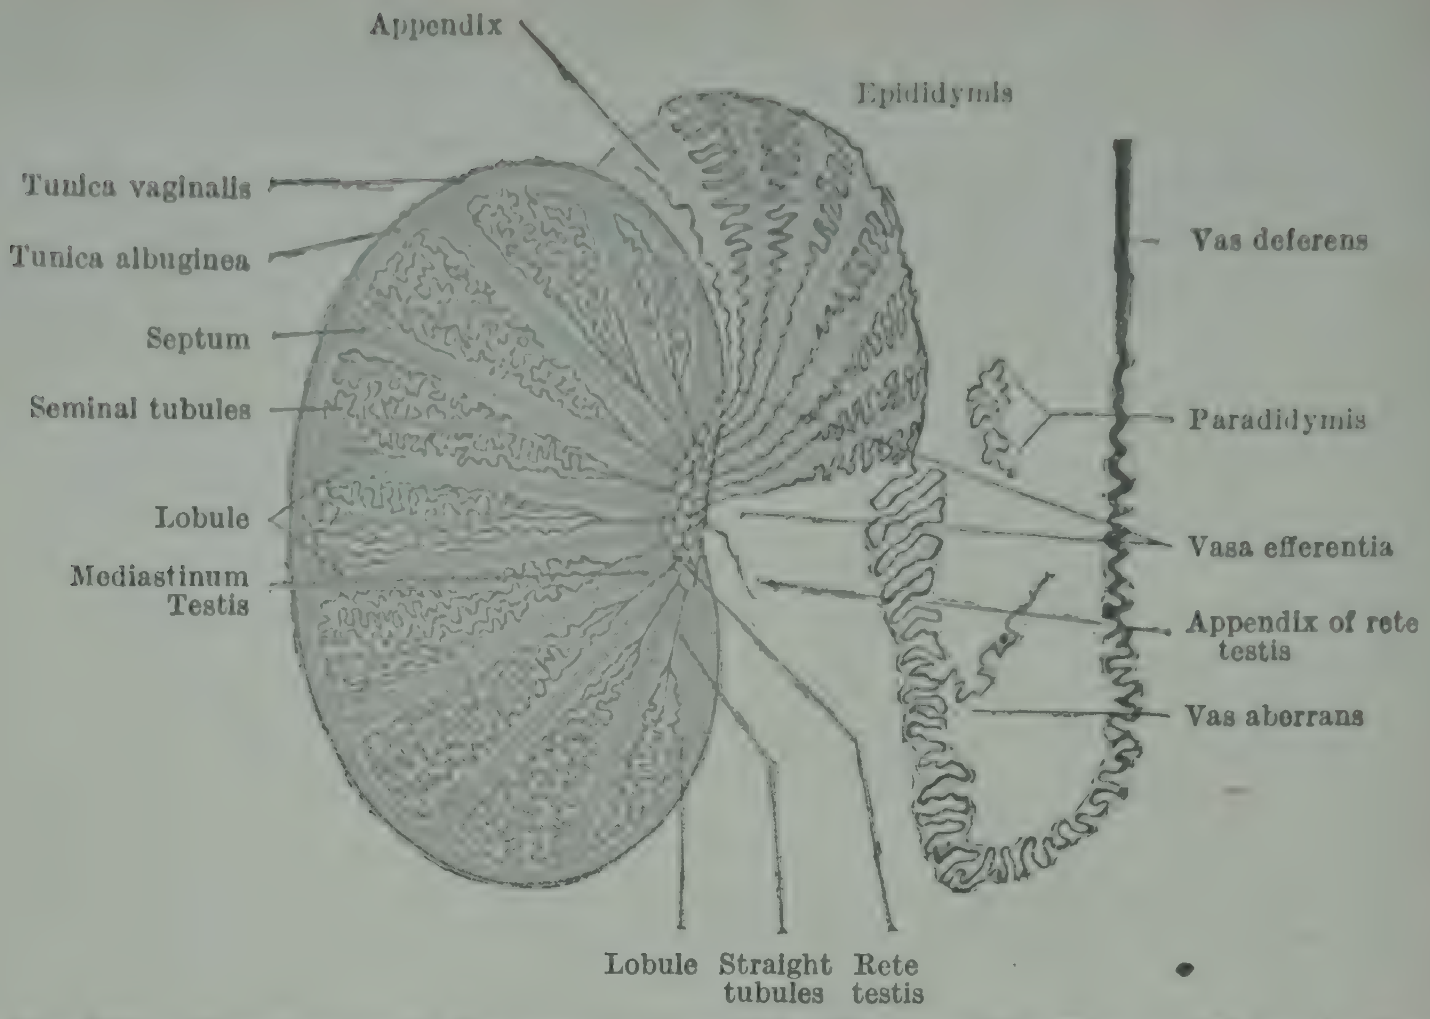

FIG. 672. Diagrammatic Representation of the Course of the Seminal Tubes in the Testis and Epididymis. (After NAGEL).

tubular glands. These open by twenty to thirty ducts into the floor of the prostatic urethra, near the entry of the ejaculatory ducts. A blind recess from the prostatic urethra, called the utriculus, is a vestige of the Müllerian duct, which, in the female, forms the Fallopian tubes, uterus and vagina. In some females, para-urethral glands homologous with the prostate are found. From the point of entry of the vasa deferentia to its orifice, the urethra represents a common passage for the urine and semen. It passes, therefore, through tissues forming the penis, which is especially adapted for the introduction of the semen into the female. In the urethra we distinguish the prostatic, the membranous and the penile portions. Into the beginning of the penile portion, the bulb of the urethra, open the ducts of the two small racemose glands of Cowper. In the penis itself, the urethra is surrounded with erectile tissue, forming the corpus spongiosum, and lies between the two corpora cavernosa, which consist of the same kind of tissue. The erectile tissue is a spongy meshwork of elastic and unstriated muscle fibres, enclosing spaces in free communication with the efferent veins of the organ. The arterioles also open into these spaces, but under normal circumstances both the arterioles and the muscle tissues of the framework are contracted, so that the blood trickles very slowly from the arterioles into the spaces, whence it escapes readily by means of the veins. If these muscle fibres be relaxed, so that the blood can pass rapidly into, and distend, the spaces, the tissue swells and becomes harder, causing " erection " of the organ.

Hyaluronidase. Extracts of testis contain an enzyme, which has the properties of a " *diffusion factor.*" * Mixed with any coloured substance, the extract greatly augments the speed and extent of diffusion of the dye, when injected intracutaneously or subcutaneously. The property is due to the presence of an enzyme, hyaluronidase, which hydrolyses the mucin-like interfibrillar substance in the dermis.† The enzyme is present in spermatozoa.

Puberty and Spermatogenesis. In the immature testis, *i.e.* from birth up to puberty, the seminal tubules are lined with cells having large nuclei. Some of these are the spermatogonia, the mother cells of the future spermatozoa, while the others form the cells of Sertoli, whose function it is to act as nurse cells to the developing spermatozoa. In hypophysectomised animals the testes remain in, or revert to, an immature condition. The actual formation of spermatozoa begins at puberty, and can be produced precociously (or in a hypophysectomised animal) by the " follicle-stimulating " hormone of the anterior pituitary (Fig. 673) which, as we have seen, is also responsible for the maturation of ova in the female. Since this hormone has a stimulating action on the production of gametes of both sexes, it is therefore often known, perhaps more appropriately, as the *gametokinetic hormone*; other pituitary hormones cause hypertrophy of the interstitial cells of the testis, and this tissue then produces male sex hormones which cause growth and development of the various accessory organs of reproduction.

* McCLEAN. *J. Path. Bact.*, 1930, **33**, 1045.
† CHAIN and DUTHIE. *Nature*, 1939, **144**, 977.

In the formation of spermatozoa, the spermatogonia divide many times to form the spermatocytes, which in their turn undergo reduction division to form the spermatids, as already described. By a further division and modification of the latter, the fully developed spermatozoa are formed. These, when mature, pass by the tubules of the testis into the epididymis, where they are stored until an ejaculation takes place, or failing that, die and are reabsorbed. Their movement is probably facilitated by the ciliated cells lining the tubule of the epididymis, as well as by the secretion of the lining membrane of the seminal vesicles. The spermatozoa are motionless while in the seminiferous tubules of the testis, but become actively motile in the vas deferens, or when mixed with prostatic secretion. They can then travel, head foremost, at

(After SMITH and LEONARD.)

about 20μ per second (70 mm. per hour). Spermatozoa recovered from the female tract soon after their introduction are always in active motion. This is soon lost, however, in most species, including man (probably in thirty to forty hours), and fertilising power is lost sooner still. Spermatozoa survive longest at *p*H.7·0 and low temperatures ; on being warmed to body temperature the activity is increased, but the length of survival shortened. The energy is derived mainly from glycolysis, oxygen usage being slight. The formation of the spermatozoa is continuous, though the rate at which this occurs is variable and is regulated by the sexual activity of the individual. In many mammals, including man, the optimal temperature for spermatogenesis is below the normal body temperature ; hence if the testis fails to descend into the scrotum, where a lower temperature is maintained, it becomes non-functional.

The Prostate is an important accessory organ of reproduction, inasmuch as its secretion acts as a vehicle of proper bulk and composition for the suspension of the spermatozoa. Theoretically, it is not indispensable for fertilisation, which, in some species, has been effected by artificial insemination with the contents of the epididymis. But without it the volume of the sperm would be so greatly reduced, and its viscosity so much increased, that fertility, as commonly understood, would probably be abolished. Though other claims have been made, there is no convincing evidence that it has other functions, such as that of furnishing an internal secretion.

The size and activity of the prostate is much influenced by the presence of the sex hormones. Normally, the active secreting cells of the acini are tall—about 25μ. After castration, the prostate undergoes involution, the cells lose in height, and their secretory activity declines ; but if the castrated animal is then given daily injections of an androgen, these effects are reversed, and even hypertrophy ensues. An œstrogen exerts the opposite effect, and in suitable doses can annul the effects of an androgen. Stilbœstrol is given for this reason in cancer of the prostate.

In the rat, but not in man, the secretion of the anterior lobe of the prostate causes coagulation of the secretion of the seminal vesicles.

In man, as age advances, the peri-urethral portion of the prostate hypertrophies and develops characteristic nodules ; if this growth is excessive it may obstruct the urethra and necessitate surgical intervention. The cause of this enlargement is not known ; the cells are of the tall type, suggesting active androgenic effects, to which perhaps the senile gland is hyper-sensitive.

The prostate forms a small amount of " resting " secretion, about 1 c.c. per day in man, and this can be collected from the meatus during massage of the prostate *per rectum ;* from dogs, after an operation by which the urine flow is diverted, much larger amounts can be collected,* up to four times the weight of the gland per hour.

The rate of secretion is increased in sexual excitement, by the stimulation of the nervi erigentes or hypogastrics, and under the influence of androgens, or of pilocarpine ; it is diminished or abolished by œstrogens.

The prostatic secretion has an acid *p*H, and is characterised by the presence of large amounts of an enzyme, acid phosphatase, with an optimum *p*H of 5–6. This enzyme is also present in abundance in the gland itself, and gets into the urine with its secretion. Other notable chemical properties are the presence of proteoses, or other proteins of low molecular weight, of very little glucose, of a high content of citrate and of spermine, and of lipides consisting of cephalin and cholesterol, often in aggregates.

The secretion arouses the spermatozoa to active movement, but the reason for this is not known.

The Semen. In the fully formed semen, the spermatozoa are mixed with the fluids secreted by the lining membrane of the epididymis, the semina vesicle, the prostate and of Cowper's glands. Nevertheless, it contains spermatozoa in enormous numbers, the semen emitted at a single act of coitus (2 to 4 c.c.) usually containing 200 to 300 million spermatozoa.* Though the majority of these are possibly capable of fertilising an ovum, this act is carried out by only one. There is no relation between numbers of spermatozoa and volume of ejaculate, nor between spermatozoa motility and age of the man. Frequent ejaculations may considerably reduce the numbers of spermatozoa in the semen.

---

* Huggins *et al.* *J. Exp. Med.*, 1939, **70**, 543.

It is probable that in ejaculation the secretion of the Cowper's glands, with which the urethra is already filled, is expelled first; then follows the glairy prostatic secretion mixed with increasing numbers of spermatozoa and finally the viscous secretion of the seminal vesicles. In the mouse and some other animals this last secretion is coagulated by a vaginal enzyme to form a solid vaginal plug which prevents loss of semen. Human semen also clots,† but is afterwards liquefied again, by the action of a proteolytic enzyme.‡

For anaerobic survival a glycolysable carbohydrate, *e.g.* glucose, fructose or mannose is essential. Semen actually, in some species, contains fructose in concentrations up to 1 per cent.§ It is formed in the seminal vesicles, but not after castration.|| Citric acid is another constituent of semen in some species,¶ and is formed in the accessory glands, chiefly seminal vesicles.

THE MALE HORMONES. Between the seminiferous tubules are groups of so-called *interstitial cells,* which appear to have an important relation to the sexual life of the individual. Removal of the testes before puberty prevents the development of the accessory organs, prostate, seminal vesicles, Cowper's glands and penis, and of the secondary sex characters; ligature of the vasa deferentia, which is followed by complete degeneration of the seminiferous tubules, but not of the interstitial cells, does not have these consequences. Hence it is assumed that the development of these characters is to be ascribed to the formation, by the interstitial cells, of an internal secretion having that influence on the individual. This is supported by the observation that when testis grafts are made into castrated animals, the male secondary sex characters develop in the usual way. Masculinisation of ovariectomised females has also been claimed to occur when testis substance is grafted.

Androgens. An androgen is a substance which causes the development of male organs and characters. It is a parallel in the male of the œstrogen in the female. A hormone having these effects has been extracted from testes; it is called *Testosterone,* and a similar substance, called *Androsterone,* is excreted in small amounts in the urine, of both sexes. In male urine, from which androsterone was isolated by Butenandt,** Schoeller and others, the total daily output of all 17-ketosteroids together is about 9 mg.: in female urine it is about 6 to 7 mg. In adrenal tumours the amount is much increased, *e.g.* it may be over 200 mg. daily. The crystalline materials are hydroxy-ketones, insoluble in water, which have been made synthetically and are closely related

to the female œstrogens.* Testosterone is usually administered as the propionate, subcutaneously injected, in sesame oil. Many other substances also have androgenic activity. It should be noted that there is no sharp line of demarcation between androgens and œstrogens, each being often capable of producing the effects of the other if given in large doses. Yet the effects of an androgen are in many ways antagonistic to those of an œstrogen (Figs. 674, 675). Among the physiological effects produced is a growth of the comb in

capons * and it also prevents the atrophy of the prostate, seminal vesicles (Figs. 676, 677), Cowper's glands, vas deferens, etc., of castrated rats.† Assay of androgens can be made by measurement of the growth caused in the comb of the capon (castrated cock) (Fig. 674), or by the increase in weight of the prostate and seminal vesicles of immature rats (Fig. 676). The international unit is 0·1 mg. of androsterone.

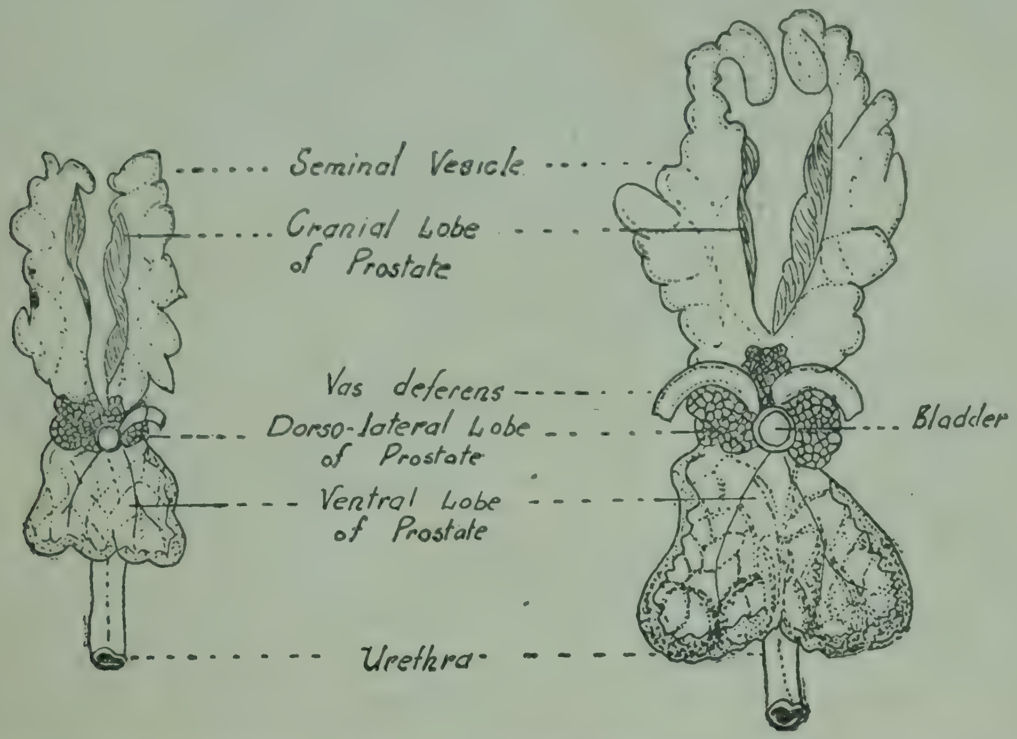

Fig. 676. Internal Genitals of two young Rats of same Litter, showing effect of Androgens. (Drawn by G. Brownlow.) (Gaddum. "Pharmacology", Oxford Press, 1940.)

In man and various other "constant breeders", *e.g.* rats and guinea-pigs, the hormone is constantly produced from puberty onwards throughout sexual life ; it is not stored, but regularly escapes in the urine. Hence atrophy of the prostate, etc., commences in a few days if castration is performed. The rate at which the hormone is produced depends on the state of nutrition and general health, but it ceases at once if the anterior lobe of the pituitary body be removed. This indicates that the anterior pituitary provides a hormone which provokes

† Moore. *J. Amer. Med. Assoc.*, 1935, **104**, 1405.

the production of androgens, and further proof of this is shown by the fact that the testicular function may be restored to hypophysectomised males by injection of fresh anterior pituitary or of the F.S.H. (gametokinetic) fraction. Conversely, androgens, and perhaps other substances of testicular origin, can inhibit the production of the gametokinetic hormone by the pituitary.

In those animals such as squirrels, which show seasonal sexual activity, the anterior pituitary seems to be non-functional as regards its gonadotropic functions during the resting phases, and this is probably the case also in all males prior to puberty.

A female hormone, or *œstrogen*, is also present in male urine. This hormone, when injected into males, leads, in some species, to epithelial growth and even cornification in the utriculus, together with diminution of prostatic gland substance and increase in its plain muscle stromata.* It should be noted that the androgens and œstrogens found in the urine of both sexes do not entirely disappear after gonadectomy: they are therefore believed to be, in part, produced in the adrenals.

DEGREE OF SEX-SPECIFICITY OF HORMONES

The sex hormones are not completely sex-specific, *i.e.* the hormones which characterise one sex are not absent from the other, nor without action on it. In the case of the pituitary hormone, we have seen that the substance which stimulates the growth and development of the gonads is probably the same in both sexes, and for that reason is sometimes called the gametokinetic hormone. The gonadotropic hormones of pregnancy urine (P.U.), of pregnant mare's serum (P.M.S.) and of castrate urine (C.U.), not only cause follicle stimulation or luteinisation, but also have effects on the testis, causing it to increase in weight, by growth of the interstitial cells (by P.U. and C.U.) or of the seminiferous tubules (by P.M.S.).

As regards the œstrogens and androgens, substances of both types are present in the urines of both sexes, though usually the androgen predominates in male urine and the œstrogen in female urine. Moreover, androgens when injected into females may produce two kinds of effect. One of these is a tendency to masculinisation, *e.g.* there is a growth of the clitoris, a masculine type of growth, and some of the male secondary characters may appear, *e.g.* growth of hair on the face in women. The female cycle may also be suppressed, perhaps as a result of an inhibitory effect on the pituitary gonadotropic hormone. The other effect may be œstrogenic in nature, *e.g.* growth of the uterus, or duct development of the mammary gland.

The administration of œstrogens to males, especially to castrates, may similarly produce feminisation, as seen in growth of the mammary glands and nipples, and growth of the prostate, utriculus masculinus, and seminal vesicles, accompanied by cessation of the secretory activity of these organs. But androgenic effects can also be obtained ; these are best seen in the reinforcement of the effects of testosterone when given together with an œstrogen. Progesterone also has effects on the development of the male mammary glands, which resemble those on the female.

The explanation of these common properties is no doubt to be sought in the chemical relationship between these hormones, and is confirmed by the fact that suprarenal cortical hormones, which are also nearly related chemically, can in large doses produce both androgenic and œstrogenic effects.

VITAMINS IN RELATION TO REPRODUCTION

Animals in a poor state of nutrition do not reproduce readily, so that in conditions of vitamin lack some faults of reproduction are not unusual. Two of the vitamins, however, seem to be especially concerned, viz. vitamin E and vitamin A.

Vitamin E (*v.* p. 824) is essential in the diet of some of the lower animals, *e.g.* rats, if reproduction is to occur. Lack of it, although not apparently interfering with the normal reproductive processes of the female up to the eighth day of gestation, ultimately leads to retarded growth of the fœtus, failure of proper development of the vascular system and allantois, and ultimate death of the fœtus. The maternal placenta develops normally. The vitamin can apparently be stored in the body for several weeks, *i.e.* actual administration of it during pregnancy is not essential, provided that plenty has been given beforehand.

In the male rat, lack of vitamin E leads to atrophy of the seminiferous tubules.

Vitamin A also plays some part in the proper maturation of the gonads, since lack of it leads to abnormalities in the œstrous cycle, and delay in reaching maturity.

COPULATION AND IMPREGNATION

The spermatozoa, stored in the epididymis and vas, are introduced into the female genital tract by the act of copulation, or coitus. After their entry they may ultimately come in contact with, and fertilise, the ovum, discharged from the ovary by bursting of a Graafian follicle. Before coitus can occur erection of the penis must take place. The mechanism of erection is twofold. The most important factor is an active dilatation of the vessels of the penis, especially of the smaller arteries. If the penis be cut across while in the flaccid condition, venous blood merely trickles away from the cut surface, whereas, if erection be excited, the flow of blood from the cut surface is increased eight to ten times, and the blood becomes bright scarlet in colour. A second factor is the contraction of the *ischio-cavernosus* or *erector penis* muscles, certain fibres of which pass over the dorsal veins of the penis and compress these vessels when they contract. Since ligature of the veins coming from the penis does not produce erection, the contraction of this muscle must be regarded as simply aiding the effects of the arterial dilatation. Hence it is possible to excite erection after the second factor has been abolished by paralysing the muscles by curare.

Before, or at the beginning of, coitus analogous changes occur in the female organs, leading to erection of the clitoris and of the erectile structures of the vulva. The glands of the vulva, especially the glands of Bartholin, secrete a mucous fluid, thus lubricating the passage into the vagina. The friction between the glans penis and the wall of the vagina ultimately causes a reflex discharge of motor impulses in both male and female (the "orgasm"). In the former, the muscular walls of the vasa deferentia and seminal vesicles enter into rhythmic contractions, thus ejaculating the spermatozoa and secretions they contain into the urethra. The spermatozoa, mixed with the secretions of the epididymis, the seminal vesicles, the prostatic glands, and the glands of Cowper, form the semen, which, at the orgasm, is ejaculated from the urethra by rhythmical contractions, from behind forwards, of the bulbo- and ischio-cavernosi muscles.

The exact physical events of the female orgasm are uncertain. It has been stated that movements take place coincidently in the uterus, so that its axis more nearly corresponds to that of the vagina, and that the os uteri dilates. After coitus the uterine contractions are diminished for some hours.* The female orgasm, however, does not play an essential part in impregnation, which, as shown by Spallanzani in the 18th century, can be effected by artificial insemination, *i.e.* injection of semen into the vagina by a syringe. It is improbable that any material is aspirated into the uterus during coitus, as was at one time supposed. A more important factor is probably the movement of the spermatozoa themselves.† As we have already seen, these are introduced into the female passage in countless numbers. They will be chemiotactically attracted by the alkaline mucus, secreted by, and filling, the cervix of the uterus. Spermatozoa move at the rate of 1 to 3 mm. per minute. Thus, on a straight course, they might traverse the distance of 16 to 20 cm. between the os uteri and the trumpet-shaped orifice of the Fallopian tubes in three-quarters of an hour. But direct injection into the uterus would shorten this time greatly, and in animals spermatozoa have been found at the peritoneal end of the Fallopian tubes within fifteen minutes after coitus. In women, spermatozoa can be found in the uterus in three minutes. Although ripe sperms remain viable for weeks within the epididymis, their life is brief once they have been introduced into the female tract, where in man few survive more than a day or two. Fertilisation of the ovum normally occurs in the Fallopian tube, and the fertilised ovum is then carried slowly down the tube into the uterus, partly by peristaltic contractions, partly by ciliary action of the tubal mucosa. If not fertilised within a few hours of ovulation, the ovum dies.

Although fertilisation is effected by a single spermatozoon, very many more must be present before it is likely to occur. The minimum number required varies according to their vigour, to species, etc., but in the rabbit, for instance, fertilisation fails if the number is less than about 10,000.‡ In man, sterility is usual if the spermatozoa are fewer than 20,000,000 per c.c.,§ *i.e.* about 60,000,000 in an ejaculate, which would normally contain about four times that number. The explanation of this strange state of affairs is that the ovum, as discharged, is imbedded in the *discus proligerus*, and so long as this remains, the spermatozoa cannot penetrate. But the spermatozoa contain the enzyme, hyaluronidase, and this, if present in sufficient amount, quickly breaks up the jelly-like complex of hyaluronic acid by which the *discus* cells are glued together.‖

Nervous Mechanism of Coitus. Although, in both sexes, coitus is attended by a high degree of psychical excitement, yet its reflex part can be carried out when all impulses from the higher centres are cut off by section of the cord in the dorsal region. The centres presiding over the reflexes are situated in the lumbar and sacral spinal cord (ejaculation and erection respectively). Like the bladder, the external generative organs are supplied from two sets of nerve fibres—from the lumbar nerves through the sympathetic, and with parasympathetic fibres from the sacral nerves.

The fibres from the lumbar nerves arise, in the cat, from the second, third, and fourth, or the third, fourth, and fifth lumbar nerve roots, and, in the dog, from the thirteenth thoracic, and the first to the fourth lumbar roots. They run in the white rami communicantes to the sympathetic chain, whence they may take one of two paths.

(*a*) The great majority of the fibres run down the sympathetic chain to the sacral ganglia, whence fibres are given off in the grey rami communicantes to the sacral nerves ; their further course is by the pudic nerves.

(*b*) A few fibres go by the hypogastric nerves to the pelvic plexus.

Excitation of these fibres causes contraction of the arteries of the penis, and of the unstriated muscles of the tunica dartos of the scrotum. In animals which possess a retractor penis muscle, excitation of the lumbar nerves causes strong contraction of that muscle. The effect of stimulation of these nerves is, therefore, to inhibit erection.

The fibres from the sacral nerves can be divided into two classes—visceral and somatic. The visceral branches run in the pelvic nerves, or *nervi erigentes.* Stimulation of these nerves produces active dilatation of the arteries of the penis or vulva, and also inhibition of the unstriated muscle of the penis, of the retractor muscle of the penis when present, and of the vulva muscles. The somatic branches supply motor nerves to the ischio- and bulbo-cavernosi, as well as to the constrictor urethræ. In the female, they supply the analogous muscles, namely, the erector clitoridis (ischio-cavernosus) and the sphincter vaginæ (bulbo-cavernosus). Both sets of sacral fibres are therefore involved in the erection of the generative organs which accompany coitus.

The internal organs, *i.e.* the uterus and vagina in the female, and vasa deferentia, seminal vesicles, and uterus masculinus in the male, differ from the external organs in receiving no efferent nerve fibres from the sacral nerves.* They are supplied with fibres, which pass out through the ventral roots of the third, fourth, and fifth lumbar nerves (in the rabbit and cat), and run through the sympathetic to the inferior mesenteric ganglia, whence they proceed by the hypogastric nerves. On stimulating these fibres, two effects are produced on the uterus and vagina, namely, a contraction of the small arteries, leading to pallor of the organs, and a strong contraction of the muscular coats. Under some circumstances, stimulation of the sympathetic nerves may cause *relaxation* of the uterus, as also may the administration of adrenaline. In the vagina, the contraction can usually be seen to start from one end and spread to the other. The whole then remains for a time in a state of powerful tonic contraction, which affects both longitudinal and circular muscles. There is also secretion of Bartholin's glands.† In the male, stimulation of these nerves excites contraction of the whole musculature of the vasa deferentia and seminal vesicals which may be strong enough to cause emission of semen from the penis. These effects on the uterus and seminal vesicles are not abolished by injection of atropine.

The ovary in monkeys has a sympathetic nerve supply from the tenth thoracic to seventh lumbar levels of the spinal cord. ‡

Removal of the sympathetic system causes impotence in males if it causes ejaculation to fail, but in some human cases this result does not ensue§ ; it has no effect on the œstrous cycle, course of pregnancy or parturition in females,‖ though in some of these lactation is inhibited.

The course of the sensory fibres which represent the afferent side of the arc, from the generative organs to the lumbo-sacral cord, has not yet been fully made out, but it seems probable that it corresponds to the course taken by the efferent fibres.

An accessory genital muscle, the *retractor penis*, is found in the dog, cat, horse, donkey, hedgehog (not in the rabbit or man). It consists of a thin band of longitudinally arranged unstriated muscle, which is inserted at the attachment of the prepuce, and is continued backwards to the bulb, where it divides into two slips which pass on either side of the anus. A few striated fibres are found in the posterior part.

The *motor* fibres to the muscle are derived from the lumbar sympathetic (*i.e.* the upper set of nerve roots), and run to the muscle in the internal pudic nerve. The pelvic nerves, on the other hand, carry *inhibitory* impulses to the muscle, thus enabling the concomitant vascular dilatation to take effect in producing erection of the penis.

PREGNANCY

Fertilisation of the ovum takes place in the Fallopian tube. In the human subject, fertility is probably highest about ten days after the end of menstruation and lowest about a week before its onset. The data published by Siegel,[*] in which the leave periods of German soldiers during the 1914 war were correlated with the incidence of pregnancy in their wives, generally supports this view. More recently, deliberate records of dates of menstruation and of acts of intercourse place the high fertility period at the tenth to thirteenth days.[†]

Directly one spermatozoon has penetrated into the ovum, a membrane is formed round the yolk, which prevents the entrance of any other spermatozoa. The fusion of the male and female pronuclei is followed immediately by division of the fertilised ovum, so that, by the time it arrives in the uterus (about eight days after fertilisation), it consists of a mass of cells known as the morula. At this time, the ovum has a diameter of about 0·2 mm. Pregnancy in the human being lasts about 280 days, *i.e.* ten periods, after the last menstrual period.

With the arrival of the fertilised ovum in the uterus, extensive changes begin in the organs of generation. The virgin uterus cavity is about 2–5 c.c.; at term it is about 5,000–7,000 c.c., and the walls are thickened in proportion. In the hypertrophy, all its elements are involved, but especially the muscle cells. There may be formation of new muscle fibres, and each fibre also grows greatly in size during the first half of pregnancy (Fig. 678).

As the contents of the uterus increase in bulk the muscle fibres undergo an extension in length to accommodate the contents without any increase of intrauterine pressure, and continue always to keep a steady but gentle grip on the contents.

Anatomically the non-pregnant uterus is divisible[‡] into (*a*) the upper segment or *corpus* (divided in some animals into two horns), in which the embryo is implanted; (*b*) a physiological "retraction ring" or anatomical internal os, (*c*) a lower uterine segment or *isthmus*, and (*d*) a cervical part, in some animals containing a sphincter, and including the *external os*.

In the early stages of pregnancy the products of conception occupy the upper segment, but as growth proceeds, the products extend into the lower segment.

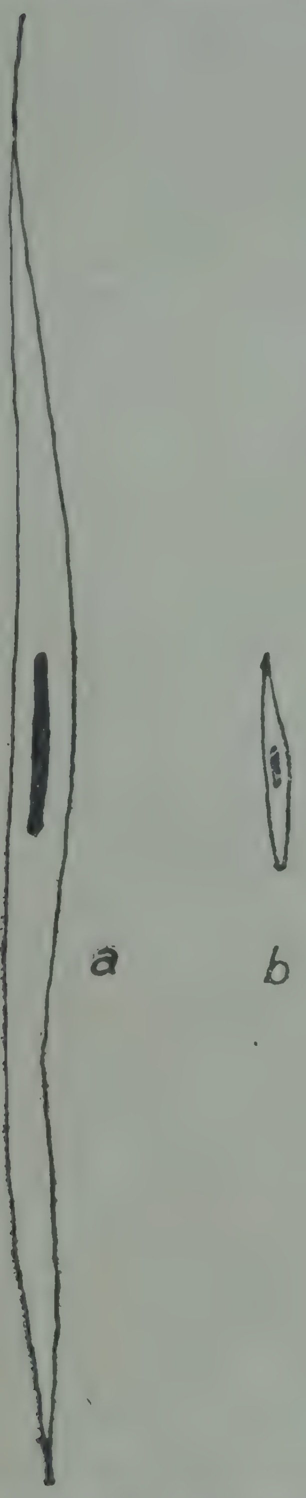

FIG. 678. Isolated Muscle Cells from the Uterus, showing the Hypertrophy during Pregnancy.

a. Fibre from uterus in ninth month of pregnancy. *b.* Fibre from a non-gravid uterus.

(After BUMM.)

During pregnancy there is a great growth of the blood vessels, which have to supply the growing wall of the uterus, and also, by means of the placenta, the nutritional needs of the developing fœtus. The increase chiefly affects the veins, which thus become capable of holding a considerable store of blood; the enlargement begins early in pregnancy, and while the fœtuses are still very small, continues more slowly while the fœtus grow rapidly, and finally, just before delivery, again increases quickly.[§] The rate of blood flow through the uterus increases at about the same rate as does the uterine blood content.[||]

Changes in the Uterine Mucous Membrane. After conception, the uterine mucous membrane shows a continuation of those hypertropic changes which we have seen to occur regularly during the premenstrual phase (Fig. 679). Within fourteen days, it has attained a thickness of ½ cm., and by the end of the second month ¾ cm. On section, it shows a compact layer, lining the cavity of the uterus, and outside this, abutting on the muscular tissue, is a spongy layer three times as thick as the compact layer. The superficial epithelium becomes flattened, loses its cilia, and degenerates. In the spongy layer, the uterine glands proliferate, the stroma cells are enlarged, and the blood capillaries are widely dilated. The stroma cells become converted into the large *decidual* cells. By the time the fertilised ovum arrives in the uterus, the process of hypertrophy of the layers of the mucous membrane has already made some progress. As it lies on the mucous membrane, the outermost cells of the developing ovum exercise a destructive influence on the adjacent cells of the mucosa, apparently through some sort of digestion, so that the ovum sinks into the membrane and reaches the sub-epithelial connective tissue. Round the margins of the depression which the ovum has made for itself, the mucous membrane grows over the protruding part of the ovum (Fig. 680). When this has taken place, the different parts of the mucous membrane receive different names. Since (in man) they are all to be cast off with the fœtus at birth, each part is spoken of as a decidua, that lining the main body of the uterus being known as the *decidua vera*, that covering the protruding part of the egg as the *decidua reflexa*, while that to which the egg is immediately attached is the *decidua serotina* or *basalis*. It is from the latter that the placenta is formed. By the end of the second week, the blood vessels in this situation are considerably enlarged. This enlargement proceeds, affecting especially the capillaries and veins, until these form venous sinuses at the junction between the mucous membrane and the muscular coat. Changes take place at the same time in the embryo. When it sinks into the mucous membrane it has a diameter of 1 mm. The blastoderm is fully formed, with its three layers; the yolk sac, the body cavity and the amnion are present. The outermost layer of the

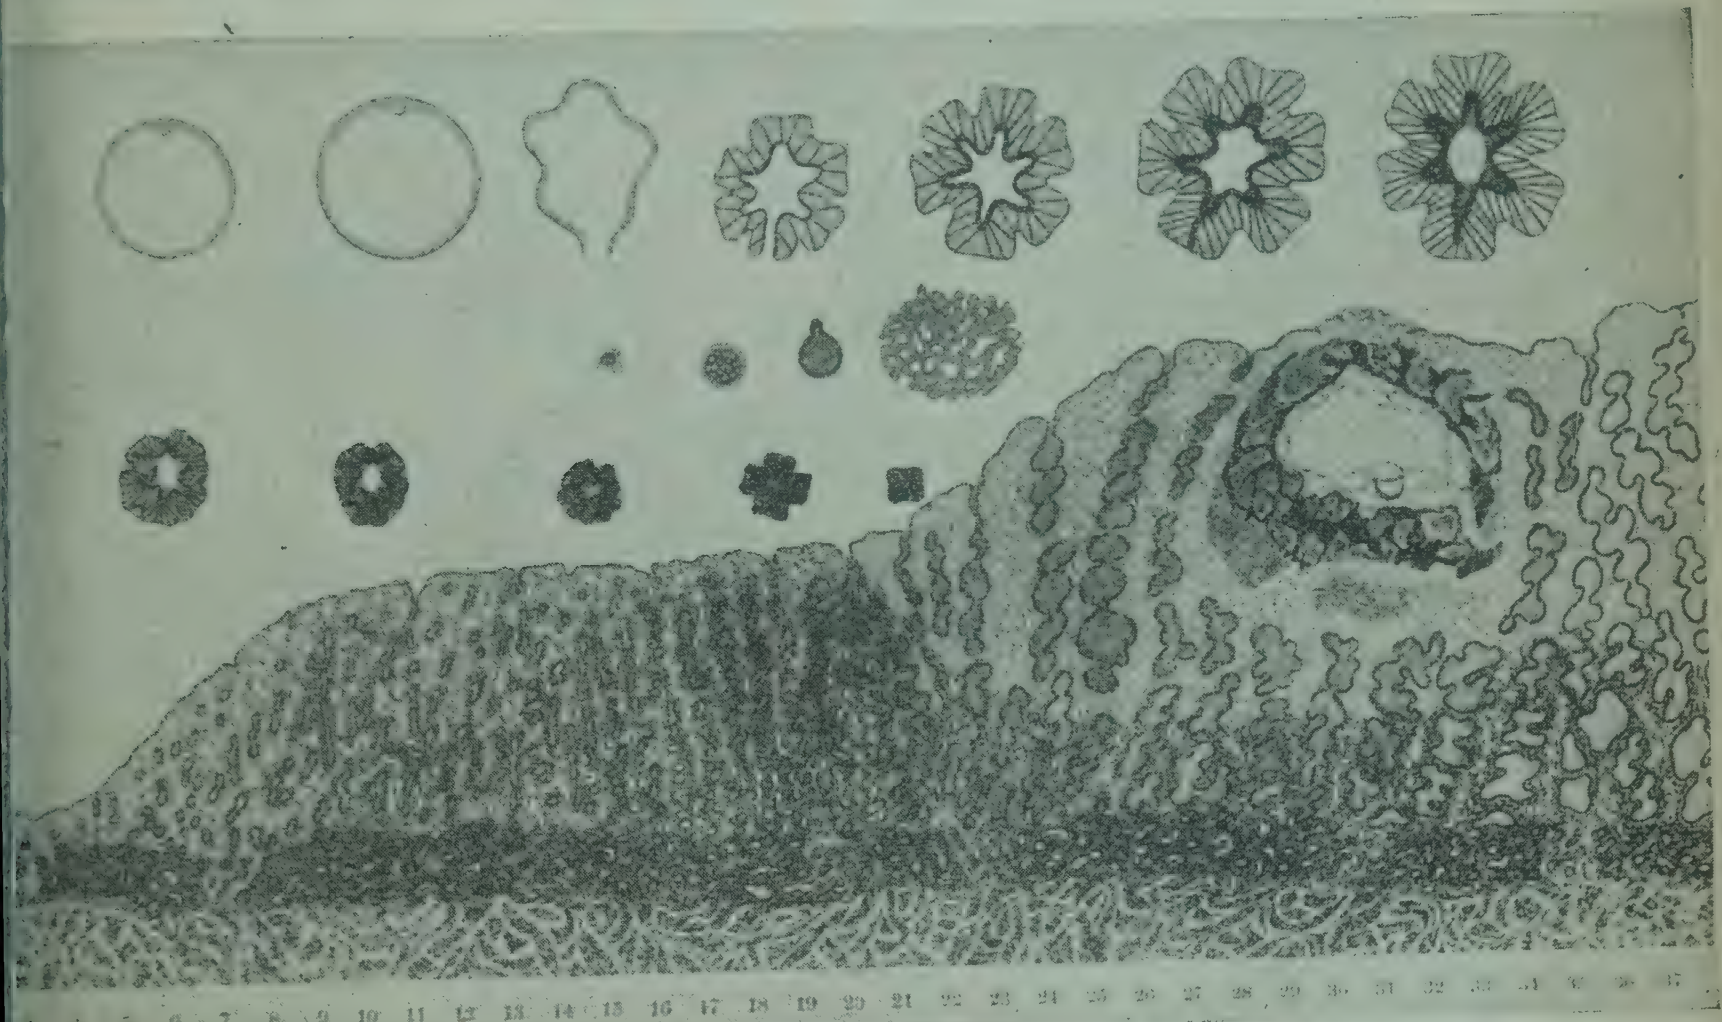

FIG. 679. Diagram showing Changes in the Human Endometrium and Ovary during first 37 days of Pregnancy. (After SCHRÖDER.)

epiblast becomes specially modified to serve for the nutrition of the embryo, and gives rise to numerous villi, the chorionic villi, so that the whole ovum has a shaggy appearance. Since this tissue takes no part in the further development of the embryo, but serves simply for its nutrition, it is often spoken of as the *trophoblast*. With the formation of fœtal blood vessels, these penetrate into the villi, together with mesoblast. The villi grow into the venous spaces, especially in the basal part of the decidua, so that, at this period, the fœtal villi are immersed in maternal blood, the fœtal blood vessels being separated from the maternal blood by a double layer of epithelium, one layer of which is maternal and the other fœtal in origin. Later, these cells become reduced to a single layer.

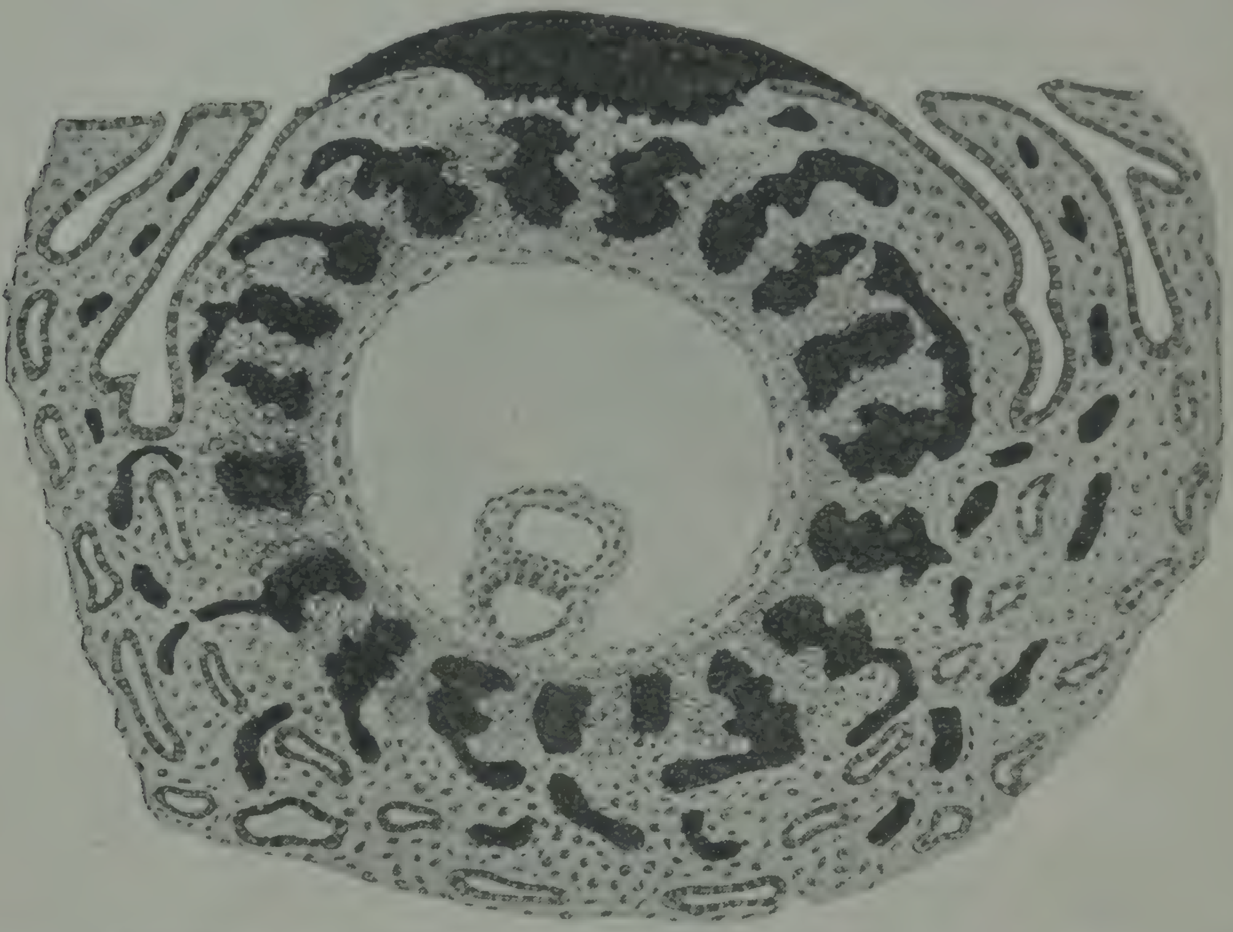

FIG. 680. Diagram to illustrate the Imbedding of the Ovum in the Decidua, and the First Formation of the Fœtal Villi in the form of a Syncytial *Trophoblast* (derived from the Outer Layer of the Ovum) which is invading Sinus-like Blood Spaces in the Decidua. (After T. H. BRYCE.)

Hormone Factors. Pregnancy is accompanied by pronounced changes in the amount and distribution of various sex hormones. Even in the early stages there is an excretion in the urine of a gonadotropic hormone similar to, but not necessarily identical with, the luteinising hormone (I.C.S.H.) of the anterior pituitary. It is called *chorionic gonadotropin* (P.U.). It reaches its maximum at about the eighth week, falls till the tenth or eleventh week to a lower level, then stays constant till delivery, and disappears a few days later.

The presence of a substance having gonadotropic actions in the urine of pregnant women,* has led to a test for pregnancy.† To 1 to 3 c.c. of urine, previously extracted with ether, glucose is added; it is then injected twice daily in various doses into immature female mice. Within 72 hours, at least one out of five mice shows the positive reaction—viz. one or more corpora lutea or blood points (hæmorrhagic follicles). An even more reliable test is the Friedman test, which utilises adult female rabbits, segregated for a month. Two i–v. injections of about 8 c.c. of morning urine are made on two days, and on the third day the animal is killed and the ovaries examined for hæmorrhagic follicles or follicular craters. If the urine is injected into hypophysectomised rats the action is only luteinising; the follicular maturation seen in immature animals, being secondary to an effect on their own pituitaries. The P.U. principle is thus mainly luteinising in its action. It is assayed by studying vaginal cornification. The serum of pregnant mares (P.M.S.) contains both follicle-stimulating and luteinising hormones; the former can be assayed by finding the increase produced in the weight of the ovaries of immature animals.

* ASCHHEIM and ZONDEK. *Klin. Woch.*, 1928, **7**, 1404.

† ZONDEK. *Klin. Woch.*, 1931, **10**, 1484.

A third gonadotropic principle (C.U.) is found in the urine of ovariectomised women, and after the menopause. It is mainly follicle-stimulating and may be a true pituitary hormone.*

International standards containing arbitrary fixed amounts of active principle have been laid down for the gonadotropic luteinising substance of human urine of pregnancy ("chorionic gonadotrophin") (0·1 mg.) and for the (follicle-stimulating) gonadotropic substance of pregnant mare's serum (0·25 mg.). These standards are kept by the Medical Research Council.†

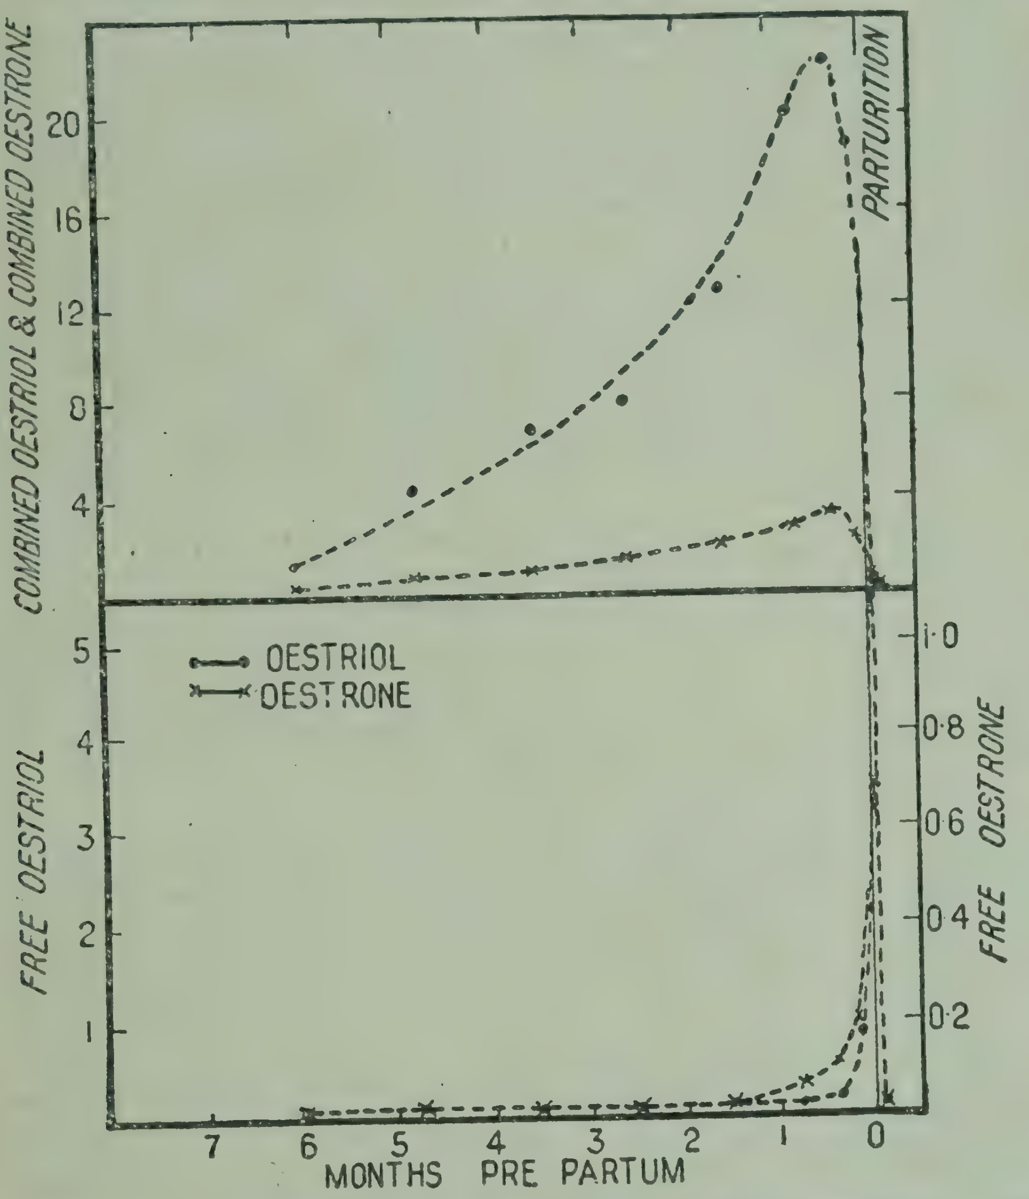

FIG. 681. Excretion of Œstrogen in the Urine during Pregnancy. Œstriol and Œstrone in free and combined forms are expressed as mg. per 24 hours. (COHEN, MARRIAN and WATSON. *Lancet*, 1935 (i.), 674.)

Another test for pregnancy ‡ consists in giving to the patient three intramuscular injections of 1 mg. of œstrone in oil over a period of five days. If menstruation does not begin within 24 hours after the last injection, the patient is considered to be pregnant.

After the eighth week, œstrogen in combined form (as a glucuronide) is excreted in increasing amount right up to the end of term.§ The enlargement of the corpora lutea, and the increase in excretion of pregnandiol glucuronidate in the urine from the eighth week onwards, show an increasing formation of progesterone. The combined action of the œstrogens and progesterone brings about enlargement and differentiation in structure of the mammary glands, and uterus, and other changes already referred to. Œstrogens can in large doses suppress lactation, but in small doses encourage growth of the mammary duct system and may sometimes stimulate the pituitary anterior lobe to produce prolactin.* As soon as labour sets in there is a sudden drop in the excretion of the combined and relatively inactive urinary œstriol and œstrone, and a sharp rise in the free and active forms (Fig. 681).†

FUNCTIONS OF THE PLACENTA. Besides playing an important part in the nourishment of the fœtus, it now seems almost certain that the placenta is a site for production of all the important hormones of pregnancy. The P.U. factor is almost certainly produced by chorionic tissue, since it is also excreted in such conditions as chorionepithelioma, in which there is no fœtus. In some species, including the human, pregnancy is not terminated by oöphorectomy, after which œstrogens and pregnandiol glucuronide continue to be excreted. Lastly, Newton has shown,‡ in the mouse, that if the fœtuses are destroyed, but the placentæ remain, œstrus is suppressed, the mammary glands develop (independently of the ovaries), and finally the placentæ are delivered at the normal term.

Nutrition of the Embryo. At the earliest period of its development, the fertilised ovum is dependent for its nourishment on the remains of the cells of the discus proligerus adhering to it, or on the fluid of the Fallopian tube in which it is immersed. The first blood vessels which are formed serve to take up nourishment from the yolk sac. In man, this source of supply is insignificant, and, from the second week onwards, blood vessels traversing the chorionic villi come into close relation with the maternal blood, from which, henceforth, the whole growth of the fœtus is to be maintained by a special development of these connections in the placenta.

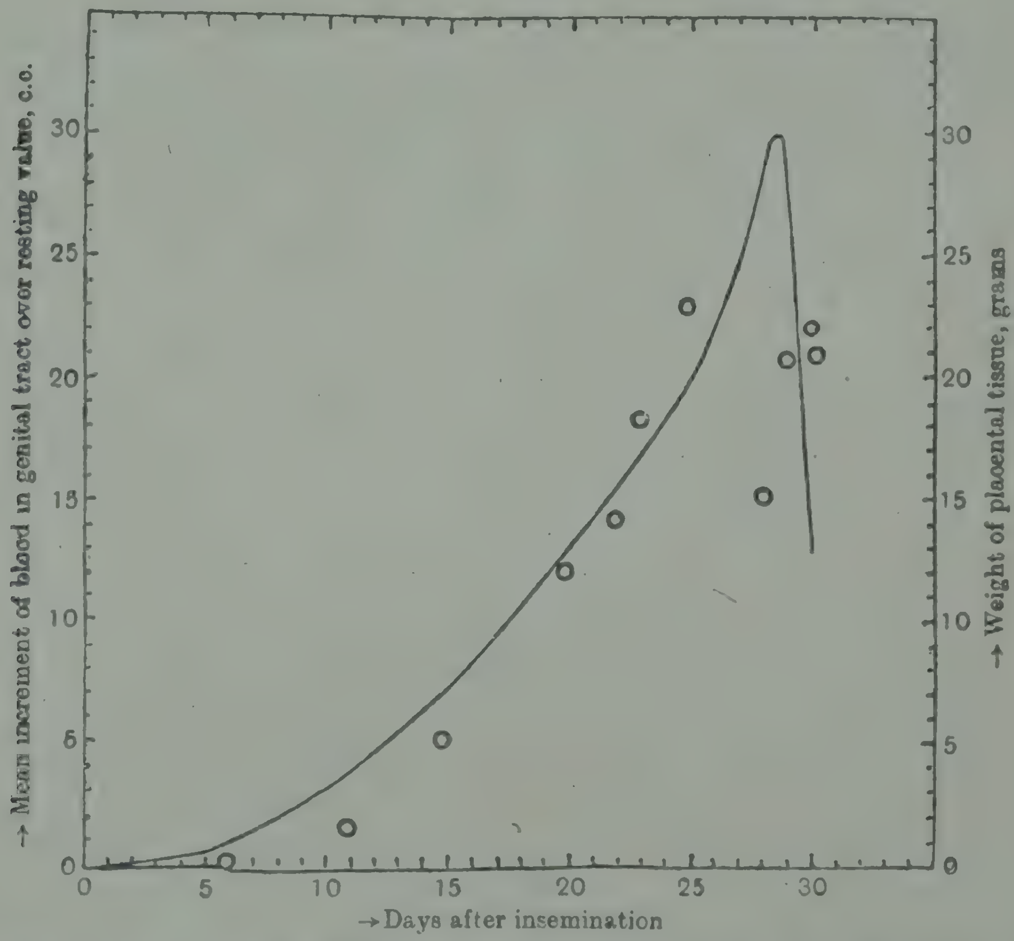

Fig. 682. Relation between Placental Weight (circles) and Volume of Blood in Uterus (line) in pregnant rabbit. (After Barcroft and Rothschild.)

In the fully formed fœtus, blood passes from the fœtus to the placenta by the umbilical artery, and is returned by the umbilical veins. There is no direct communication between fœtal and maternal circulations. The placenta represents the fœtal organ for respiration, nutrition, and excretion. Thus, the umbilical artery carries to the placenta a dark, venous blood, which in this organ loses carbon dioxide and takes up oxygen, so that the blood of the umbilical veins is arterial in colour. The oxygen requirement of the fœtus is small, probably less than half of that of the same weight of maternal tissue. It is protected from all loss of heat, movements are sluggish, or for the most part absent, and the only oxidative processes are those required in the building up of the developing tissues. On the other hand, the fœtus has need of a rich supply of foodstuffs, which it must obtain through the placental circulation. It is imagined that the epithelium covering the villi represents a membrane through which the necessary foodstuffs and oxygen pass from the maternal to the fœtal blood, and carbon dioxide, urea and other metabolic products in the reverse direction. The placenta contains a considerable amount of glycogen and fat, which may perhaps act as stores of material for the use of the fœtus in emergency.*

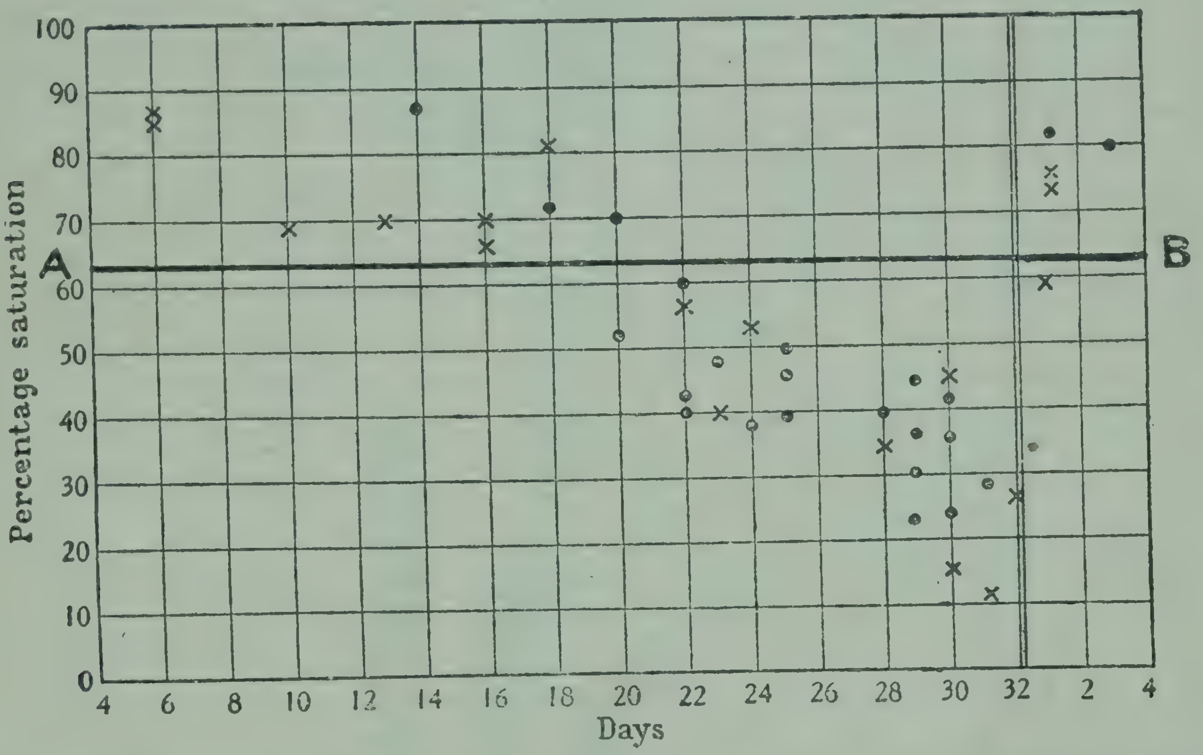

FIG. 683. Percentage Saturation with Oxygen of Maternal Blood leaving the Pregnant Horn of the Uterus at different stages of Pregnancy in the Rabbit. AB represents the average saturation of blood leaving the non-pregnant horn. Parturition on thirty-second day. (BARCROFT, FLEXNER, HERKEL, MCCARTHY and MCCLURKIN.)

As might be anticipated from their rapid rate of growth, the amount of blood in the uterus, placenta and fœtus rapidly increases during pregnancy; the fœtal goat, for instance, shows an increase of blood volume from about 16 c.c. at the sixty-eighth day to 300 or 400 c.c. at term. Expressed as a percentage of the weight of the fœtus, however, the amount falls slightly during pregnancy from about 25 to about 14 per cent., but if expressed as a percentage of the weight of fœtus plus placenta, the amount is more nearly constant at about 9 per cent. In other words, as pregnancy advances, the fœtus grows more rapidly than the placenta, but the blood volume roughly keeps pace with the growth of the combined uterine contents.

Two factors are clearly of importance in facilitating the exchange between fœtal and maternal bloods, viz. the circulation rate in the fœtus, and the circulation rate in the maternal placenta. In the fœtal sheep and goat, the output of the fœtal heart provides a fairly constant volume of blood per unit weight of fœtal tissue during the latter half of pregnancy, but the volume per unit weight of whole tissue to be circulated, *i.e.* of fœtus plus placenta, steadily increases during the latter half of pregnancy, the volume per gramme per minute being about three times as much at full term as it was at about half term.

---

* ELLIOTT, HALL and HUGGETT. *J. Physiol.*, 1934, **82**, 160.

On the maternal side there is a great increase in the vascularity of the uterus, which, in fact, runs closely parallel to the increase in weight of the placentæ (Fig. 682). Since the growth of the fœtus soon outstrips that of the placenta, however, it would appear that the maternal blood circulation rate tends to lag behind the fœtal one. The relation between these two circulations becomes of paramount importance in connection with the supply of oxygen to the fœtus since, as pregnancy advances, the maternal venous blood leaving the placenta becomes less and less saturated with oxygen (Fig. 683).

Fig. 684. Diagram of the Fœtal Circulation. (After Gray.)

The Fœtal Circulation. In the fœtus, from the middle of intra-uterine life, we find certain arrangements of the circulation which have long * been supposed to be directed to providing the heart itself, and the forepart of the body, especially the rapidly growing brain, with oxygenated blood, while the less important tissues of the limbs and trunk receive almost venous blood (Fig. 684). These old beliefs have been vindicated by direct experiment, in which radio-opaque solutions have been injected into the fœtal circulation, and X-ray cinematograph records taken.† As the arterial blood of the umbilical vein passes from the placenta, *viâ* the *ductus venosus*, into the inferior cava, it is mixed with the sluggish stream of venous blood, returning from the lower limbs and lower part of the trunk. Some of the umbilical vein blood, of course, can pass directly into the liver. The greater part of it, however, traverses the ductus venosus, to enter the inferior vena cava, by which it is carried to the right auricle. Here the bulk of it impinges on the Eustachian valve, and is directed thereby through the *foramen ovale* into the left auricle, whence it passes into the left ventricle, to be driven into the aorta. By the aorta, this partially arterialised blood is carried chiefly to the coronary vessels of the heart, and to the head and fore limbs. A small fraction of it, however, passes on through right auricle and ventricle to the pulmonary artery. The venous blood from the fore parts is also carried by the superior vena cava to the right auricle, right ventricle, and pulmonary artery. Of the but slightly arterialised mixture of bloods thus carried to the pulmonary artery, only a small part passes through the lungs, the greater part traversing the patent *ductus arteriosus* to be discharged into the descending aorta, whence about a third of it flows to the lower limbs and trunk, and two-thirds to the placenta by the umbilical arteries. In the fœtus, therefore, the work of the circulation is largely carried out by the right ventricle. The great thickness of the left ventricular walls, which is so characteristic of the adult, does not become evident until shortly before birth. The umbilical artery, accordingly, carries chiefly venous blood to the placenta, where it is arterialised by interchange with the maternal blood, and the arterialised blood is then returned to the fœtus by the umbilical vein—a state of affairs comparable with that resulting from passage of blood to and from the gills of fish. Conversely, of course, the maternal blood conveyed to the uterus and placenta is arterial, and that returning is venous.

J. Barcroft found the following oxygen contents of the various fœtal bloods in the sheep :—

Blood of umbilical vein	= 79	per cent.	oxygen	saturation
,, thoracic inf. ven. cava . . .	= 56	,,	,,	,,
,, carotid artery	= 41	,,	,,	,,
,, jugular vein	= 33	,,	,,	,,
,, aorta (umbilical artery) . .	= 23	,,	,,	,,

He believes that, as postulated, there is a crossing of the circulations, though not a complete one, and estimates that about two-thirds of the blood from the " upper " circulation passes on to the lower one, while of the blood returning from the lower circulation two-thirds pass on to the upper.

SUPPLY TO THE FŒTUS. The rate at which oxygen is acquired by the blood circulating through the fœtal side of the placenta will depend especially on the relative rates of the fœtal and maternal placental circulations, and on the oxygen tensions on the two sides of the membranes. The most favourable conditions would be when the circulation rates on both sides were rapid, and the difference between the oxygen tensions of maternal and fœtal bloods great. Such information as we have is derived chiefly from the study of the rabbit, sheep and goat, and it is uncertain how far the conclusions drawn from these species can be transferred to man.

We have seen that, as pregnancy advances, the circulation rate on the maternal side fails to augment at the same rate as that on the fœtal side, which increases even more rapidly than does the weight of tissue to be supplied. In view of this it is not surprising to find that the percentage oxygen saturation of the blood leaving the uterus (much of which comes from the placenta) steadily falls towards the end of pregnancy, when it may reach a very low figure, *e.g.* 20 per cent., as against about 65 per cent. saturation in the non-pregnant uterine venous blood, or 75 per cent. in the post-partum uterine venous blood.

---

* SABATIER. Traité complet d'anatomie, 1791, ii., 493.

† BARCLAY, BARCROFT, BARRON and FRANKLIN. *Brit. J. Radiol.*, 1939, **12**, 505.

The surprising fact which emerges from these results is that the fœtal blood coming from the placenta has so much greater a saturation with oxygen than has the maternal venous blood. Yet it has been shown that the gradient of tensions is such that the exchange can be accounted for by diffusion across the intervening membrane,* *i.e.* the *tension* in the fœtal blood returning by the umbilical vein is *not* higher than that in the maternal venous blood. The key to this apparent discrepancy has been found by the study of the dissociation curves of fœtal and maternal bloods. It has been shown † that the curve of the fœtal blood is steeper than that for maternal blood, *i.e.* at a given oxygen tension the fœtal blood takes up more oxygen than does the maternal blood (Fig. 685). This appears to be partly because the maternal blood, owing to raised H-ion concentration, has a lowered oxygen affinity, but chiefly because the hæmoglobin of fœtal blood is different from that of the adult, in having a higher oxygen affinity.

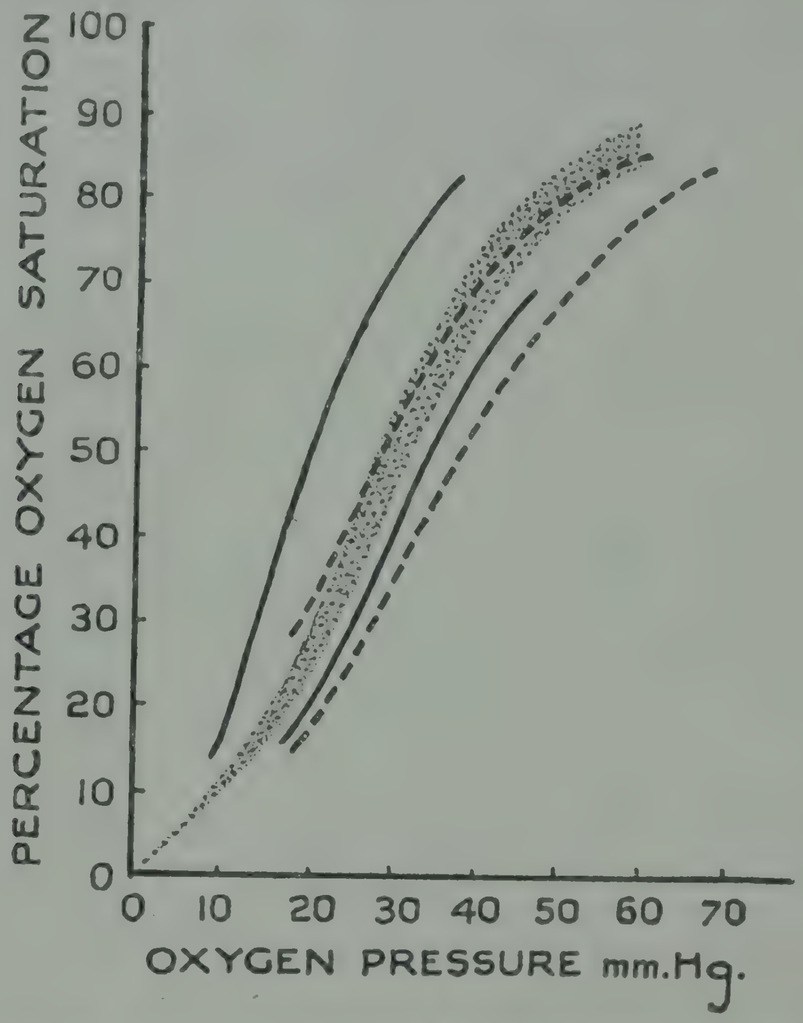

FIG. 685. Oxygen Dissociation Curves of Fœtal and Maternal Goats. The two left curves are from fœtal and the two right from maternal bloods. The shaded area covers the range of dissociation curves of normal adult goats. Stage of gestation: continuous lines, $19\frac{3}{7}$ weeks; interrupted lines, $14\frac{1}{7}$ weeks. (After BARCROFT and others. *Journ. Physiol.*, 1934, **83**, 192.)

Various relations are possible between the directions of flow in the maternal and fœtal vessels of the placenta, as suggested in Fig. 686. That which would give the highest oxygen tension in the fœtal blood would be as shown in A (the condition in the rabbit) in which the fœtal blood on leaving the capillary is in relation with the maternal blood just entering; in B, on the other hand, the fœtal blood would be in equilibrium with maternal venous blood. Probably in man the arrangement is as in C, which, supposing that diffusion equilibrium were reached, would result in a fœtal oxygen tension in the umbilical vein blood higher than that in the maternal venous blood, but lower than that in the maternal arterial blood.

---

* HUGGETT. *J. Physiol.*, 1927, **62**, 373.

† HASELHORST and STROMBERGER. *Ztsch. Geb. Gyn.*, 1930, **98**, 49; 1931, **100**, 48; BARCROFT *et al.* *J. Physiol.*, 1934, **83**, 192.

Actual determination of the oxygen saturation of the various bloods supports this conclusion. J. Barcroft found in the goat and sheep that the percentage saturations are somewhat as follows at about the middle of fœtal life :—

Arterial blood to uterus	95	per cent. oxygen saturation	Maternal circuit.
Venous blood from uterus	60	,, ,, ,,	
Umbilical artery (to placenta)	15–45	,, ,, ,,	Fœtal circuit.
Umbilical vein (from placenta)	70–80	,, ,, ,,	

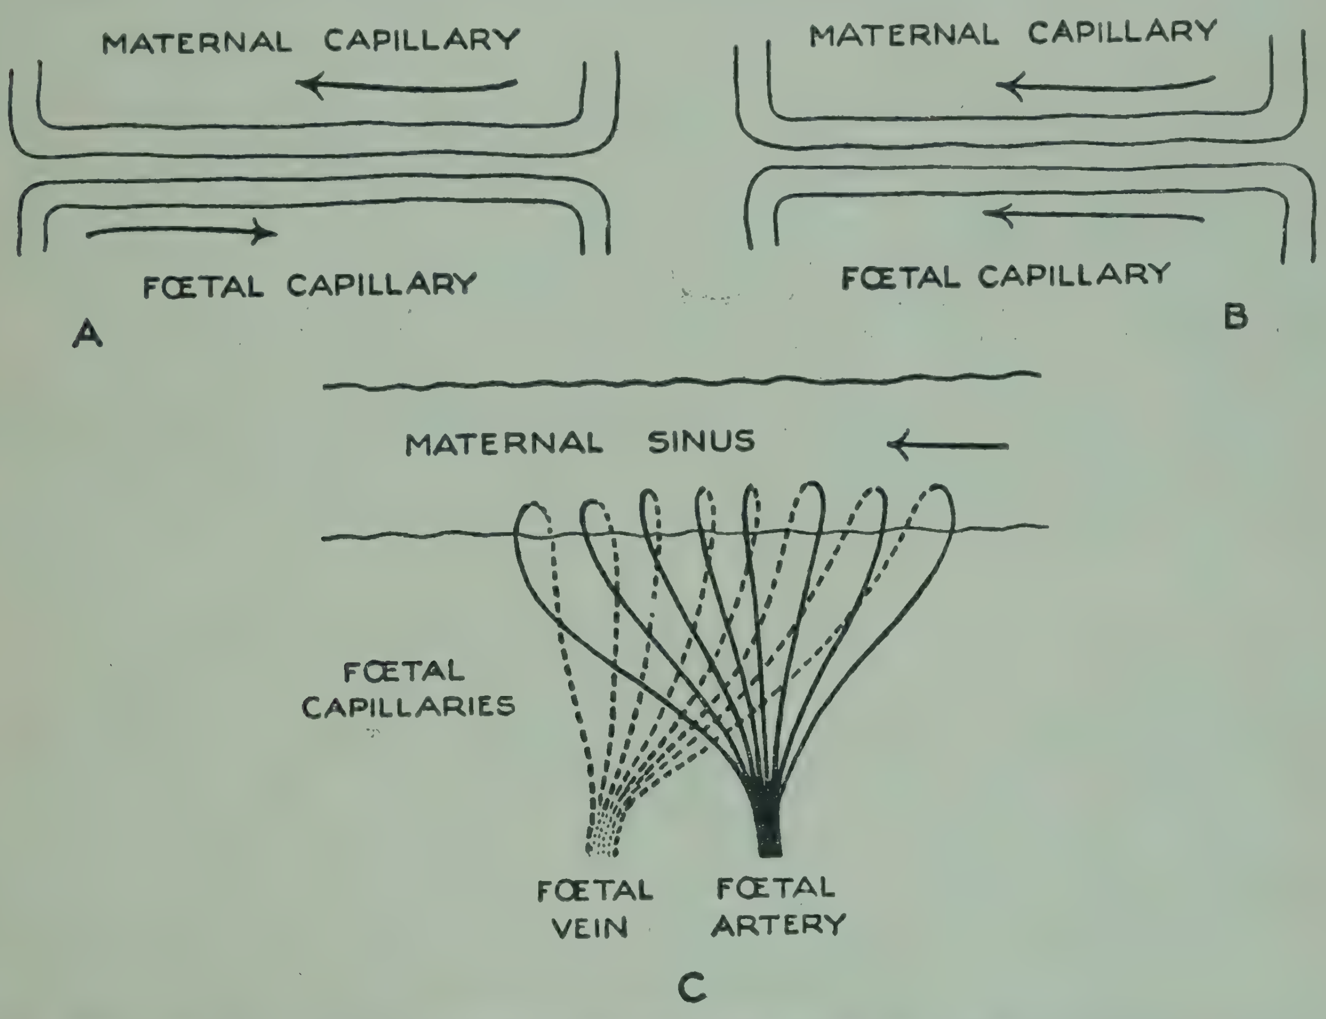

Fig. 686. Possible Relationships between Maternal and Fœtal Circulations. A, opposite flow ; B, parallel flow ; C, " perpendicular " flow. (Newton, " Recent Advances in Physiology.")

As regards the transfer of carbon dioxide, similar considerations will apply. There seems no reason to invoke any other aid than that of diffusion, for effecting the transfer from fœtal to maternal blood.

Changes at Birth. The first breath taken by the newborn child is due to the effect of slight, or sometimes definite, asphyxia consequent upon separation of the placenta from the uterus and to a lesser extent to the influence of cold and of drying of the skin. With sufficiently advanced fœtuses, opening of the uterus or of the uterus and sac in air leads to respiration, but opening under warm saline solution does not. Ligation of the umbilical cord or of the arteries supplying the uterus invariably causes respiration.* Respiratory movements, probably also asphyxial in origin, always occur late in intra-uterine life, but the amniotic fluid thus aspirated into the lungs is reabsorbed. The respiratory centre of the fœtus acts less readily than that of the adult animal.† This appears to be due to an inhibitory influence exerted by the forebrain.

As the time for birth approaches, the oxygen saturation of the blood in the umbilical vein in the human is about 50 per cent., and that in the fœtal carotid artery falls to a level not much above that of the umbilical artery, so that the respiratory centre is now more easily released from inhibition.*

---

* Corey. *J. Exp. Zool.*, 1932, **61**, 1.

† Huggett. *J. Physiol.*, 1930, **69**, 144.

With the first breath taken by the newborn child, several mechanical conditions of the circulation are modified. The resistance to the blood flow through the lungs being diminished, the blood passes from the pulmonary arteries through the lungs into the left auricle. The pressure in the left auricle is thus raised, while that in the right auricle falls, so that the foramen ovale is maintained closed. The oxygen saturation of the arterial blood of infants rises within an hour and continues to improve so that the adult level is reached in from one to two weeks.† Even before birth, proliferation of the lining membrane may be seen both in the ductus arteriosus and in the ductus venosus; and with the mechanical relief of the vessels afforded by respiration and the changed conditions of the fœtus, this proliferation goes on to complete obliteration of the vessels.

PARTURITION

In the first half of pregnancy the uterus is quiescent, and this is attributed to the inhibitory effect on it of progesterone. It is also unresponsive to oxytocin. Later, contractions of rhythmic character appear, at first feebly, then more powerfully. These contractions ordinarily give rise to no sensations, but are felt when they are augmented in consequence of reflex stimulation. During the greater part of pregnancy they have little or no effect on the contents of the uterus. During the last weeks or days of pregnancy, however, these contractions, which have now become more powerful, have a distinct physiological effect. Not only do they, by pressing on the fœtus, cause it, in most instances, to assume a suitable position for its subsequent expulsion, but, affecting the whole body of the uterus, including the longitudinal muscular fibres surrounding its neck, they assist the general enlargement of the organ in dilating the internal *os uteri*, so that the upper part of the cervix is obliterated and drawn up into the body of the uterus some little time before labour has commenced. Towards the end of term also, the uterus becomes sensitive to oxytocin, and this may be a fact of importance.

With these changes in the uterus are associated changes in the round ligaments and in the vagina and vulva. The muscular fibres of the round ligaments become much hypertrophied and lengthened, and these structures can therefore appreciably aid the uterine contractions in the subsequent expulsion of the fœtus. The vaginal walls become of looser texture, and so afford less resistance to distension during the passage of the fœtal head.

Considerable discussion has taken place as to the cause for the onset of labour or parturition, which in man occurs at a nearly constant period of 281 days after conception. It is perhaps significant that the period of gestation is a multiple of the sex cycle (œstrous in animals, menstrual in women). Most of the explanations which have been suggested, such as the great irritability of the uterus at the termination of pregnancy, the loosening of the fœtal membranes, the return of the menstrual congestion after ten missed periods, thrombosis of the placental sinuses, simply replace one question by another. Doubtless the reason why labour occurs at a definite time must be sought for in extrinsic, rather than in uterine, changes. It is probably hormonal in causation, and the problem may be viewed from an interesting angle if we inquire why it is that the presence of the fœtus is tolerated for so long. The quiescence of the uterus is now generally attributed to the production of progesterone; if, in the rabbit, ovulation is artificially induced on the twenty-fifth day of pregnancy, by injection of a dose of the luteinising principle of human pregnancy urine, it is found that parturition does not occur at the normal time of thirty-two days, but at the fortieth day. This is associated with the presence of maximal-sized corpora lutea at the thirty-second day, whereas in a normal pregnancy these are showing degeneration at that time.

---

* Barcroft, Barron, Cowie and Forsham. *J. Physiol.*, 1939, **96**, 12 P.

† Smith and Karplan. *Amer. J. Dis. Childr.*, 1942, **64**, 843.

The presence of the fœtus is not a necessary condition of the continuance of pregnancy, but the placenta appears to be important. If in pregnant mice the fœtuses are destroyed at the twelfth to fifteenth day of pregnancy, the placenta being retained, "pseudo-parturition" with delivery of the placentæ takes place at normal full term,* and is followed, as is normal delivery, by an œstrus period. This indicates that the placenta plays an important part in inhibiting œstrus and so in determining the date of parturition: it also suggests that an œstrus-producing factor is operative at about that time. It is attractive to speculate that the sudden drop in the excretion of combined œstrin and the accompanying increase in the excretion of free œstrin which immediately precede delivery in the human subject may be decisive factors, since it has been shown that the injection of large doses of œstrin into pregnant animals at any stage leads to abortion.

One view at present is that an important factor in the onset of parturition is a reduction in the inhibition exercised up to that time by the presence of progesterone, and so an increasing sensitiveness of the uterus to the action of oxytocin from the posterior pituitary. It is unquestionable that the administration of oxytocin causes rhythmic contractions of the parturient uterus very similar to those of normal labour (Burn and Bourne †), and it is also true that in some species abortion follows removal of the ovaries or of the corpora lutea. There is also some evidence that a liberation of oxytocin from the posterior pituitary may be a decisive factor. Stimulation of the supraoptico-hypophyseal tract results in increased uterine contractions, and a reflex secretion of oxytocin has been described as a result of distension of the genital canal in rabbits.‡ Removal of the pituitary, however, does not always affect the time of onset of parturition § though there is evidence of difficulty in the deliveries. Moreover, although it has been shown that oxytocin produces greater uterine responses when œstrin is also present,‖ this has not been substantiated by experiments on excised uteri treated with these substances.¶

According to Moir, the uterine contraction is a peristaltic one, passing downwards towards the cervix, the contraction of which comes last, and is feeble. The cervix responds differently from the body of the uterus to drugs, and possibly has a different innervation. It has been shown by Newton ** that the cornua of the pregnant goat's uterus respond to oxytocin whereas the cervix is insensitive, while adrenaline relaxes the excised cornua and contracts the cervix.

To understand the physiology of labour it must be realised that not only do waves of contraction pass over the uterine muscle, to be followed by relaxation, but also that adjustments in the length of the muscle fibres occur, by which a "grip" is kept on the contents, should these change in bulk. In other words, "slack" is taken up or paid out according to conditions. Actual parturition, in the woman, is generally divided into three stages. In the first stage the contractions chiefly act in dilating the os uteri. The bulk of the expulsive work is done by the upper segment. A wave of contraction starts at the upper part of the corpus, passes to the lower segment and on to the cervical portion.* The head is pushed down against the latter, and so at the passing off of the contraction, some slack is taken up by the upper segments and some paid out by the cervix, so that the head, once down, cannot return: there is, in the second place, a passive dilatation by the pressure of the fœtal bag of membranes, filled with amniotic fluid, which is forced down as a fluid wedge into the os by the contractions of the uterine corpus. The uterine contractions are essentially rhythmical, being feeble at first, and increasing gradually in intensity to a maximum which endures a certain time, and then gradually subsides. The frequency and duration of the contractions increase as labour advances.

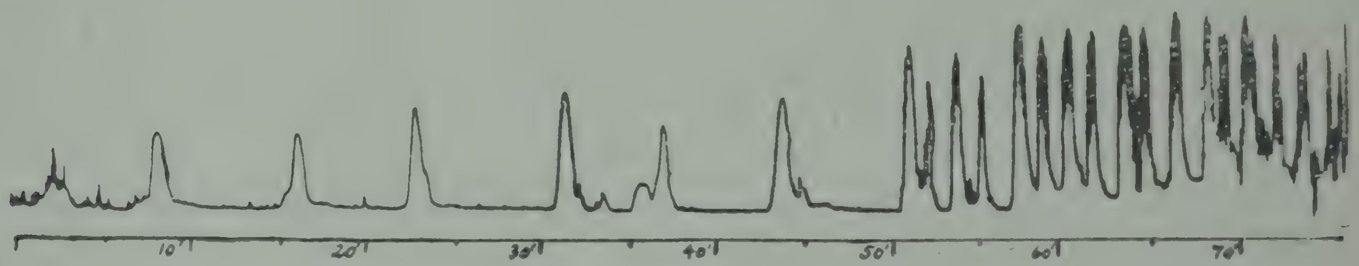

FIG. 687. Record of intra-uterine pressure of woman in labour. Note first stage pains up to the 50′ mark. Second stage pains recorded during next twenty-five minutes; they begin suddenly. The head of the child was born at 75′ where the pressure momentarily drops, and the body just after the last rise of the lever. The patient was a multipara. (BOURNE and BURN.)

Finally the cervix and os become fully dilated. The membranes generally rupture towards the end of the first stage of parturition.

The second stage begins as soon as the os uteri is fully dilated and the fœtal head has entered the pelvis, when the contractions change in character, being much more prolonged and frequent ("labour pains") and attended by more or less voluntary contractions of the abdominal muscles. This action of the abdominal muscles is associated with fixation of the diaphragm and closure of the glottis, so that pressure is brought to bear on the whole contents of the abdomen, including the uterus. After each wave has pressed the head down a little further, a relaxation follows: in this the head ascends a little, but not much, because of the progressive adjustment in length of the uterine fibres. No expelling force can be ascribed to the vagina, since it is too greatly stretched by the advancing fœtus. In this way, the fœtus is gradually thrust through the pelvic canal, dilating the soft parts which impede its progress, and is finally expelled through the vulva, the head normally being born first (Fig. 687).

A third stage of labour is generally described. This consists first in a considerable closing-in of the uterus, until it can regain grip of the greatly reduced contents; then, about twenty to thirty minutes after the birth of the child, a renewal of uterine contractions results in the expulsion of the placenta and decidual membranes, and the closing, by compression, of the venous sinuses.

Nervous Mechanism. We possess little experimental knowledge of the nervous mechanism of parturition. Goltz observed the normal occurrence of heat, impregnation, and parturition in a bitch whose spinal cord had been completely divided in the dorsal region during the previous year. On the other hand, destruction of the lumbo-sacral cord completely abolishes the normal uterine contractions of parturition, so that this act must be regarded as essentially reflex, presided over by a controlling " centre " in the grey matter of the cord. The activity of the centre can be inhibited or augmented by impulses arriving at it from the peripheral parts of the body, as by the stimulation of sensory nerves, or from the brain, as under the influence of emotions. The nerve paths from the centre to the uterus have been already described.

---

THE PUERPERIUM. After delivery the uterus undergoes involution, and lactation soon commences. In the latter phenomenon the lactogenic hormone of the pituitary plays a decisive *rôle*. Suckling of the child is important in accelerating the involution of the uterus, which is caused to enter into powerful rhythmic contractions each time the child is put to the breast (Fig. 688). Excretion of œstrin and of gonadotropic hormones in the urine rapidly falls off and reaches the normal level in a week or ten days. Menstruation recommences when lactation is finished.

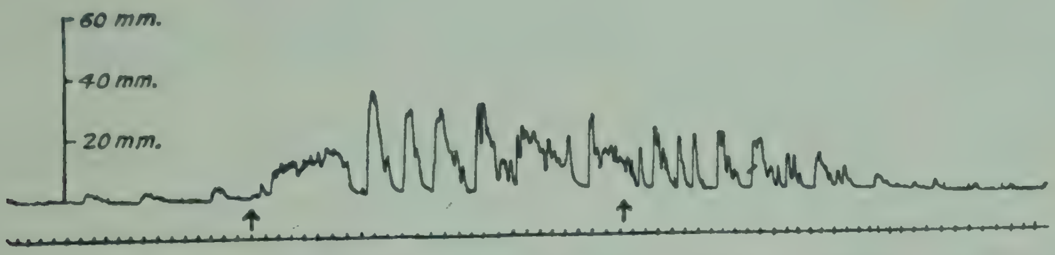

FIG. 688. Contractions of Human Puerperal Uterus. Suckling (between the arrows) caused increased contractions. (After MOIR. *Edin. Med. J.*, 1934, **41,** 93.)

CHAPTER LIII

THE SECRETION AND PROPERTIES OF MILK

After birth the nutriment supplied to the child normally depends on the supply of milk by the mammary glands. Nutrition now involves further activity on the part of the infant, the alimentary canal being concerned in the digestion of the milk supplied by the mother, and the kidneys being made use of for getting rid of waste material.

Growth and Functional Differentiation of the Mammary Glands. The preparation of the mammary glands for the subsequent nourishment of the newborn child begins in the first month of pregnancy, and is marked by swelling of the glands, rapid proliferation of the duct epithelium, and production of many new secreting alveoli. As we have seen, there are probably at least three hormonal factors concerned in these processes—œstrogen and progesterone from ovaries and placenta (an optimal ratio is 240 I.U. œstrone to 1 mg. progesterone), and prolactin from the anterior pituitary. Œstrogens, progesterone and pituitary hormones are also available in the course of the normal menstrual cycle, and are no doubt responsible for the periodical enlargement of the breasts at each menstrual period. Throughout these changes, and throughout pregnancy, however, the secretory activity of the enlarged glands is held in abeyance.

The œstrogens cause an increased vascularity of the mammary tissue and enhance its permeability to progesterone : they induce growth, chiefly of the duct system, and of the epithelium of the nipple, while progesterone causes growth and differentiation, up to the threshold of lactation, in the secreting alveoli. Many steroids, and also diethylstilbœstrol, have a similar effect. Œstrogens and progesterone are effective in ovariectomised animals, and, when given in large doses, can produce growth and development of the mammary glands, and even lactation, in males. But they are ineffective in causing mammary growth in ovariectomised and hypophysectomised animals, though the effect on the nipple is obtained.

Doubt exists as to the part played by the anterior pituitary. One view is that the œstrogen and progesterone incite the pituitary to produce two new hormones, called respectively Mammogen I and Mammogen II. Others think that the effects can be attributed to a collaboration between already recognised anterior pituitary hormones, and particularly the growth hormone and prolactin, on the one hand, and œstrogen and progesterone on the other. Implantation of pituitary after hypophysectomy restores the proliferating effect, and hence collaboration between a pituitary hormone, œstrogen and progesterone seem essential at an early stage, as well as later.

The placenta can probably also play during pregnancy a part similar to that of the anterior pituitary, since if pregnant animals of some species are hypophysectomised, mammary development continues. In mice, the fœtus can be killed by crushing, but the placentæ remain till term : mammary growth then continues : but if the placentæ are also removed, the glands atrophy.*

Lactation. With the expulsion of the fœtus at birth the overgrown gland cells enter into a condition of activity, and the secretion of the gland, once formed, is continued independently of the fœtus, or, indeed, of any of the pelvic organs. For this initiation and maintenance of secretion, hormones of the anterior pituitary are mainly responsible. Certainly lactation is at once arrested after hypophysectomy,† while on the other hand, if preliminary breast growth be induced, by previous dosage with œstrogen and progesterone, injection of crude anterior pituitary extracts will cause lactation in immature females, or even in males. They have been successfully employed clinically in cases of failure of lactation.[*]

---

* Newton and Beck. *Endocrin.*, 1939, **1**, 65.

† Selye, Collip and Thompson. *Endocrinol.*, 1934, **18**, 237.

Among the anterior pituitary hormones which are responsible for the induction of lactation, the lactogenic hormone, prolactin, is important: but it has been found that, when pure, it is not by itself competent to precipitate full lactation or to maintain and reinforce a declining lactation.[†] Its effect is possibly due to an influence on carbohydrate metabolism. The presence of the adrenocorticotropic hormone, together with prolactin, is also probably essential for lactation.

Other endocrine organs also play an essential *rôle* in the determination and maintenance of lactation. The adrenals, for instance, are essential, and after their removal lactation ceases, probably because of fundamental changes in general metabolism. It has been shown that, of the various adrenal steroids, the essential one is that responsible for carbohydrate metabolism (17-hydroxy-11-dehydro-corticosterone), though there must also be present enough desoxycorticosterone to conserve normal salt and water balance.

The thyroid appears to play no indispensable part in the initiation of lactation, but contributes unquestionably to its upkeep: thyroidectomy often diminishes the milk yield, while administration of thyroxine definitely raises the milk fat content. The influence of the thyroid is probably indirect, and due to its effect on the general metabolism. Parathyroid hormone is also essential for full milk yield, which is not surprising in view of the high calcium content of milk.

An important question is why, in most cases, lactation does not commence until after parturition. One view is that lactation is held in abeyance by some such factors as the presence of the corpora lutea, or the placenta, both of which would act by formation of hormones, or by the mechanical distension of the uterus, which would presumably be reflex in nature. None of these suggestions adequately accounts for the phenomenon in all cases, or in all species. It seems more probable that by full term the mammary glands are fully developed, and only await the stimulus of prolactin, in presence of other essential hormones, for full lactation to commence. There is an increase in the prolactin content of the anterior pituitary towards term, and during the period of nursing, which is probably sufficient to initiate and maintain lactation, provided the milk is regularly drawn off.

During the latter half of pregnancy, a watery fluid can generally be expressed from the nipple. In certain mammals, this watery secretion gives place to a secretion of true milk at the end of gestation, or during the process of parturition itself. In the woman, though the formation of milk may be hastened if a child has been put to the breasts during the latter part of pregnancy, secretion normally begins on the second or third day, even if the child has been born dead and no attempt at suckling has taken place.

Removal of Milk. Normally, the only condition which is necessary for secretion to continue during six to nine months after parturition is the repeated removal of the secreted milk. The process of suckling removes the milk already formed, and this leads to the secretion of more milk. This it probably does, in part, by causing reflexly an increased formation of lactogenic hormone in the anterior pituitary.[‡] The reflex may originate from the nipples, but the release of tension on the uterine walls seems to be an accessory condition, since emptying of the uterine contents may precipitate lactation, while distending the emptied uterus with paraffin wax delays or inhibits it.

A more important factor in suckling is probably a release of oxytocin into the blood by a reflex which acts upon the posterior pituitary :[*] this causes contraction of the plain muscle of the capacious milk sinuses, and so aids in the expulsion of the milk. It is of importance, therefore, to distinguish between milk secretion and the expulsion or removal of the milk in any way.

[‡] Selye. *Amer. J. Physiol.*, 1934, **107**, 535.

It is well known that if milking is suspended, further formation of milk soon ceases, while more frequent milking leads to production of a larger total milk yield. This appears to be because, as soon as the pressure in the mammary alveoli reaches a certain figure—some 25–40 mm. Hg.—further secretion of milk ceases : frequent emptying therefore, by keeping the pressure on the secreted milk low, encourages further secretion. An increase of blood sugar, or administration of thyroxine, cause in cows an increase in the volume and concentration of the milk.[†] If a woman does not nurse her child, the swelling of the breasts gradually passes off, the milk disappears, and the glands undergo a process of involution. Under normal conditions the secretion of milk lasts for six to nine months, and may in rare cases extend over more than a year. The amount secreted increases at first with the growth and size of the child, and often may reach 1·5 to 2 l., or occasionally 3 l. daily. The table above represents the average amount of milk secreted during the thirty-seven weeks after confinement. It will of course be greater with strong, big children, and smaller with weakly children.

Table showing Amount of Milk Secreted by a Nursing Woman

Time	Milk secreted daily
INCREASE	
1st day	20 grammes.
2nd ,,	97 ,,
3rd ,,	211 ,,
4th ,,	326 ,,
5th ,,	364 ,,
6th ,,	402 ,,
7th ,,	478 ,,
2nd week	502 ,,
3rd–4th week	572 ,,
5th–8th ,,	736 ,,
9th–12th ,,	797 ,,
13th–16th ,,	836 ,,
17th–20th ,,	867 ,,
21st–24th ,,	944 ,,
25th–28th ,,	963 ,,
DECREASE	
29th–32nd week	916 grammes.
33rd–36th ,,	909 ,,
37th week	885 ,,

Colostrum. Before the secretion of true milk begins, the fluid which is obtained from the breasts is known as colostrum. It may be expressed from the breasts immediately after delivery and is ingested by the child during the first two days. The colostrum is formed only in slight quantities. It is an opalescent fluid, often somewhat yellowish, containing fat globules which, if the fluid be allowed to stand, form a yellowish layer on the top. Under the microscope, in addition to the fat globules, may be seen the so-called colostrum corpuscles, which are multinucleated cells loaded with particles of fat. They are probably leucocytes or phagocytes which have wandered into the alveoli and have taken up fat globules. Some of the corpuscles may be desquamated secretory cells. Colostrum is distinguished from true milk by containing little or no caseinogen. It contains about 8 per cent. of proteins, namely, lactalbumin and lactoglobulin, which coagulate on boiling. Lactose and fat are present in smaller, and salts in greater amount than in ordinary milk. It is popularly supposed to have a laxative effect on the child.

A fluid resembling colostrum is obtained at later stages if withdrawal of milk is suspended for a few days. The explanation of colostrum is that it is formed by retention of the milk as soon as the intra-alveolar pressure reaches a level at which secretion ceases, the contents tend to come into equilibrium with the blood, and the resultant fluid is colostrum.

---

[*] Ely and Petersen. *J. Dairy Sci.*, 1941, **24**, 211.

[†] Folley and White. *Proc. Roy. Soc.*, 1936, **120B**, 346.

THE SECRETION OF MILK. When fully formed, each mammary gland consists of fifteen to twenty lobes embedded in connective tissue. Each obe is made up of a mass of secreting alveoli, which lead by narrow ducts into one large lactiferous duct. These lactiferous ducts, one from each lobe, open on the nipple, undergoing in the nipple itself an oval enlargement. Before pregnancy, the alveoli as well as the ducts are lined with a cubical epithelium. Early in pregnancy a marked difference develops between the epithelium of the alveoli and that of the ducts.

The secreting cells increase in size and especially in height, and numerous small fat cells, mitochondria and spherical "pseudo-yolk" granules are present.* At later stages the fat globules increase in size and collect towards the lumen, while the pseudo-yolk granules disappear. When lactation sets in the cells contain elongated mitochondria and one or two large fat globules next to the lumen; ultimately the fat globules are discharged, together with a little cytoplasm, by a budding-off process, into the secretion in the lumen (Fig. 689). During the stage of enlargement and also during lactation there are frequent mitotic divisions in the alveolar cells. A few cells degenerate and are shed, as also are a certain number of leucocytes.

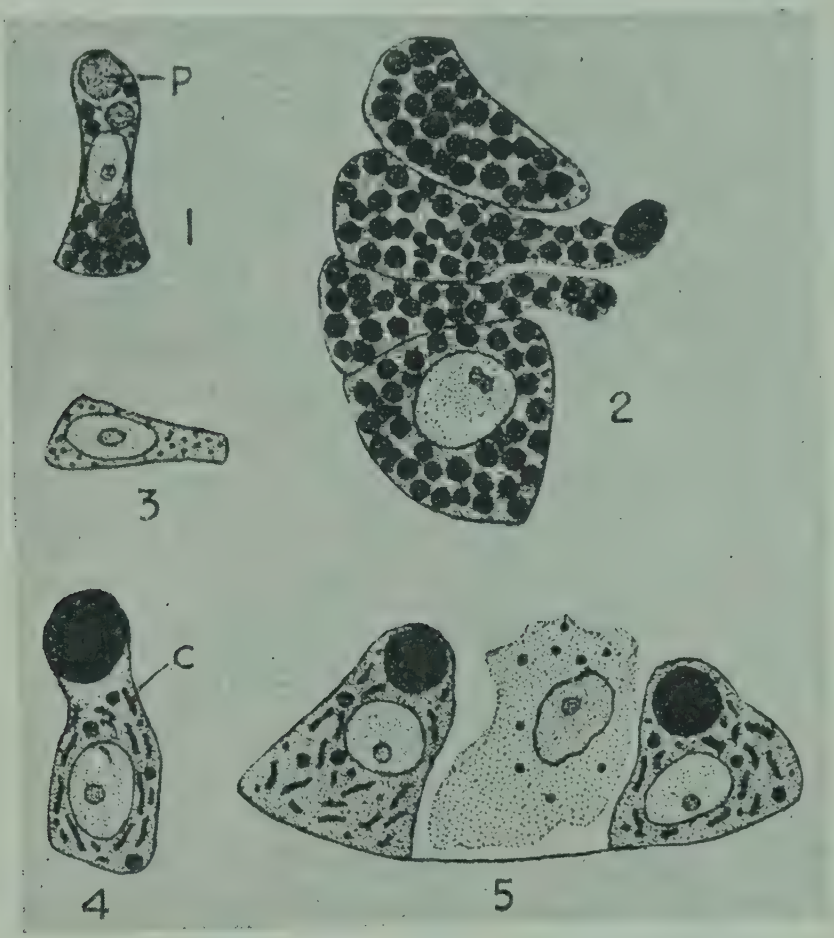

FIG. 689. Cells of Mammary Gland of Rat. (1) and (2) On eighteenth day of pregnancy: Fig. 2 shows elimination of a large fat drop. (3) A cell after fat has been secreted, a few hours before parturition. (4) Cell in full lactation, seven days after parturition. (5) Two normal cells and one that is degenerating and passing into the lumen; twelfth day of lactation. p = pseudo-yolk spheres, c = chondriosomes. (JEFFERS. *Amer. J. Anat.*, 1935, **56**, 257.)

The secreting mammary gland is very vascular, about 300 to 400 volumes of blood being needed for each volume of milk produced.

We know very little about the biochemistry of milk secretion. It seems impossible at present to explain the very close adaptation between the activity of the secretory cells and the needs of the infant or young animal. Two at least of the constituents of milk, caseinogen and lactose, are peculiar to this secretion. It would seem that the caseinogen is produced by the gland cells by synthesis from the amino acids and probably also from globulin of the blood stream, and that the lactose is derived, also by synthesis, from the blood sugar, and perhaps also from lactate. Slices of surviving lactating mammary gland can form lactose from glucose, but not from fructose, mannose or galactose.† The fat similarly originates in the blood fat,‡ and much of it ultimately in the fat of the food, or of the body depots. The phosphorus compounds of milk are derived from the inorganic phosphate of the blood.

† GRANT. *Bioch. J.*, 1935, **29**, 1905; 1936, **30**, 2027.

‡ GRAHAM, JONES and KAY. *Proc. Roy. Soc.*, 1936, **120B.**, 330.

The food of the mother may be varied within very wide limits without altering the composition or amount of the milk secreted, provided that the food is sufficient in amount. The only constituent of the milk for which we have direct evidence of alteration by changes in the food supply of the mother is the fat. It is well known that the composition of butter may be affected according to the food supplied to the cow. A large supply of oilcake, for instance, may result in the production of a butter which is deficient in the saturated fatty acids and is therefore oil at ordinary temperatures. Abnormal fats and fatty acids such as iodised fats or erucic acid, when administered to an animal in lactation, may appear among the fats of the milk.

Not only can the secretion and composition of the milk be affected reflexly through the nervous system, as *e.g.* under the influence of emotions, but the influence may be reciprocal. This is especially marked in the case of the pelvic organs. The act of suckling excites rhythmic contractions of the uterus (*v.* Fig. 688). Putting the child to the breast shortly after birth is, therefore, an important means of causing contraction of the uterus, and stopping any tendency to hæmorrhage from the venous sinuses opened by the separation of the placenta and fœtal membranes. The nursing of the child is thus an important means of procuring a proper involution of the uterus after labour.

PROPERTIES OF MILK

Fully formed milk presents certain features which are common to all mammals. We may therefore deal with the composition of cow's milk and point out later in what respects human milk differs therefrom. Milk is an opaque, white fluid, with characteristic odour and sweetish taste. Its specific gravity varies between 1028 and 1034. The pH = 6·6—6·8, and it therefore contains no bicarbonate ; as it contains buffers, *e.g.* phosphates and caseinogen, it may be titrated, with suitable indicators, against either acids or alkalies. One hundred cubic centimetres of average fresh milk, when titrated to methyl orange, require 41 c.c. $n/10$ acid for neutralisation. When titrated to phenolphthalein the same amount requires 18 c.c. $n/10$ alkali for neutralisation. When exposed to the air, milk rapidly undergoes changes in consequence of infection by micro-organisms. The most common of these changes is the formation of lactic acid by the *bacillus lacticus.* Exceptionally, the milk may undergo a species of alcoholic fermentation, as in the formation of *kephir,* which is made by the fermentation of mare's milk.

Composition of Milk. FATS. The opaque appearance of milk is due chiefly to the presence of multitudes of fine particles of fat. On allowing the milk to stand, or by centrifugation, the particles rise to the surface, forming cream, and by mechanical agitation, especially if the milk is slightly sour, they may be caused to run together with the formation of butter. The reason why the fat globules do not run together naturally is probably because, in any protein solution, such as that in which the globules are suspended, the protein tends to aggregate, with the formation of a pellicle, at the surface, so that an emulsion once produced in such a fluid will tend to be more or less permanent. The fats of milk consist for the greater part of the neutral glycerides, tripalmitin, tristearin, and triolein. In smaller quantities it contains the triglycerides of butyric acid, and all other saturated fatty acids, of even carbon numbers up to lignoceric (C_{24}), and various unsaturated acids also. It also contains some lecithin and cholesterol.

The milk plasma, the fluid in which the fat globules are suspended, contains various proteins, lactose, and inorganic salts, with a small amount of lecithin and nitrogenous extractives.

PROTEINS. The chief protein of cow's milk is *caseinogen*, a phosphoprotein soluble in dilute alkalies. It may be prepared from separated milk by the addition of weak acids. The precipitate may be washed by decantation, and purified by solution in dilute ammonia and precipitation by acetic acid two or three times. The precipitate is extracted with alcohol and ether, and forms a snow-white powder which is practically insoluble in water and dilute salt solutions. It is easily dissolved on the addition of a little alkali, when it yields solutions which are acid to litmus. When rubbed up with chalk it dissolves, displacing carbon dioxide and forming a calcium caseinogenate. A solution of caseinogen in NaOH or KOH is transparent and passes easily through a clay cell. The calcium caseinogenate forms opalescent solutions. Apparently the compound is hydrolysed by water with the formation of caseinogen acid, which is in a state of partial solution as swollen-up aggregates. It is impossible, therefore, to filter calcium caseinogenate through a clay cell. It is mainly in this form that caseinogen is contained in milk, hence the opalescent appearance of the milk plasma. On treating caseinogen with chymosin, it is converted into a modification known as *paracasein*, which in the presence of calcium salts is thrown out as insoluble *casein*. To this process is due the clotting of whole milk by rennet, which is made use of in the preparation of cheese, the curd consisting of a spongework of casein enclosing fat globules in its meshes. On allowing the clot to stand it shrinks, pressing out the whey.

From the whey may be obtained two other proteins, known as *lactalbumin* and *lactoglobulin*. These resemble the albumin and globulin of blood serum. They are coagulated on heating, and form a pellicle on the surface, as milk does. In human milk there is more lactalbumin (about 0·7 per cent.) than caseinogen (about 0·3 per cent.). According to some authors a third protein is present in the whey, to which the name whey protein has been given, and which is supposed to be split off from the caseinogen under the action of chymosin.

Milk can be boiled without undergoing general coagulation. If it be allowed to stand and become slightly sour by the formation of lactic acid, at a certain degree of acidity boiling the milk causes its complete coagulation. Later on the acid produced is sufficient in itself to precipitate the caseinogen. Both these processes—namely, coagulation of half-sour milk by heating, and spontaneous clotting of milk by the production of acid—are made use of in different countries for the manufacture of cheese.

Carbohydrate. The lactose is most easily obtained from whey, which is boiled to precipitate the remaining proteins. On filtering and evaporating slowly, the milk sugar crystallises out. Lactose is a disaccharide which on hydrolysis by acids, or by the lactase of the intestinal juice, yields glucose and galactose. It may be found in the urine of nursing women when the breasts are not kept empty, owing to reabsorption into the blood of the lactose formed in the mammary glands.

Salts. The salts of milk include calcium, sodium and potassium as phosphates, citrates, proteinates and chlorides. It is said to be deficient in iron.

Significance of Constituents. The composition of milk depends on many factors, such as diet, health, frequency of milking, exercise, emotional states, etc. Human milk shows a change in composition in the course of lactation, as shown in the Table below, the protein declining, the lactose and fat increasing slightly.

Average Composition of Human Milk (After Bell[*])

Time.	Protein.	Lactose.	Fat.
5 days	2·00	6·42	3·2
9 ,, ...	1·73	6·73	3·7
3–4 weeks	1·37	7·11	3·6
5–6 ,, ...	1·30	7·11	4·0
7–8 ,, ...	1·21	7·11	4·0

Milk contains vitamins A, B_1, B_2, C and D in adequate amount.

[*] Bell. *J. Biol. Chem.*, 1928, **80**, 239.

Milk is excellently adapted to the needs of the growing animal. In the first place, we find a proportionality between the total solids of the milk and the rate at which the young animal grows. The milk taken by the animal serves only in part for the production of energy, a great proportion of it being required for the building up of new tissue. In no respect is this correspondence seen better than in the comparative analyses of the ash of milk and of the young animal of the same species. Thus, the calcium content of human milk is 0·04 per cent., and that of rabbit's milk about 0·9 per cent. This close correspondence is necessary only where the growth is very rapid, so that the greater part of the constituents of the milk have to be utilised in the building up of the animal tissues. The slower the growth of the animal the greater the divergence between the composition of the milk and that of the newborn animal.

The relation between rate of growth and protein content of the milk is well illustrated by a comparison of the composition of the milk in different animals. In the following Table (Proscher) it will be seen that the more rapidly an animal grows the greater is the protein content of the milk supplied by its mother :

	Time in which the body weight of the newborn animal was doubled. Days.	Protein. Per cent.
Man	180	1·6
Horse	60	2·0
Cow	47	3·5
Goat	19	4·3
Pig	18	5·9
Sheep	10	6·5
Dog	8	7·1
Cat	7	9·5

We should expect that the milk, which is the sole food of the growing infant, would contain a relatively greater proportion of protein than is necessary for the adult. In an experiment by E. Feer, quoted by Bunge, a child weighing 8,226 g. at the thirtieth week took 951 g. of milk daily. Human milk contains :

Protein	1·6 per cent.
Fat	3·4 ,,
Sugar	6·1 ,,
Ash	0·2 ,,

The child was therefore receiving daily :

Protein	15·4 g.
Fat	32·3 ,,
Sugar	58·0 ,,
Ash	1·9 ,,

According to the same proportions a man of 70 kilos. fed entirely on milk would take in

Protein	129 g.
Fat	275 ,,
Sugar	494 ,,
Ash	16 ,,

It is interesting to note that the protein of this diet is somewhat above that in the diets ordinarily accepted as standard, but there is a large excess in the fat and in the total Calorie value, as would be expected from the more rapid metabolism and the relatively larger body surface of the young child.

The fitness of caseinogen for building up the tissues of the body is evident when we compare the products of its hydrolysis with those of the proteins in other foodstuffs. It will be seen from the Table on p. 44 that practically every amino-acid and allied substance employed in the building up of the various proteins is represented in caseinogen. The only exceptions are glycine, which can easily be synthesised in the body, and cysteïne, which is present, however, in lactalbumin.

We thus see that, under normal conditions, the young animal is supplied, through its natural food, with all the foodstuffs in the proportions which it requires for its normal nourishment and growth. It is not easy, however, satisfactorily to replace the natural milk of an animal by that of another species. In civilised communities it is becoming more and more the custom to endeavour to feed infants with cow's milk, more or less modified, in the vain endeavour to reproduce the properties of human milk. Among all classes, this involves the administering of a milk differing in its properties and in the relative proportions and qualities of its proteins, fats, carbohydrates, and salts, from human milk. So-called "humanised" milk is only a rough imitation of the natural mother's milk. Among the poorer classes this artificial feeding means the replacement of a natural sterile food, throwing very little work on the digestive organs of the child, by a foreign milk, very difficult to digest and often teeming with micro-organisms. In some cases it is necessary to adopt artificial feeding because there is an insufficient secretion of milk. It is therefore important to know what are the main differences in composition between human and cow's milk. In human milk, the caseinogen is, not only absolutely, but also relatively, less than in cow's milk, while the latter is relatively poorer in lactose. Human milk is poorer in salts, especially in lime, containing only one-sixth of the amount present in cow's milk. The main difference may be summarised as follows :—

	Water.	Proteins.		Fat.	Lactose.	Salts.
		Caseinogen.	Albumin			
Human milk . .	88·5	0·3	0·7	3·7	6·7	0·2
Cow's milk . .	87·1	2·3	0·7	4·0	4·8	0·7

The simplest modification of cow's milk to adapt it for the human infant is to dilute it, and add cream and lactose.

CHAPTER LIV

HEREDITY [*]

FROM the fertilised human ovum, there is formed, as a result of some fifty successive mitotic divisions, an individual consisting of about 2^{48} cells,[†] and partaking of many of the minutest characteristics of both its parents. An egg cell has much the same appearance, whether it belong to an echinoderm, a fish, or a woman. In the process of development, by a simple repetition of a series of cell divisions, this undifferentiated protoplasm is formed into the complex organs with the potentialities and habits which distinguish the type from which it has been derived. There must, therefore, be some difference between different eggs. We cannot wonder that the intimate nature of this process has been the subject of speculation from the very birth of science. Running through these speculations were two main ideas, which have been labelled the theories of "evolution" and of "epigenesis." By the "evolutionists" the egg was believed to contain an embryo fully formed in miniature, as the bud contains the flower or the chrysalis the butterfly. Development, therefore, was only the unfolding of something already existing. If, however, this theory be pushed to its utmost, and if the egg contain a complete embryo, this must itself contain eggs for the next generation, and so on *ad infinitum*, a conclusion which of course is absurd. According to the theory of epigenesis, the structure of the egg is wholly different from that of the adult, its development into the new individual consisting in the continual formation one after the other, of new parts previously non-existent as such. There is no doubt that this view is fundamentally correct.

The difficulty with which we have to contend is the understanding of the orderly sequence and correlation of the cell divisions and differentiations which result in an adult individual of the same type as the parents. The fact that, under approximately identical conditions, one mammalian ovum will give rise to a mouse and the other to a man, indicates that there must be some preformed differentiation in the nuclear structures, *i.e.* chromosomes, of the ovum itself. We have already seen that in some types the germ cells are separated off from the rest of the embryo at a fairly early stage. If, in the two-celled stage of the frog's egg, one cell be destroyed by means of a hot wire, the other cell develops to form half an embryo, thus suggesting that each cell of the two-celled embryo could give rise only to the corresponding half of the body. This limitation of development, however, occurs only if the intact cell be left in connection with the cell that has been injured. If, in echinoderm larvæ, the cells be entirely separated, even as late as the eight-celled stage of division, each cell will give rise to a whole embryo, differing from a normal embryo only in respect of size. In man too, "identical twins" result similarly from separation of the two cells formed by the first division of the fertilised ovum. This suggests that the number of divisions that each cell can undergo is predetermined in the egg itself, but shows also that the cells into which the egg divides are, at first at any rate, equipotential. We must assume, therefore, that the reason why one cell under ordinary circumstances forms only one half of the embryo is that its development is regulated and determined by the presence of the other cell in connection with it and forming the other half of the embryo. That is to say, the development of the egg involves the adaptation to environment of a protoplasm of certain properties and powers of eaction. The final product of development depends (1) on the nature of the protoplasm (including the nucleus) of which the egg is composed, and (2) on the environmental conditions to which the egg is subjected during the rapid growth and multiplication attending its development. We could therefore speak of a morphology of inheritance, but the morphology would be ultra-microscopic and have relation to the molecular structure of the protoplasm of which the egg was composed.

---

[*] The subject of genetics is now highly specialised, and it must be understood that all that can be attempted here will necessarily be of the nature of a very superficial synopsis of salient points.

[†] HALDANE. *Proc. R. S.*, 1948, **135B**, 168.

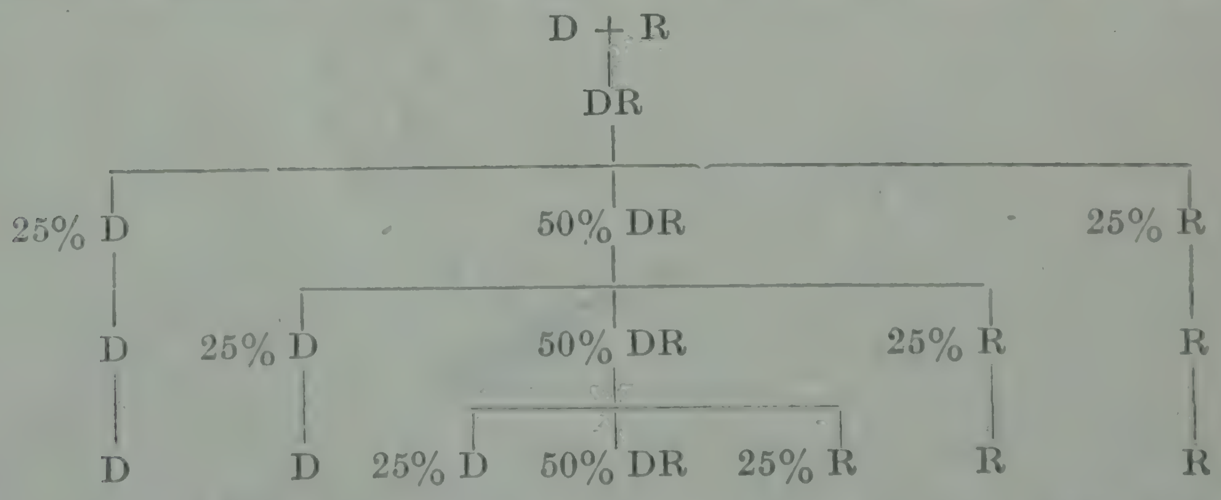
In the transmission of the potentialities of development from parent to fertilised egg, we must regard the nucleus as the essential structure. In ordinary development the spermatozoon furnishes only half a nucleus and a centrosome, the ovum supplying the other half nucleus and the whole of the cytoplasm. In division of the egg, the only part of the cell which can divide so that each daughter cell shall include an equal part of both parental germs is the nucleus. The constant number of the chromosomes in each species, and their accurate division on mitosis, suggest that the hereditary transmission of the potentialities of the cell is bound up with the chromosomes. It is now believed that every inheritable character is located in a chromosome, or part of a chromosome. If this be the case, one might regard the differentiation into various tissues, which occurs in the process of development, as occasioned by the modification or actual loss of the constituent parts of one or more of the chromosomes present in the pluripotential fertilised egg-cell. There is no doubt that many tissues do become thus differentiated at a fairly early period in development, having undergone in the process an absolute modification of their potentialities, which must be at any rate shared by the chromosomes of their constituent cells. The extent to which this limitation of powers of development occurs varies widely in different animals. In the higher animals, such as man, epithelium will reproduce epithelium and liver cells will reproduce liver cells, while nerve cells once definitely characterised are absolutely incapable of multiplication. On the other hand, in crustacea, a whole limb may be torn off and be regenerated from the tissues of the stump. Destruction of the optic lens in the salamander is followed by its regeneration from the anterior part of the optic cup, a tissue which had no part in its primary formation. Worms will form a new head after decapitation. In these animals, therefore, the cells in many parts of the body possess the power of directed growth, if need arise in case of injury, and are able to form tissues of many different kinds.

We have mentioned the small size of the larvæ formed from isolated cells of the segmenting egg as a proof that the number of cell divisions of the somatic part of the developing animal is predetermined and limited. This conclusion must not be taken too absolutely. Many of the tissues, even of the highest animals, possess the power of almost unlimited regeneration by cell multiplication as a response to injury. Under normal conditions, the growth of such tissues is limited, not by absence of power to divide, but as a result of a mutual interaction between them and the surrounding cells. We might almost speak of a struggle for existence between the various tissues of the body, which, in the healthy organism, results in a balance of multiplicative powers. If this balance is upset by any means, such as stimulation of certain cells by the presence of intracellular parasites, or their destruction by irritants or other abnormal conditions (*e.g.* exposure to X-rays), one tissue may enter into active growth at the expense of the surrounding tissues, and the result is a morbid growth such as cancer. It is possible that in the latter case a new factor comes into play. All tissues of the body, as we have seen, begin to die from the time that they are born. They have a certain span of life, a certain limitation to their generations, which results in the phenomenon of senescence, such as occurs in a culture of protozoa. In protozoa this phenomenon is the signal for rejuvenation by conjugation. It is possible that, in cancer, something of the same nature occurs. It is, at any rate, significant that in a rapidly growing cancer, many of the dividing cells present the phenomenon of meiosis, a phenomenon which is otherwise found only in the ripening sexual cells. Given adequate conditions of nutrition, there seems to be no limit to the growth of cancer cells. In mice, a cancer may be transferred from one individual to another by inoculation, and this process may apparently go on indefinitely.

In sexual reproduction, the new individual partakes of characteristics of both its parents. It therefore resembles neither of its parents in all details. The conjugation of the two parent cells, from which it is derived, has been preceded by a throwing out of half the chromosomes from each parent cell. It is therefore natural to ascribe the variations, which occur among the members of one family, to a qualitative difference in the chromosomes which have been retained in the formation of their respective egg cells. Can we regard the chromosomes as representing separate qualities of the individual, or must we assume that all qualities are presented to a greater or less extent in every chromosome? In the case of many qualities, especially those which distinguish the species as apart from the individual variation or family characteristic, we must probably accept the latter idea as correct. In this case, the child can be regarded as representing an arithmetical mean of both its parents. In certain respects, however, a quality seems to be transmitted from parent to offspring, either completely or not at all. This is specially applicable to those characters which have been rapidly produced by artificial selection, characters which, if artificial selection be abandoned, rapidly disappear, with reversion to the type from which the special strain was initially produced. These characters are alternative or *allelomorphic*— *e.g.*, tallness or shortness, blue eyes or brown eyes.

LAWS OF INHERITANCE

Mendel's First Law. The way in which these characteristics are transmitted was first studied by Mendel and has been formulated as "Mendel's laws". *The first law is* that of the *segregation of characters*, and is illustrated by his first experiments, which were carried out on peas. On crossing a tall plant with a dwarf plant, seeds were obtained all the plants from which were tall. On recrossing the plants of this generation among one another, a third generation (F2) was obtained, in which 25 per cent. of the plants were dwarfs and 75 per cent. were tall. Crossing the dwarf plants among themselves led to the production of dwarf plants through successive generations. Of the 75 per cent. tall plants one-third, and all their descendants, continued to produce tall plants when self-fertilised, whereas of the remaining two-thirds of the tall plants 25 per cent. produced dwarfs and 75 per cent. produced tall plants. On continuing the process of breeding, the dwarf plants, when self-fertilised, always produced dwarfs, whereas of the tall plants 25 per cent. produced tall plants which bred true, while the remaining 50 per cent. produced the same percentage of tall and dwarf as in the preceding generations. Mendel explained these results by the assumption that a character could be either *dominant* or *recessive*. If both characters were present together in one plant it would partake of the dominant type; the fact that this plant possessed the recessive character would be shown only by the result of breeding. In the case of the peas, the tall character was dominant over the dwarf. Thus when the tall and dwarf pea were crossed, the first generation of plants would exhibit the dominant character and be tall. In the second generation, however, 25 per cent. of the individuals would be pure dominants (D + D), 25 per cent. would be pure recessive (R + R), while 50 per cent. would be mixed (D + R). The pure dominants bred together would always give rise to nothing but pure dominants, the recessive to recessive, while the mixed type would always, as before, give rise to 25 per cent. pure dominants, 50 per cent. mixed, and 25 per cent. pure recessives. These results may perhaps be made clearer by the Table below :—



It has been suggested that a very large number, if not all, of the characters of an individual might be brought under this law. This might be done by indefinitely subdividing the characters, but the question would then become beyond the limits of analysis or experimental investigation. There is no doubt that many qualities are subject to Mendel's law, and their study has been of considerable assistance in guiding the efforts of our breeders and horticulturists in the formation of new varieties desirable for their value to man.

In respect of many qualities, the Mendelian idea of dominance seems to fail. Thus in man, the progeny of a cross between a white and a black race are more or less intermediate between the two, and vary according to the amount of black and white blood introduced in succeeding generations. Definite black and white individuals are not produced, but merely individuals of various degrees of brownness. This is known as *blending*.

Genes. The explanation now given of Mendel's first law is a simple one. The hereditary properties are comprised within the chromosomes, the chromatin of which consists of long molecules of nucleoprotein, arranged in a definite molecular pattern, which is reproduced with almost unerring accuracy when new cells are formed. This is because the newly formed chromatin is laid down on that from the parent cells, which, so to speak, provides a ready-made molecular mould, or pattern, to which the new material must conform.

Special groupings or molecules, consisting of varieties of desoxy-ribose nucleic acid, retain their position in the pattern and their configuration, and these definitely located groups are called *genes*. These, of course, are paired in the somatic cells, but single in the gametes. Each gene has a definite place in its chromosome, and in some simple instances chromosome maps have been drawn up, indicating the locations of the various genes. The human chromatin probably contains thousands of genes, each endowed with highly specific potentialities. When the two genes of an allelomorphic pair are identical in the somatic cells, then the single factors in each gamete are identical, and the condition is called *homozygous :* if they are different, it is called *heterozygous*, in which case half the gametes will have one of the allelomorphic factors and the other half the other one. Suppose we take two characters T and t, representing tall and short respectively, and mate together a gamete from a pure tall plant and one from a short plant. The somatic cells of these parents are TT and tt and the gametes T and t respectively. The fertilised cell will be Tt and the new plant from this will produce gametes, half of which, owing to their formation by reduction division, will be T and half t. If these are mated together, then by the law of chance we should get the combinations TT, Tt and tt in the ratios 1 : 2 : 1 (3 dominants to 1 recessive), and, of these, the first and last being homozygous would breed true, while the second being heterozygous would, on subsequent propagation, segregate in a similar way into pure and mixed types.

Mendel's second law relates to the *independent association of genes*, and states that the various possible allelomorphic pairs are independent of each other in inheritance. For instance, if we consider two factors Aa and Bb, in which A and B are dominant ; and cross, say, an individual who is BBaa with one who is bbAA, then the gametes of the first will be Ba and of the second bA, and the somatic cells resulting will be Bb Aa. These will produce gametes of types BA, Ba, bA and ba, in equal numbers, and when they are crossed, in accordance with the laws of chance, the offspring will be of the types **BBAA, BBAa, BbAA, BbAa,** BBaa, Bbaa, bbAA, bbAa, and bbaa, in the ratios 1 : 2 : 2 : 4 : 1 : 2 : 1 : 2 : 1 or, in every sixteen :

9 with both dominants A and B.
3 with one dominant (A) and one recessive (b).
3 with one dominant (B) and one recessive (a).
1 with both recessive characters (a and b).

The 9 : 3 : 3 : 1 is obtained obviously by the combination of two 3 : 1 ratios of dominant to recessive characters, *e.g.* in peas, A = tall, a = short, B = purple flowers, b = white flowers. If we cross a tall purple with a short white, the result will be all tall purples, but if these are self-pollinated we get :—

$$3:1\begin{cases}12\text{ Tall} = 9\text{ purple} + 3\text{ white,}\\ \;\;4\text{ Short} = \underbrace{3\text{ purple} + 1\text{ white,}}_{3\,:\,1,}\end{cases}$$

or, rearranged :—

$$3:1\begin{cases}12\text{ Purple} = 9\text{ tall} + 3\text{ short,}\\ \;\;4\text{ White} = \underbrace{3\text{ tall} + 1\text{ short,}}_{3\,:\,1}\end{cases}$$

By similar independence, where three allelomorphic characters are considered, we get various combinations of dominant and recessive, in accordance with the laws of chance, with ratios 27 : 9 : 9 : 9 : 3 : 3 : 3 : 1. The possible variations in crossings where an indefinite number of characters are considered is thus limitless.

The Determination of Sex

In many animals it is known, and in all it is probable, that one of the somatic chromosome pairs is different in the two sexes, one sex having a certain pair of chromosomes, the "sex chromosomes," which are represented by only one, or by one complete and one vestigial chromosome in the other sex, and there is good reason to suppose that the initial determination of sex is connected with this difference.*

When the reduction of the chromosomes takes place during gametogenesis and the individuals of each pair of chromosomes pass into different germ cells, one complete sex chromosome passes into each germ cell, in the sex that has two similar chromosomes, called XX (female in mammals); in the other sex where there is only one chromosome similar to these and the other one is either rudimentary (XY type) or lacking (XO), then one of the gametes will receive the X-chromosome, and the other one either no corresponding chromosome, or else the modified Y-chromosome. Thus the sex which is of XY or XO type (male in mammals) produces gametes of two kinds, while the gametes of the sex with the complete pair of sex chromosomes are of one type only. Thus when fertilisation takes place the original dimorphism of the zygotes is maintained. The chromosome mechanism at fertilisation is shown diagrammatically in Fig. 690.

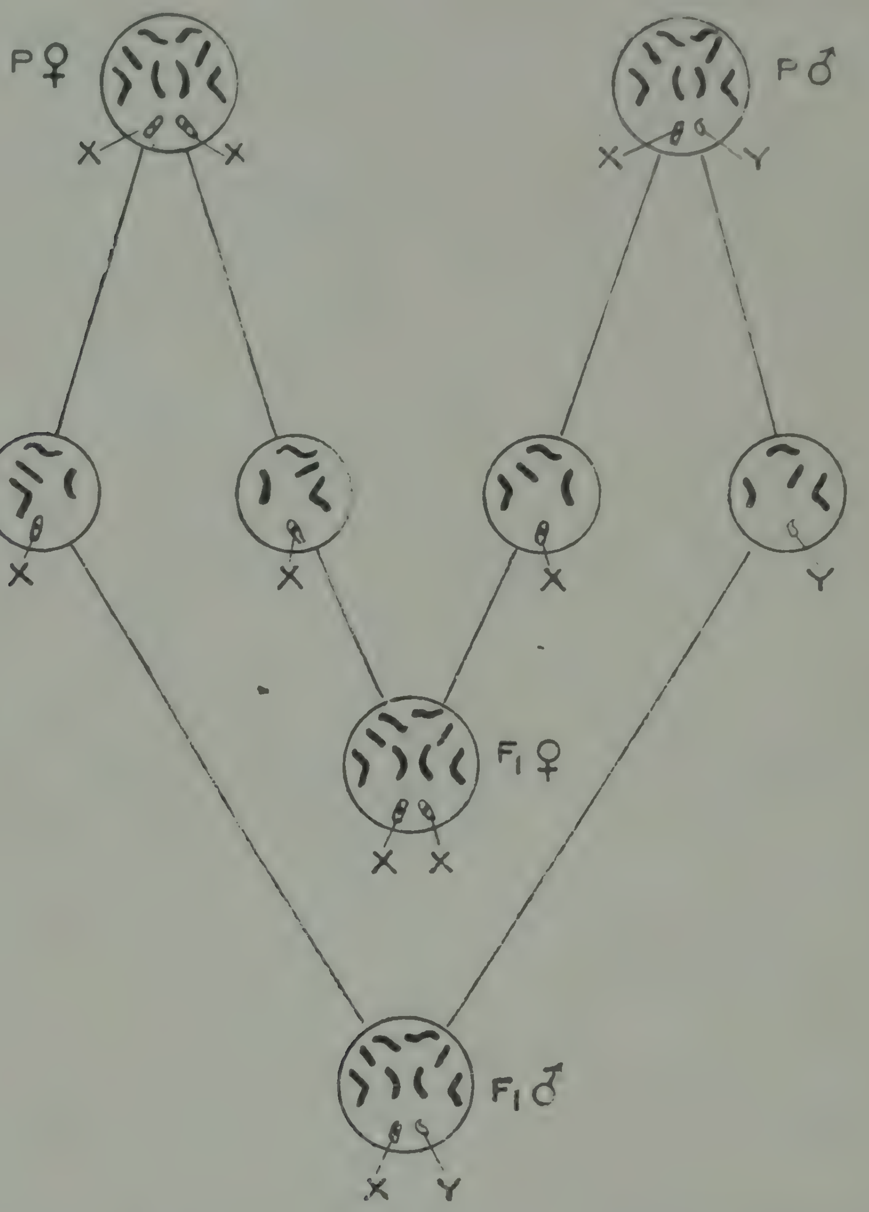


Fig. 690. Diagram to illustrate Principle of Sex-determination in an animal with 10 Somatic Chromosomes (5 pairs). P♀, Female somatic cell. P♂, Male somatic cell. G, The two ripe ova (both X), and two ripe spermatozoa (one X and one Y). F_1♀, Fertilised ovum which forms a female. F_1♂, Fertilised ovum which forms a male.

The sex which produces dimorphic gametes is therefore "heterozygous" for sex, while the other is "homozygous." The study of the correlation between sex and chromosome constitution has been greatly facilitated by the study of sex-linked characters, such as hæmophilia, their mode of inheritance lending strong support to the supposition that sex is initially dependent on chromosome constitution.

The sex carrying the extra chromosome varies in different groups of animals. In Lepidoptera and birds, for instance, the female is heterozygous and produces two kinds of ova, while the spermatozoa are homozygous, and in this case, therefore, the sex of the future embryo depends on the type of ovum fertilised. In Diptera and mammals (including man), on the other hand, the ova are all of the same type, but there are two kinds of spermatozoa. In the now well-known case of the fruit fly, Drosophila, there are four pairs of chromosomes, comprising three pairs of ordinary chromosomes in both sexes, together with an XX pair in the female, and an X and Y in the male (Fig. 691). The spermatozoa are, therefore, of two types, having three ordinary chromosomes and an X, or three ordinary chromosomes and a Y. Ova fertilised by the former produce females, and those fertilised by the latter produce males. In the human subject the male again is

---

* McClung. *Biol. Bull.*, 1902, 3, 43; Winiwarter. *Arch. de Biol.*, 1938, **49**, 119.

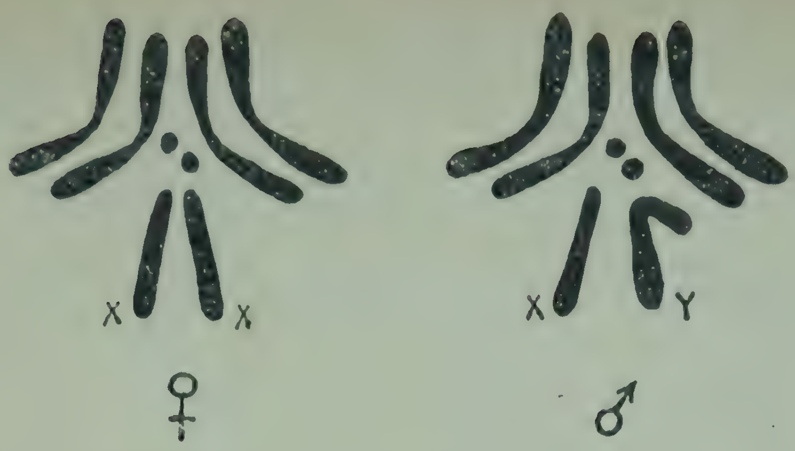

FIG. 691. Female and Male Groups of Chromosomes (Diploid) of *Drosophila melanogaster*. (After MORGAN, in Cowdray's *General Cytology*.)

heterozygous, the somatic number of chromosomes (according to Painter, Evans and Swezy, and others) being 46 + XX in the female and 46 + XY in the male. The Y chromosome is the smallest. The spermatozoa, therefore, contain 23 + X or 23 + Y, so that fertilisation of ova (23 + X) by the former results in females, and by the latter, in males. There is little doubt that, normally, the modelling of the embryo to the male or female pattern is primarily dependent upon its chromosome constitution, but there is equally little doubt that, in rare cases, other factors may lead to the chromosome constitution being over-ridden, causing the embryo to be partially or entirely diverted to the sex to which it was not predestined, and resulting in the production of intersexes or sex reversals. The underlying cause for such change is most often due to exposure of the embryo to hormones characteristic of the opposite sex. Thus in cattle, the free-martin is a masculinized female which while *in utero* was exposed to hormones from a male twin.

In man, *pseudohermaphrodites* occur, both male, *i.e.* in which the gonad is a testis, and female, *i.e.* in which the gonad is an ovary. The external genitalia and secondary sex characters approximate more or less accurately to those of the opposite sex. The male type is probably due to the influence of female hormones derived from the maternal circulation, the female type to the effect of excessive adrenal cortical hormones.

True hermaphrodites, possessing both types of gonads, are extremely rare.

Linkage

Mendel's second law is not of universal application, owing to the existence of what is termed linkage. Experiment shows that certain factors are inseparable or only partly separable from certain others. Some factors are sex-linked, a good example being in *Drosophila*. When a white-eyed male is mated to a wild red-eyed female, all the first

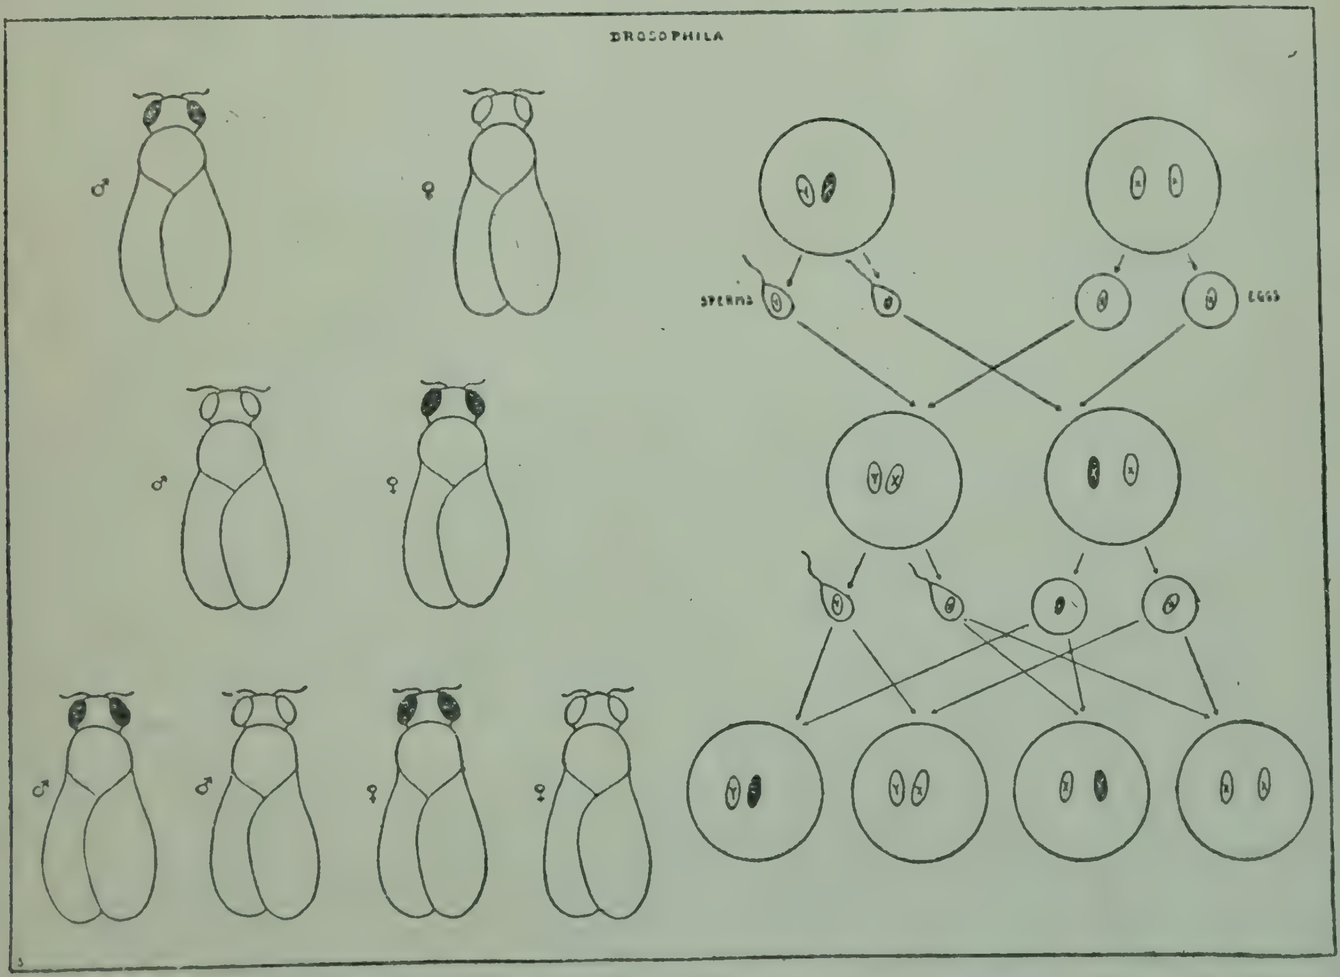

FIG. 692. Sex-linkage in *Drosophila*. Three successive generations at left: red eyes shown in black. The history of the sex-chromosomes through three generations shown at right. X-chromosome of original male in black. (SHARP, after MORGAN.)

generations (F_1) are red-eyed. When these are inbred, the F_2 consist of three red eyes to one white, all the latter being males. Consideration of these results indicates that the eye-colour factor is transmitted by the X-chromosome but not by the Y. Representing (WX) as the chromosome with the linked gene, red + sex, and (wX) as = white + sex, we have in this case :—

P_1. (wX)Y × (WX) (WX)
(white-eyed male) (red-eyed female)
F_1 = (WX)Y : (WX) (wX) (all red-eyed)
(male) (female)
F_2 = (WX) (WX) : (WX) (wX). 50 per cent. females ; all red-eyed,
and (WX)Y, 25 per cent. red-eyed males,
and (wX)Y, 25 per cent. white-eyed males.

When, as a fresh experiment, a red-eyed male is mated with a white-eyed female, then we get all the F_1 males white-eyed and all the F_1 females red-eyed.

This case is illustrated pictorially in Fig. 692.

Examples of sex-linked inheritance in man are colour-blindness and hæmophilia; these are borne by the X-chromosome and are recessive characters, hence they are carried by the female to a portion of the male descendants, but the females do not themselves suffer from the condition, unless, very exceptionally, both their parents were affected, or the father affected and the mother a carrier.

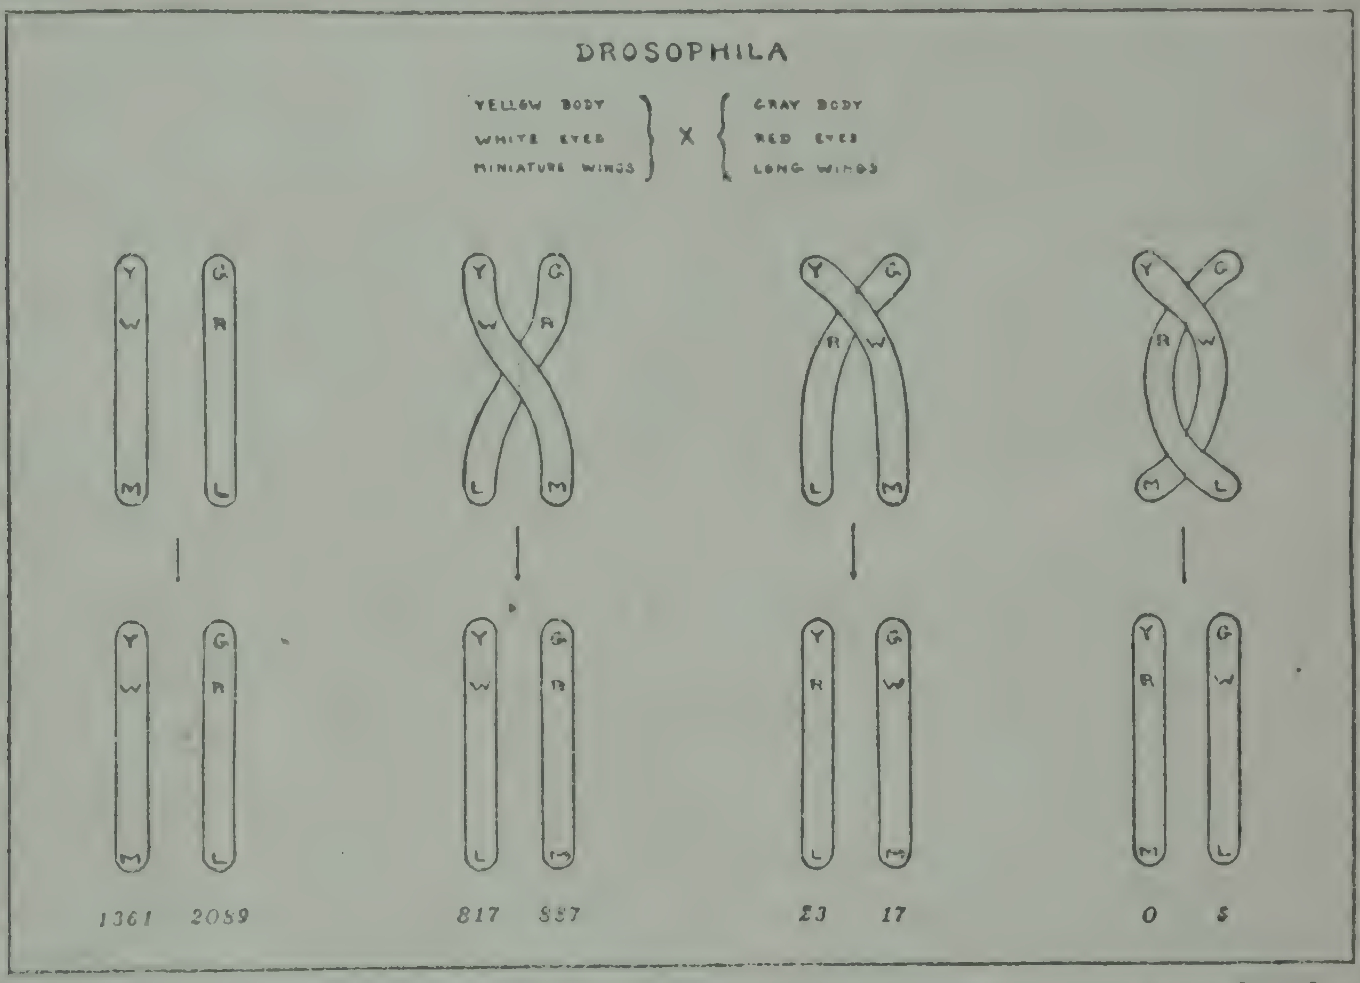

FIG. 693. Diagram to show Formation of New Linkage Groups by Single and Double Crossing-over. (From SHARP, after MORGAN.)

Linkage exists between various other pairs of characters, and the inference is that the genes concerned in the transmission of linked characters must be situated on the same chromosome, and hence be transferred together. The evidence for this, which is again chiefly derived from *Drosophila*, is that there are only as many independent factor-pairs as there are chromosomes in the gamete, or somatic chromosome-pairs. Hence, we conclude that the genes connected with a particular group of characters are located on a particular chromosome. From evidence derived from the detailed study of the phenomenon of crossing-over, it is further believed that for each gene is reserved a particular place in the chromosome, like each bead in a necklace, and that normally this position is faithfully retained in the ensuing generations.

Crossing-over. Although many phenomena of heredity are explicable on the supposition that the genes of a chromosome retain their positions relative to one another from generation to generation, thus giving rise to linkage, yet it appears that this does not always apply as regards the two chromosomes of a somatic pair, carrying therefore similar, though not identical, genes. Let us suppose that, in such a pair, we have two series of genes ABCDEFG, etc., and abcdefg, etc. Then, when reduction division occurs in the formation of the gametes, it may happen that an interchange occurs, so that the gametes may be ABCdefg, etc., and abcDEFG, etc. (Fig. 693).

When this happens, although the linkage persists, there is a certain percentage of departures from the simple Mendelian law of independent association, and it is clear that the further apart on the chromosome any two genes are placed, the more likely will the exchange be to occur.

From the frequency with which this phenomenon of crossing-over happens for particular characters, their relative distance apart on the chromosome has been estimated, and gene-maps of the chromosomes deduced. Double crossing-over also occurs, *e.g.* ABcdeFG, owing to twisting and cleavage having occurred twice in the process of reduction division. These interesting phenomena belong to the special subject of heredity and genetics and cannot be further discussed here.

Mutation. It has been said above that the genic pattern in the chromosomes is reproduced with *almost* unerring accuracy. But not absolutely. All breeders of animals and plants are aware that, occasionally a new feature will suddenly appear and be transmitted thenceforward as an hereditary character. These spontaneously appearing characters are called mutations. On the basis of the gene hypothesis, mutation would be regarded as due to some stable alteration in the properties of the gene concerned, and once the change has occurred in a chromosome of a gamete, a new pattern is established and the mutation persists. We are in complete ignorance as to how these mutations are brought about, so that we cannot, by any means known at present, produce a given mutation, though we can utilise those which occur spontaneously so as to retain the new quality in the breeding of subsequent generations. It has been shown that by the action of X-rays, and by colchicine mutations in *Drosophila* can be made to happen about 150 times as frequently as in nature, and this observation opens up further possibilities of exploring, and perhaps ultimately of controlling, this process. It would seem that the active rays have altered some of the genes, but it appears to be quite fortuitous which ones are affected. It may be that the apparently spontaneous mutations of nature are brought about by the action of cosmic rays acting in a similar manner.

In other instances, mutations have been shown to be associated with a change in the number of chromosomes : this occurs in some plants ; thus Gates has found mutants of *Œnothera* with 15, 20, 21, 22, 23, 27, 28, 29 and 30 chromosomes.

The study of mutation has led to important modifications in our views as to the way in which, in the course of evolution, new forms have appeared. According to the principle of Natural Selection, as put forward by Darwin, any variations, if profitable, would be preserved by natural selection, and thus the process of evolution was a continuous one. The struggle for existence was an essential part of the hypothesis, since by its operation the less well endowed individuals were eliminated, and thus the swamping of the profitable characters was avoided. We now know that mutants arise suddenly, and will breed true, so that swamping will not occur if the mutation is one which brings any biological advantage ; the struggle for existence, though not essential for the production of new and better types, does lead to the loss of those types not able to compete.

INDEX

Abdominal muscles, respiratory movements of 712
Abdominal reflex, spinal segments concerned in, 215
Abducent nerve, effect of injury to, 376
Abrin, nature of, 701
Abscess, formation of, 699
Absorption spectra, cytochrome showing, **514**
  hæmoglobin derivatives showing, **512**
Acapnia, spinal vasomotor centres affected by, **653**
Acclimatisation, high altitude and factors concerned in, 775, **777**
  hot climates and, 1051
Accommodation, eye showing, 389–391
  time factor of, 192
Acetaldehyde, fat formation from carbohydrate and, 942
Acetate, buffer action of, 65
  fat metabolism and, 945
  oxidation of, **143**
Aceto-acetic acid, fat metabolism and, **945**
  tyrosine metabolism and, 929
Acetone bodies, excretion of, 988
  calorific value of, **791**
  formation of, **945**
Acetylcholine, actions of, 351
  adrenal medulla affected by, 1067
  assay of, **363**
  autonomic nerve stimulation producing, 361
  curare antagonism to, 197
  heart affected by, 588
  motor end-plate and, 197
  pial vessels affected by, 672
  respiratory centre affected by, 765
  salivary glands affected by, 847
  skeletal muscle affected by, 137
  structure of, **29**
  uterine muscle affected by, 165
Ac-globulin, blood clotting and, 530
Achromatic spindle, nature of, 1097
Achromatic threshold, factors affecting, 414
Achroo-dextrin, nature of, 843
Acidæmia, definition of, 504
Acid phosphatase, prostate formation of, 1122
Acid-base balance, renal regulation of, 1011
Acidosis, alveolar carbon dioxide pressure affected by, 757
  ammonia excretion in, 932
Aconitic acid, structure of, **31**
Acromegaly, nature of, **1082**
Acrosome, nature of, 1099
Action potentials, cerebral cortex showing, 319
  definition of, 118
  dorsal roots showing, 247–**248**
  mode of production of, **86**–87
  motoneurone showing, **241**
  nerve showing, **175**
  plain muscle showing, 167–**168**
  pulmonary vagus fibres showing, **760**
  skeletal muscle contraction relation to, **131**
  spinal cord showing, **246, 247**
  sympathetic ganglion showing, **238–239**
Activator, enzyme action and, 93
Actomyosin, nature of, 139
Adaptation, nature of, 4
  sensory receptors showing, **220**
Addison's disease, nature of, 1061
Adenase, action of, 936
Adenine, metabolism of, 936
  structure of, **48, 52**
Adenosine, structure of, 49
Adenosinetriphosphatase. *See* A.T.P.
Adenylic acid, structure of, 49, **52**
Adiadochokinesis, nature of, **341**
A.D.P., structure of, 49
Adrenal cortex, anterior pituitary gland control of, 1063
  ascorbic acid in, 828
  carbohydrate metabolism affected by, 972
  functions of, 1060
Adrenal cortical hormones, actions of, 1061
  rate of production of, 1062
Adrenal gland, anterior pituitary interaction with, 1093
  gonads affected by, 1093
  gonads relation to, 1063
  hair growth affected by, 1032
  history of, 1055
  nervous control of, 1093
  structure of, 1059
  sympathetic nerve supply to, 348
Adrenal medulla, functions of, 1064
  structure of, 1059
Adrenalectomy, anterior pituitary extract injection affected by, **973**
  effects of, 1060
  lactation affected by, 1145
Adrenaline, actions of, 351, **1065**
  adrenal cortex stimulation by, 1062
  anoxia effect on output of, **652**
  anterior pituitary extract effect on reactions to, **970**
  arrectores pilorum affected by, 1028
  blood clotting time affected by, 532
    lactate affected by, **961**
    sugar affected by, **961**
    sugar regulation by, 976
  bronchi affected by, 721
  destruction in body of, 1067
  exercise and effects of, 676
  glomerular filtration affected by, 999
  heart affected by, **590**
    efficiency affected by, 605
    oxygen usage affected by, **605**
  intestinal movements affected by, 893
  liver glycogen affected by, **961**, 963
  nasal mucosa affected by, **709**
  pial vessels affected by, **672**
  portal circulation affected by, 669
  sympathin comparison with, 361
  synaptic response affected by, 239
  temperature regulation aided by, 1038
  tyrosine relation to, 928
  uterine muscle affected by, **164**, 165
  uterus and cervix affected by, 1141
  vasoconstrictor action of, 659
Adrenergic transmission, sites of, **362**
Adrenocorticotropic hormones, actions of, 1086
  adrenal cortex affected by, 1063

Adrenocorticotropic hormones, lactation affected by, 1145
Adsorption, law of, 75
  nature of, 67
Adsorption complexes, factors concerned in formation of, 75
Aerobic oxidases, action of, 99
After-discharge, motoneurones showing, **244,** 245
  reflex response showing, **254–255**
After-image, cause of, 432
  nature of, 426
After-potentials, nature of, **177**
  sympathetic ganglion showing, **238–239**
Age, accommodation of eye change with, 391
  arterial pressure variation with, 613
  basal metabolic rate variation with, 794, **833**
  calorie requirements variation with, **833**
  cardiac output variation with, 568
  protein intake variation with, 834
  pulse rate affected by, 599
  pulse wave velocity change with, 635
Agglutination, blood sedimentation rate affected by, 501
Agglutinin, formation of, 704
Agglutinogens, nature of, 501
Aglomerular fish, renal secretion in, 1007
Agraphia, nature of, 472
Air dust, lungs protection from, 779
Air humidity, heat loss affected by, **1045**
  measurement of, 1047
Air velocity, climatic conditions affected by, **1049**
  measurement of, 1047
Alanine, structure of, 40
Albumins, properties of, 45
Albuminoids, nature of, 51
Albuminuria, causes of, 988, 1002
Alcaptonuria, nature of, 929
Alcohol, calorific value of, **791**
  metabolism of, 839
Alexia, nature of, 472
Alignment chart, blood and, **735**
  body surface calculation by, **794**
Alimentary glycosuria, nature of, 963
Alimentary tract, referred pain from, 353
Alkalæmia, high altitude and production of, 775
Alkali reserve, measurement of, 503
  nature of, 732
Alkalosis, alveolar carbon dioxide pressure affected by, 757
Allantoin, formation of, 937
Allemorph, nature of, 1154
Allergic reaction, intestinal absorption and, 914
Allocortex, nature of, 293
All-or-none law, cardiac muscle and, 545
  nerve showing, 180
  plain muscle showing, 168
  skeletal muscle showing, **127–128**
Alloxan, pancreas affected by, 966
Alpha waves, nature of, 321
Altercursive intubation, nature of, **884**
Altitude, blood volume variation with, 495
Alveolar air, composition of, **724**
Alveolar carbon dioxide pressure, barometric pressure changes effect on, **756**
  constancy of, **725**
  high altitude effect on, **775**
Alveolar gases, partial pressure of, 725
Alveolar membrane, nature of, 709
Alveolar oxygen pressure, high altitude effect on, **775**
Alveoli, structure of, 709
Amacrine cells, retina containing, **403**
Amblyopia, nature of, 376
Amboceptor, nature of, 704
Ametropic eye, accommodation range measurement in, 391
Amine oxidase, ephedrine action on, 1069
Amino-acids, chemical properties of, 39
  deamination of, 100
  electrolyte nature of, 76
  essential and non-essential, **809**
  fate after absorption of, 915
  ketogenic and antiketogenic, 928
  structures of, 40–41
  synthesis in body of, 923
  urine containing, 986
Amino-acid decarboxylases, action of, **97**
Aminophorase, action of, 924
Aminopolypeptidase, action of, 880
Ammonia, excretion of, 932
  kidney formation of, 985
  urea formation from, 926
Ammonium salts, specific dynamic action of, 928
Ammonotelic animal, nature of, 924
Amœboid movement, factors affecting, 169
Amphoteric electrolytes, nature of, 39
Ampulla, nature of, 268
Amylase, action of, 37, 880
  succus entericus containing, 889
Amylopectin, nature of, 37
Amylopsin, action of, 880
Amylose, nature of, 37
Anabolism, definition of, 3
Anacrotic pulse, cause of, 634
Anæmia, cyanosis in, 772
  spleen concerned in, 682
Anæmic anoxia, nature of, 771
Anaerobic bacteria, examples of, 3
Anæsthetics, pupil affected by, 379
  temperature regulation affected by, 1037
Anal sphincters, defæcation and action of, **898**
  innervation of, **896**
Analgesia, nature of, 481
Anaphylactic shock, blood clotting time in, 534
Anaphylaxis, nature of, 51, 706
Anarthria, nature of, 472
Anastomotic circulation, principle governing, **618**
Androgens, capon's comb affected by, **1124**
  nature of, 1123
  prostate affected by, 1122
Androsterone, adrenal cortex containing, 1061
  structure of, 1123
Anelectrotonus, nature of, 189–**190**
Aneurin, actions of, 826
Animal behaviour, cerebral cortex removal affecting, 322
Anisometropia, nature of, 399
Ankle jerk, spinal segments concerned in, 215
Anovulatory cycle, occurrence of, 1107
Anoxæmia, coronary vessels affected by, 602
  nature of, 771
Anoxia, carotid body affected by, 763
  cerebral circulation affected by, 672
  cyanosis in, 772
  respiration affected by, **757**
  types of, 771
  vasomotor centre affected by, 650
Anoxic anoxia, nature of, 771

Anserine, nature of, 140
Anterior pituitary gland, adrenal cortex control by, 1063
  carbohydrate metabolism control by, 969
  correlating action of, 1092
  hormones secreted by, 1080
  hypothalamus relation to, 358
  mammary glands affected by, 1144
  ovary affected by, **1112**
  spermatogenesis affected by, **1121**
  testis affected by, 1125
Anterior pituitary hormones, correlating action of, 1092
Anti-bodies, formation of, 704
Anti-diuretic hormone, action of, 1013, 1088
  factors controlling output of, 1090
Antidromic shock, motoneurone affected by, **241**
  sympathetic ganglion affected by, 239
Antidromic vasodilator nerves, 647
Antigens, nature of, 703
Anti-hormones, nature of, 1058
Antiketogenic amino-acids, nature of, 928
Antiperistalsis, ascending colon showing, 897
  duodenum showing, 874, 893
Antitoxins, production of, 701
Aortic body, function of, 594
  respiratory centre affected by, 764
Aortic nerve, function of, 593
Apatite, nature of, 815
Apex beat, cause of, 562
Aphagocyte, nature of, 697
Aphasia, types of, 471
Apneusis, mechanism of, **762**
  nature of, **752**
Apnœa, cause of, 767
  nature of, 755
  over-ventilation causing, **770**
Apocrine sweat glands, nature of, 1029
Apoplexy, nature of, 315
Aqueous humour, secretion of, **382**
Arachnoid, nature of, 693
Arachnoid villi, nature of, **694**
Arcuate fibres, nature of, 335
Arginase, action of, 926
  corticosterone action on, 1064
Arginine, creatine formation and, 933
  structure of, 41
  urea formation and, 925
Argininephosphate, nature of, 139
Argyll-Robertson pupil, nature of, 289
Arrectores pilorum, action of, 1028
  nerve supply to, 347
Arterenol, nature of, 361
Arterial blood, factors affecting rate of reduction of, **743**
  gas pressures in, **740**
Arterial pressure, adrenaline action on, 659, **1065**
  anoxia effect on, **650**, **652**
  aortic nerve stimulation effect on, **592**
  asphyxia effect on, **650**
  cardiac output effect on, 621
  carotid sinus pressure effect on, **596**
  cerebral circulation affected by, 671
  coronary blood flow affected by, 601
  diuresis caused by rise of, 1012
  exercise effect, **677**
  gravity effect on, 683
  heart volume affected by, **577**
  heart work affected by, 575, **604**
  magnitude of, **538**
Arterial pressure, measurement of, **610**
    in man of, **612**
  plethora effect on, **679**
  post-pituitary extract effect on, 1087
  pulmonary arterial pressure relation to, 665
  pulse wave velocity affected by, 631
  respiration affected by, **766**
    effect on, 667
  spinal cord section effect on, 642
  urine composition affected by, **998**
  urine flow and composition affected by, **1001**
  vagus nerve stimulation effect on, 586
Arterial pulse, characteristics of, 629
Arterial velocity pulse, nature of, 627
Arteries, blood pressure in, 609
  capacity changes with pressure changes in, **539**
  structure of, **539**
Arterioles, chemical regulation of, **658**
  innervation of, 642
  nerve supply to, 347
  pituitrin action on, 1087
  resistance in, 617
  structure of, 539
Arterio-venous anastomoses, sites of occurrence of, 540
  skin containing, 1028
    temperature control by, 1044
Artificial parthenogenesis, methods of, 1101
Artificial respiration, methods of, 718
Arytenoid muscle, action of, 466
Ascorbic acid, actions of, 828
  adrenal cortical hormones relation to, 1062
Aspartic acid, structure of, 41
Asphyxia, nerve affected by, 187
  respiratory movements in, 754, 769
  spleen affected by, 682
  vasomotor centre affected by, **650**
Aspirin, action of, 1053
Astasia, cerebellar ablation causing, 339
Asthenia, cerebellar ablation causing, 339
  cerebellar injury in man causing, **341**
Astigmatism, types of, **398**
Asynergia, nature of, 341
Ataxia, cerebellar lesions causing, 339, 341
  muscle afferent impulses and, 316
Athlete, pulse rate in, 599
  vagal tone in, 588
Athletic records, limiting factors in, **154**, 155
Atmospheric pressure, effects of high and low, 773
A.T.P., acetylcholine synthesis and, 364
  adrenal cortex affected by, 1062
  energy in, 68
  energy-rich bonds in, 52
  myosin and, 148
  skeletal muscle contraction and, 148
    heat production and changes in, 159
  structure of, 49
Atropine, acetylcholine actions affected by, 362
  action of, 352
  eye affected by, 391
Atwater-Benedict calorimeter, use of, **792**
Audito-psychic area, functions of, 303
Auditory centre, location of, 303
Auditory nerve, nerve impulse conduction in, 460
Auditory organ, diagram of, **450**
Auditory reflexes, nervous pathways of, 286
Auditory sensation, central nervous pathways of, **286**
Auerbach's plexus, composition of, 163

Auerbach's plexus, gastric movements affected by, 871
  peristaltic movement and, 891
Auricle, pressure changes in, **558**
  structure of, **549**
  vagus action on, 586
Auricular flutter, nature of, 555
Auriculo-ventricular bundle, course of, **551**
  vagus action on, 587
Auriculo-ventricular node, structure of, 552
Auriculo-ventricular valves, structure of, **549**
Autocoid, nature of, 1057
Autonomic functions, integration of, 354
Autonomic ganglia, functions of, 348
Autonomic nervous system, afferent fibres of, **352**
  anatomy of, **344**
  nature of, 212
  plain muscle innervation by, 163
Autonomic reflex arc, vagus function in, 354
Aviation, circulatory problems in, 684
  oxygen requirements in, 776
Avidin, nature of, 827
Axilla, temperature of, 1035
Axis cylinder, structure of, 172
Axon reflex, hypogastric reflex as, **349**
  metabolites stimulation of, 659
  vasodilator fibres in, **649**

Babinski sign, sleep and, 330
  spinal cord section and, 234
Bacteria, large intestine containing, 894
  leucocyte action on, 699
  serum action on, 700
Baillarger, lines of, **295**
Bainbridge reflex, nature of, 597
Ballistocardiogram, use of, 569
Barány's test, nature of, 272
  cerebellar lesions and, 341
Barger's method for osmotic pressure measurement, **61**
Barometric pressure, alveolar carbon dioxide pressure affected by changes in, **756**
  effects of high and low, 773
Basal ganglia, functions of 313–**314**
  internal capsule relation to, **309**
Basal metabolic rate, age effect on, **833**
  hypophysectomy effect on, 1085
  sex differences in, 1038
  thyroid gland effect on, 1070
Basal metabolism, nature of, 793
Basilar membrane, nature of, **454**
Basophile cells, characters of, **524**
Beats, nature of, 461
Bell and Magendie law, nature of, 181
Benadryl, action of, 662, 706
Benedict's respiration apparatus, use of, **785**
Berger rhythm, factors affecting, **320**
Beri-beri, nature of, 825
β-hydroxybutyric acid, heart utilisation of, 948
β-oxidation, nature of, 944
β-oxybutyric acid, calorific value of, **791**
Beta waves, nature of, 321
Betz cells, position of, 297
Bicarbonate, buffer action of, 65
  carbon dioxide carriage in blood by, 731
  carbonic anhydrase action on, 736
Bidder's ganglion, site of, 542
Bidwell's experiment, nature of, 430
Bile, composition of, 882
Bile pigments, entero-hepatic circulation of, 886
  nature of, 883
Bile salts, composition of, 883
  entero-hepatic circulation of, 886
  fat absorption affected by, 909
  hydrotropic action of, **909**
Bile secretion, 883
  secretin action on, 877
Bilirubin, formation of, 521
  nature of, 883
Biliverdin, formation of, **522**
  nature of, 883
Binocular rivalry, nature of, 433
Binocular vision, advantages of, 445
Bioelectric potentials, nature of, 85
Biological value of proteins, determination of, 809
Biotin, nature of, **827**
Bird, accommodation in eye of, 388
  blood, coagubility in, 531
  eye accommodation in, 447
  red blood cell formation in, **519**
  visual field of, **410**
Birth, circulatory changes at, 1140
Bismuth, excretion of, 895
"**Black-out,**" cause of, 684
"**Black-tongue,**" nature of, 828
Bladder, denervation effect on emptying of, **1023**
  innervation of, **1018**
  pressure measurement in, **1020**
  structure of, 1016
  sympathetic stimulation effect on, 348
  tonus in, 167
Blending, heredity and, 1155
Blindness, cortical damage causing, 305
  nervous lesions causing, 289
  types of, 434
Blind spot, colour fields limitation round, 415, **416**
  measurement of, **408**
Blind zone, extent of, **410**
Blink reflex, reticular formation stimulation effect on, **312**
"**Block,**" spinal cord showing, 263
Blood, alignment chart of, **735**
  alkali reserve of. *See* Alkali reserve.
  amino-acids, pituitary hormones action on, 1085
    protein meal affecting, 915
  calcium, parathyroidectomy effect on, 1076
  carbon dioxide carriage by, **731**
  carbon dioxide dissociation curve of, **732**
  cells. *See* Erythrocyte, Leucocyte, etc.
  cholesterol, fat absorption effect on, 911
  coagulation of, 527–535
    nature of, 493
  composition of, **505**
  electrical conductivity of, 504
  fat, meal taking effect on, 951
  flow, factors controlling intermittent to constant, 622
    measurement, of, 627
    plethysmograph measurement of, **644**
    temperature effect on, 1044
  gases, arterial and venous, **726**
    measurement of, **497–499**
    solubility of, **727**
  gas tensions in, 739
  glycolysis in circulating, 150
    lungs effect on, 605

  - sugar, adrenal cortical hormone effect on, **973**
    - adrenaline action on, **961**
    - factors regulating concentration of, 1091
    - glucose ingestion effect on, **953**
    - hunger relation to, 900
    - insulin action on, 968
    - lactation affected by, 1146
    - liver glycogen relation to, 960
    - normal regulation of, 975
    - regulation of, 954
    - stomach movements affected by, 874
  - transfusion of, 503
  - velocity of, 622
    - measurement of, 624
  - vessels, branching effect on flow in, **618**
    - nervous control of, 642
    - peripheral tone of, 654
  - viscosity of, 501
    - corpuscular content affecting, **619**
  - volume, measurement of, 494
    - shock relation to, 663
    - sleep effect on, 330
    - temperature effect on, 1046
  - white cells. *See* Leucocytes.
- **Body** fluid, temperature effect on movement of, 1046
- **Body** surface, metabolic rate relation to, 793
  - nomogram for calculation of, **794**
- **Body** temperature, limits to variation in, 1051
  - regulation of, 1036
    - history of, 981
  - shivering relation to, 1054
- **Body** temperature, sympathetic system removal effect on, 350
- **Body** weight, basal metabolic rate affected by loss of, 795
- **Bohr** effect, nature of, 729
- **Boiler-maker's** disease, basilar membrane damage in, 457
- **Bone,** composition of, 815
  - growth of, 815
  - parathyroid effect on, 1078
  - vitamin A effect on growth of, **821**
  - vitamin C effect on growth of, 830
  - vitamin D effect on growth of, 823
- **Bone,** marrow, blood cell formation in, 518
  - granulocyte formation in, 525
- **Borate,** buffer action of, 65
- **Bowman's** capsule, blood supply to, 991
  - fluid collection from, **996**
- **Bragg-Paul** pulsator, use of, 719
- **Brain,** blood flow to, 629
  - blood supply to, 670
  - glucose usage by, 670
    - and pyruvate usage by, 746
  - meninges of, 693
  - oxygen usage of, 670
  - pressure in, 671
  - section, result at different levels of, **273**
  - starvation and loss in weight of, **797**
  - stem, structure of, **210, 211**
  - sympathetic nerve supply to, 347
  - vitamin B_1 action on, 826
- **Bread,** gastric secretion response to, 869
  - war-time modification of, 837
- **Breath-holding** tests, nature of, 768
- **Breath** sounds, nature of, 714
- **Brewster's** stereoscope, use of, **448**
- **Brightness** difference threshold, light intensity effect on, **417**
- **Broca's** area, function of, 471
  - location of, 300
- **Bronchi,** air dust removal by, 779
  - movements of, 722
  - parasympathetic stimulation effect on, 350
  - respiratory movements of, 712
  - structure of, 708
- **Bronchial** murmur, nature of, 714
- **Bronchial** musculature, factors affecting, 720
- **Bronchioles,** structure of, 709
- **Brown-Séquard** syndrome, nature of, 235
- **Brunners'** glands, secretion by, 888
- **Bubble** stromuhr, use of, **624**
- **Buffer** mixtures, pH range of, **65**
- **Buffer** systems, action of, **64**
- **Buffy** coat, nature of, 501
- **Bulbo-cavernosus-muscle,** action of, 1018
- **Bulbo-spinal** preparation, nature of, 232
- **Burch's** experiment, nature of, **431**
- **Butter,** formation of, 1148

- **Cadaverine,** nature of, 97
- **Caffeine,** diuretic action of, 1015
  - structure of, 48
- **Caisson** disease, nature of, 778
- **Calcarine** cortex, retinal representation in, **304**
- **Calciferol,** nature of, **823**
- **Calcification,** factors concerned in, 816
- **Calcium,** absorption from intestine affected by, 907
  - balance sheet of, **812**
  - blood clotting affected by, 528
  - bone formation and, 816

- **Calcium**, cardiac muscle affected by, **581**
  - cell membrane permeability affected by, 16
  - excretion of, 985
  - ganglion cells affected by, 366
  - histamine action affected by, 721
  - metabolism, parathyroid effect on, 1078
    - vitamin D action on, 823
  - milk clotting and, 862
  - nerve accommodation affected by, 193
  - nerve affected by, 186
    - response to stimulus affected by, 175
  - trypsinogen activation by, 879
- **Calcium** absorption, factors affecting, 813
- **Calorie**, definition of, 789
- **Calorie** requirements, factors affecting, 832
- **Calorimetry**, history of, 981
  - indirect, 792
- **Cancer**, growth of, 1153
- **Cane** sugar, gastric juice action on, 861
- **Capillaries**, blood pressure in, 609
  - capacity of, 540
  - circulation through, 636
  - contractility of, 637
  - exercise effect on muscle, **742**
  - fragility of, 638
  - innervation of, 661
  - leucocyte emigration from, **698**
  - nerve supply to, 347
  - permeability of, 81
  - resistance to blood flow offered by, 617
  - structure of, 539
- **Capillary** electrometer, principle of, 118
- **Capillary** permeability, factors affecting, 689
  - shock relation to, 663
  - tissue fluid formation and, 687
- **Capillary** pressure, factors affecting, 638
  - magnitude of, **538**
  - measurement in man of, 638
  - tissue fluid formation affected by, 688
- **Capillary** tone, pituitrin action on, 1087
- **Capon's** comb, androgens and œstrogens effect on, **1124**
- **Carbamino-acids**, nature of, 39
- **Carbamino-compounds**, hæmoglobin as, 737
- **Carbohydrate**, anti-ketogenic action of, 947
  - calorific value of, **791**
  - chemical nature of, 30
  - exercise and usage of, 154
  - fat as source of, 944
    - formation from, 941
  - gastric digestion of, 862
  - intermediary metabolism of, **962**
  - intestinal absorption of, 913
  - ketosis affected by, 965
  - pancreatic digestion of, 880
  - salivary digestion of, 843
  - sparing action on protein of, 802
  - specific dynamic action of, 803
  - stomach emptying time affected by, 873
- **Carbohydrate** metabolism, 952
  - bilirubin formation affected by, 522
  - exercise effect on, 806
  - hormonal control of, 969
  - insulin action on, 969
  - lactation affected by state of, 1145
  - respiratory quotient showing amount of, **805**
  - starvation effect on, 797
  - vitamin B_1 action in, 826
- **Carbon**, balance sheet of, 788
- **Carbon** dioxide, absorption coefficient of, **726**
  - blood carriage of, **731**
- **Carbon** dioxide, blood carriage of, velocity affected by, **625**, 627
  - carotid body affected by, 763
  - cerebral circulation affected by, 672
  - dissociation curves, blood and plasma comparison, **732**
    - oxygen effect on, **734**
  - Fick principle use of, 569
  - glycogen formation from, 959
  - heart affected by, 591
  - oxygen dissociation curve affected by, **728**
  - pressure, air and blood comparison, **740**
  - reduction rate of arterial blood affected by, **743**
  - respiration affected by, **756**
    - after vagotomy affected by, **761**
  - skin loss of, 1032
  - tissue production of, 745
  - vasomotor centre affected by, **651**
- **Carbonic** anhydrase, action of, 97, 736
  - oxyntic cells and, 863
- **Carbon** monoxide, absorption coefficient of, **726**
  - blood volume measurement by use of, 494
  - hæmoglobin determination by use of, 497
  - toxic effects of, 778
- **Carboxyhæmoglobin**, dissociation curve of, 779
  - formation of, 511
  - molecular weight of, 45
  - oxygen dissociation curve affected by, 729
- **Carboxylase**, action of, **97**
- **Carboxypolypeptidase**, action of, 880
- **Cardiac** cycle, coronary flow variations in, **603**
  - pulse tracings relation to, 633
  - sequence of events in, 556–561
- **Cardiac** efficiency, adrenaline effect on, 605
- **Cardiac** impulse, cause of, 562
- **Cardiac** index, nature of, 568
- **Cardiac** murmurs, cause of, 563
- **Cardiac** muscle, chronaxie of, 114
  - ions action on, **581**
  - length effect on response of, 577
  - metabolism of, 604
  - myoglobin function in, 744
  - properties of, 544
  - structure of, **541**
- **Cardiac** nerves, action of, 588
- **Cardiac** output, arterial pressure affected by, 621
  - basal metabolic rate calculation from, 795
  - circulation time relation to, 623
  - coronary vessel tone affected by, 603
  - determination of, 568
  - exercise effect on, 675
  - factors affecting, 573
  - heart work affected by, **604**
- **Cardiac** reflexes, nature of, 595
- **Cardiac** sphincter, deglutition and action of, **854**, 857
- **Cardiometer**, use of, 568
- **Cardio-accelerator** centre, location of, 592
- **Cardio-aortic** nerve, function of, 593
- **Cardio-inhibitory** centre, action of, 592
  - respiratory centre action on, **600**
  - vagus nerve excitability affected by state of, 587
- **Cardio-pneumatic** movements, nature of, 570
- **Carnivor**, protein storage in, **801**
- **Carnosine**, nature of, 140
- **Carotene**, vitamin A relation to, 822
- **Carotid** body, respiratory centre affected by, **763**
  - structure of, 595

Carotid sinus, innervation of, **594**
  nerve endings in, **218**
  perfusion of, **596**
  reflex secretion of adrenaline from action of, 1067
  respiratory centre affected by, **764, 766**
  stretch receptors in, 594
Carotid sinus nerve, function of, 354
  impulses in, **597**
Casein, iso-electric pH of, 74
Caseinogen, amino-acids in, 44
  gastric juice action on, 862
  mammary gland manufacture of, 1147
  properties of, 47, 1149
Castration, effects of, 1104
  pituitary changes following, 1079
  seminal vesicles affected by, **1125**
Catalase, action of, 97
Catalyst, definition of, 88
Cataract, treatment of, 388
Catelectrotonus, nature of, 189–**190**
Cathepsin, action of, 915
  nature of, 861
Cathode ray oscillograph, use of, **118,** 119
Cell, differentiation of, 19–21
  electric potentials in, 85–87
  plasma membrane of, 15
  structure of, 9
    phospholipides in, 951
Cell count, blood viscosity affected by, **619**
Cell membrane, permeability of, 15, 81–82
  permeability in muscle of, 137–138
  structure of, 16, **17**
Cellulose, fæces composition affected by dietary, **900**
  properties of, 38
Central excitatory state, nature of, 239
  time relations of, **258**
Central inhibitory state, nature of, 239
  time relations of, **259**
Central nervous system, acetylcholine formation in, 364, **365**
  functional levels in, 229
  history of, 198
  hypoglycæmia effect on, 956
  nerve fibre structure in, 204
  structure of, 209, **210**
  theory of inhibition in, **260**
  vitamin A action on, 821
Central reflex time, factors controlling, 253
Centrosome, cell division affecting, 1096
  function of, 13
Cephalin, thromboplastin containing, 531
Cerebellar nuclei, connections of, 334
  stimulation of, 340
Cerebello-frontal tract, course of, 338
Cerebello-rubro-thalamic tract, course of, 338
Cerebello-tegmental tracts, course of, 337
Cerebellum, connections of, 335, **336**
  functions of, 338
  structure of, **333**
Cerebral circulation, 670–672
Cerebral cortex, animal behaviour affected by removal of, 322
  associative functions of, **301**
  autonomic functions control by, 359
  cerebellar connections with, **336, 337**
    stimulation effect on, 339
  conditioned reflexes after damage to, 328
  cytoarchitectonic map of human, **294**
  electrical activity of, 319
  eye movement representation in, 376
Cerebral cortex, functions of, 318
  hypothalamic connections with, 356, 358
  localisation of function in, **299**
  micturition control by, 1025
  motor areas of, 305
  neurone types in, **296, 297**
  removal, effects of, 233
  sensory areas in, 302
  speech centres in, 471
  stimulation, respiration affected by, 753
  structure of, 293
  thalamus connections with 291
Cerebral hemispheres, development of, 293
Cerebro-spinal fluid, circulation of, 695
  calcium in, 814
  location of, 693
Cerebrum, coronal section of, **314**
Ceruminous glands, secretion of, 1029
Cervix uteri, parturition effect on, 1140
  reactions of, 1141
Charpentier's bands, nature of, **426**
Cheese, formation of, 1149
Chemotaxis, leucocyte action and, 699
  nature of, 3, 483
Cheyne-Stokes breathing, mechanism of, 771
Chloride excretion, post-pituitary regulation of, 1013
Chloride, daily requirement of, **812**
  ptyalin action and, 843
  reabsorption in kidney of, **1005**
  skin storage of, 1032
  sweat containing, 1029
  urine containing, 984
Chlorocruorin, nature of, 516
Chlorophyll corpuscles, starch formation by, 22
Cholane ring, adrenal cortical hormones and, **1061**
  structure of, **28**
Cholanic acid, nature of, 883
Cholecystokinin, action of, 886
Choleglobin, nature of, 521
Choleic acids, nature of, 883
Cholesterol, adrenal cortical hormones relation to, 1062
  bile salts relation to, 883
  intestinal absorption of, 913
  metabolism of, 952
  structure of, **28**
  vitamin D relation to, **824**
Cholic acid, bile secretion affected by, 884
  structure of, **28**
Choline, acetylcholine synthesis and, 364
  lipotropic action of, 949
  structure of, **29**
Choline acetylase, action of, 364
Choline esterases, action of, 362
  motor end plate containing, 197
Cholinergic nerves, sweat glands supplied by, 1031
Cholinergic transmission, sites of, **362, 365**
Chondroitin, nature of, 50
Chorda tympani, effect of stimulation of, 847
Chorionepithelioma, hormone excretion with, 1134
Chorionic gonadotropin, nature of, 1132
Chorionic villi, formation of, **1132**
Choroid plexus, cerebro-spinal fluid formation by, 694
Chromaffine substance, nature of, 1060
Chromatic aberration, eye correction of, 444
  eye showing, **393**
Chromatin, composition of, 17, 48

Chromatography, nature of, 75
Chromatolysis, nature of, 204
Chromophobe cells, nature of, 1079
Chromoproteins, nature of, 47
Chromosomes, cell division affecting, 1096
  gene maps of, 1159
  heredity and, 1153
  species number of, 1097
Chronaxie, muscles showing different values of, 194
  nature of, 114
Chyle, nature of, 686
Chylomicrons, fat meal affecting, **910**
  nature of, 506
Chymosin, action of, 862
  caseinogen affected by, 1149
Chymotrypsin, action of, 880
Ciliary movement, nature of, 169–170
Ciliary muscle, action of, 389
  nerve supply to, 350, 390
Circulation, artificial schema of, **620**
  capacity changes in, 621
  history of, 489
  hot climate effect on, 1051
  hydrodynamics of, **615**
Circulation rate, reduced barometric pressure effect on, 776
Circulation time, measurement of, 623
Circulatory shock, events in, 663
Circus movement, nature of, **555**
Citrate, acetylcholine synthesis and, 364
  blood clotting affected by, 528
  semen containing, 1123
Citrin, action of, 830
Citrulline, structure of, 41
  urea formation and, **927**
" **Clasp-knife** " reaction, decerebrate preparation showing, 265
Clearance tests, nature of, 1002
Climacteric, nature of, 1103
Climate, factors affecting tolerability of, **1050**
Clonus, nature of, **129–130**
" **Closing** tetanus," nature of, 189
Clothing, temperature regulation affected by, 1046
Cluster hypothesis of colour vision, 439
Cobalt, hæmopoietic factor and, 520
  function in diet of, 813
Cocaine, adrenaline action affected by, 351
  taste affected by, 484
Co-carboxylase, structure of, **94**
Cochlea, structure of, 453
Cochlear telephonic action, 456
Cochlear microphonic action, 455
Coefficient of utilisation, exercise effect on, 676
  factors affecting, 742
Co-enzyme I, E_h of, 101
  lactic dehydrogenase action on, **98**
  structure of, **93**
Co-enzyme system, nature of, 93
Coitus, events in, 1127
  nervous mechanism of, 1128
Colchicine, cell division affected by, 1097
  mutations induced by, 1159
Cold, metabolic rate affected by, 1037
Cold spots, distribution of, **475**
Collagen, gastric digestion of, 862
  properties of, 51
Colloid goitre, nature of, **1074**
Colloid osmotic pressure, measurement of, **71**
  nature of, 57
Colloidal ions, nature 76
Colloids, coagulation of, 77
  electrical properties of, 73
  interaction between, 77
  properties of, 69
Colon, defæcation and action of, **898**
Colostrum, nature of, 1146
Colour, difference threshold of, **423**
  extinction curve of, **415**
  intensity threshold for, 414
  threshold, limits of, 422
  visual fields of, **410,** 415
Colour blindness, detection of, 434
  sex-linked inheritance of, 1158
  types of, 436
Colour index, nature of, 497
Colour patch apparatus, **424,** 425
Colour triangle, nature of, **373**
Colour vision, lateral geniculate body structure and, 288
  theories of, 437
Combination tones, nature of, 451, 462
Comfort, physical factors affecting, 1051
Commutator, neurone activity and, 207, **208**
Compensatory pause, nature of, **547**
Complement, nature of, 704
Complemental air, value of, **716**
Complementary colours, nature of, 372
Complement-fixation test, 705
Compressor urethra, action of, 1018
Concealed reflex, nature of, 266
Conchiolin, nature of, 51
Conditioned reflex, formation of, 324
  gastric secretion and, **865**
  laws of, 325
  nature of, 323
Conditioned stimulus, nature of, 324
Conduction, heat loss by, 1039
Cone, diameter at fovea of, **419**
  diameter, visual acuity and, 416
  fovea centralis containing, 408
  light affecting shape of, 405
  structure of, **404**
  theories of vision and, 437
Conjunctival reflex, nature of, 380
Consciousness, site of, 318
Consonance, nature of, 462
Consonants, production of, 470
Constrictor pupillæ, nerve supply to, 350
Contact stimuli, righting reflexes and, **281**
Contraction remainder, nature of, 135
Contracture, types of, 136
Contrast phenomena, eye showing, 430
Convection, heat loss by, 1039
Convergence, neurone activity showing, **208**
  reflex response and principle of, **256**
Copper, function in diet of, 813
  functions of, 23
  hæmoglobin formation and, 520
Coproporphyrin, formation of, 523
  nature of, 516
" **Core-conductor** " model, nature of, **192**
" **Cori cycle,**" nature of, **961**
" **Cori ester,**" structure of, **34**
Cornea, focal length of, 387
  nerve endings in, **217**
  radius of, **386**
  sensation in, 481
  structure of, 377
Coronary circulation, arterial pressure effect on, 601
  blood oxygen saturation effect on, **602**
  cardiac cycle effect on, **603**

Coronary circulation, measurement of, 573
  volume of, 600
Coronary vessels, adrenaline action on, 591
  nervous control of, 602
  vasodilator nerves to, 646
Corpus Arantii, nature of, 550
Corpus luteum, formation of, **1107**
  mammary glands affected by, 1104
  menstrual cycle and changes in, 1118
  œstrus cycle affected by, 1113
Corpus striatum, functions of, 313, **314**
  motor cortex connections with, 311
Corti, organ of, **455**
Cortical epilepsy, nature of, 308
Cortical unit, nature of, **298**
Cortico-cerebellar tracts, destination of, 337
Cortico-nuclear tract, nature of, 311
Cortico-spinal tracts, composition of, 226
  spinal shock and, 230
Corticosterone, lactation affected by, 1145
  structure of, **28, 1061**
Cough, reflex mechanism of, 759
Coupled reactions, nature of, 68
Cranial autonomic afferent fibres, course of, 354
Crayfish adductor, double innervation of, **162**
Creatine, metabolism of, 933
  structure of, **53**
Creatinephosphate, adrenal cortex affected by, 1062
  properties of, 139
  skeletal muscle contraction and, 149
    heat production and changes in, 159
  structure of, **53**
Creatinine, excretion of, 986
  excretion, diet effect on, **924**
  metabolism of, 933
Creatinine clearance, value of, 1003
Creatinuria, cause of, 934
Crescent cells, nature of, 844
Cretin, nature of, 1069
Crico-arytenoid muscles, action of, 466
Crico-thyroid muscle, action of, 466
Crista acoustica, nature of, 268, **269**
Crossed extensor reflex. *See* Extensor reflex.
Crossing-over, heredity and, 1158
Crotonic aldehyde, fat formation from carbohydrate and, 942
Cryptopyrrole, nature of, **515**
Crystallin, properties of, 46
Crystalline lens. *See* Lens.
C.U., nature of, 1133
Cupola, nature of, 268, **269**
Curare, acetylcholine antagonism to, 197
  action of, 351
  end-plate potentials affected by, 196
  eserine antagonism to, 188
  sympathetic ganglia affected by, 240
  temperature regulation affected by, 1037
Cutaneous receptors, types of, 216, **217**
Cutaneous sensations, 474
Cutis, structure of, 1028
Cyanhæmoglobin, nature of, 513
Cyanide, circulation time measurement by, 623
  cytochrome affected by, 514
  cytochrome oxidase affected by, 99
  heart metabolism affected by, 747
  vasomotor centre affected by, **652**
Cyanosis, nature of, 772
Cyclol structure, nature of, 43
Cysteine, acetylcholine synthesis and, 364
  lactalbumin containing, 1151
  metabolism of, 931
  structure of, 40
Cystine, lens containing, 385
  structure of, 40
Cytochrome, heart containing, 747
  location of, 13
  nature of, 514
  skeletal muscle containing, 140
Cytochrome oxidase, action of, **99**
Cytochrome peroxidase, action of, 100
Cytochrome reductase, action of, 100
Cytolysins, formation of, 704
Cytoplasm, fluid nature of, **14**–15
  structure of, **12, 13**
Cytosine, structure of, **49**

Dark adaptation, nature of, 414
Dead space, measurement of, 725
  value of, 718
Deafness, basilor membrane damage in, 457
Deamination, enzymes concerned in, 100
Decapitate preparation, nature of, 229
Decerebrate preparation, lengthening and shortening reactions in, 265
  properties of, **232**
Decerebrate rigidity, cerebellar stimulation effect on, 339
  mechanism of, **273–274**
  nature of, 229, **232**
Decerebration, blood sugar affected by, 964
Decibel, definition of, 464
Decidua, formation of, 1131
Decidual cells, nature of, 1131
Decorticate preparation, properties of, 233
Defæcation, mechanism of, 897
  spinal cord section affecting, 234
Defence, chemical methods of, 700
Defibrinated blood, nature of, 493
D.F.P., action of, 351, 362
Deglutition, nervous mechanism of, 858
  process of, 852
Deglutition apnœa, mechanism of, 767
Dehydration, effects of, 1052
  treatment of, 811
Dehydrogenases, actions of, 96
  heart containing, 747
Deiter's nucleus, connections of, **269,** 270
  decerebrate rigidity and, **273**
  function of, 233
Delayed conditioned reflex, nature of, 326
Delta waves, nature of, 321
Demarcation current, nature of, 116
Denaturation, nature of, 38
Dendrons, nature of, 203
Denervated tissues, adrenaline action on, 1067
Depolarisation, nerve impulse and, **194**
  sense receptor stimulation and, 221
Depot fat, composition of, 939
  functions of, 942
Depressor nerve, function of, 593
Depressor reflex, nature of, 595, **655**
Depth perception, hypotheses of, 448
Dermatographism, nature of, 662
Desoxycorticosterone, actions of, 1062
  kidney affected by, 1010
  structure of, **1061**
Deuterium, amino-acid metabolism studied by, 923
  depôt fat lability shown by, 942
  nature of, 920
Dextrins, properties of, 37–38
Dextrocardiogram, nature of, 566

Diabetes insipidus, lesions producing, 358
nature of, 1013, 1089
thirst in, 901
Diabetes mellitus, alveolar carbon dioxide pressure affected by, 757
anterior pituitary cause of, 1085
causes of, **977**
G : N ratio in, 944
metabolism in, 967
thirst in, 901
treatment of, 978
Diabetogenic hormone, actions of, 971
diet effect on secretion of, 972
growth hormone relation to, 1084
Dialysis, nature of, 55, **56**
Diaphragm, respiratory movements of, 710
vomiting and action of, 874
Diastole, cardiac events in, 556
heart filling in, 567
pressure changes in heart in, **559**
Diastolic murmur, cause of, 563
Diastolic pressure, measurement of, **611**
measurement in man of, 612
Diastolic volume, oxygen usage of heart relation to, 579
Diathermy, principle of, 115
Dibenamine, actions of, 351
Dicarboxylic amino acid, transamination and, 923
Dicrotic wave, nature of, 634
Dicoumarin, action of, 530
vitamin K relation to, **825**
Diet, adequate types of, **838**
calorie requirements of, 832
calorie value, vitamin B_1 requirements related to, 826
class differences in, **836**
fæces composition affected by, **900**
foodstuffs distribution in, **834**
nitrogen excretion variation with, **924**
pancreatic juice composition affected by, **881**
protein variation in, 802
starvation metabolism affected by previous, 799
Difference thresholds, types of, 423
Difference tones, nature of, 451, 462
Differential cell count, average values of, 523
Diffusion coefficient, measurement of, 54
Diffusion, complexities of, 79
Digestion, history of, 781
time course of, 918
Digitalis, heart affected by, 579
Dihydroxyacetone, structure of, **30**
Di-iodotyrosine, structure of, 40, **1072**
Dilator pupillæ, nerve supply to, 347
Dilemma, reaction time and, 319
Dilution diuresis, nature of, 1012
Dinitro-α-naphthol, temperature affected by, 1037
Diodrast T*m*, value of, 1009
Diœstrus, vaginal changes in, **1108**
Dioptre, definition of, 387
Diphasic action potential, cause of, **119**
Diphosphoglyceric acid, structure of, **53**
Diphtheria anti-toxin, production of, 702
Diploid number, nature of, 1097
Diplopia, strabismus causing, 376
Disaccharide, nature of, 36
"**Discobolus position,**" nature of, 272
Discrimination, conditioned reflexes showing, 325
cortical areas concerned in, 302
Discrimination, touch showing, 478
Discus proligerus, hyaluronidase action on, 1128
nature of, 1106
Disease, food intake affecting, 834
Dissonance, nature of, 461
Diuresis, diabetes mellitus causing, 977
hormonal factors controlling, 1090
types of, 1012
Diuretic hormone, action of, 1088
Diuretics, action of, 1015
osmotic type of, 1006
Divergence, neurone activity showing, 207, **208**
Diver's palsy, nature of, 778
Dominant character, nature of, 1154
"**Dominator,**" nature in vision of, 440
Donnan equilibrium, nature of, 82–84
red blood cells and, 510
Donnan ratio, nature of, 735
Dorsal roots, potential changes in, 247, **248**
Dorsal root section, effects of, 228
Dorsal root stimulation, vasodilatation caused by, **648**
Douglas bag, use of, **723**, 787
Draper's law, nature of, 373
Drosophila, sex chromosomes in, **1157**
Ductus endolymphaticus, nature of, 268
Ductus venosus, fœtal circulation in, 1137
Duodenal bulb, stomach emptying and, 871
Duodenal contents, sampling of, 875
Duodenum, food absorption in, **919**
gastric secretion stimulation from, 866
movements of, 893
secretion in, 888
stomach emptying and pressure in, 873
Duplex theory of colour vision, 437
Duplicity theory of vision, 418
Dura mater, nature of, 693
Dwarfism, nature of, **1083**
Dye, blood volume measurement by use of, 494
Dyslysin, nature of, 886
Dysmetria, nature of, 341
Dyspnœa, nature of, 717, 769

Ear, diagram of, **450**
Ear ossicles, movements of, 452
Eck fistula, nature of, 669
Ectoplasm, properties of, 14
Edestin, amino-acids in, 44
iso-electric *p*H of, 74
properties of, 46
Edridge Green lantern, use of, **435**
Effective temperature, nature of, **1048**
Egg albumin, amino-acids in, 44
iso-electric *p*H of, 74
molecular weight of, 72
properties of, 45
Egg white, biotin action and, 827
intestinal absorption of, 914
Egg yolk, vitamin A content of, 822
Ehrlich cells, heparin formation in, 533
Ejaculation, nerve centre of, 1128
Elastin, properties of, 51
Electrical stimuli, types of, 110
Electro-acoustic effects, cause of, 456
Electrocardiogram, recording of, 564
vagus nerve stimulation effect on, 587
Electro-dialysis, nature of, 80
Electroencephalograms, types of, **321**
Electro-endosmosis, nature of, 80

Electrolytes, osmotic pressure of, 61
proteins as, 76
Electroneuronography, nature of, 224
Electrophoresis, nature of, 74
Electrotonic current, nature of, **191, 192**
Electrotonic potential, motor end plate and, 196
nature of, 190–**191**
spinal roots showing, 247, **248**
sympathetic ganglia showing, 240
synaptic transmission and, **237**
Electrotonus, nature of, **189**
Eleidin, skin containing, 1028
Embryo, development of, 1131
nutrition of, 1134
tissue cultures from, 21
Emergency theory of adrenaline action, 1068
Emmetropic eye, accommodation range in, 391
Emotion, heart rate affected by, 598
pupil size affected by, 379
sweating response to, **1030**
Emphysema, nature of, 715
Emulsification, nature of, 27
Emulsin, action of, 89
Emulsoid, definition of, 70
Endocardiac pressure, measurement of, **557**
Endocrine actions, correlation of, 1091
Endocrine grafts, factors controlling growth of, 1092
Endocrine organs, history of, 1055
methods of investigation of, 1058
nervous control of, 1093
End-plate potentials, nature of, 196
Endurance test, nature of, 768
Energy, conservation in body of, **2**
Energy rich bonds, use of, 68
Energy-rich phosphate, skeletal muscle contraction and, 149
Enterocrinin, nature of, 889
Enterogastrone, actions of, 867
Entero-hepatic circulation, nature of, 886
Enterokinase, action of, 93, 879
Environmental constant, nature of, 1040
Enzyme action, kinetics of, **91**
Enzymes, catalytic nature of, 90
classification of, **95**
nature of, 90
specificity of, 89
synthetic action of, 94
Eosinophile cells, character of, **524**
infection and action of, 699
Ephapses, nature of, 237
Ephedrine, action of, 351, 1069
Epicritic sensation, nature of, 481
Epididymis, ciliary movement in, 169
sperm storage in, 1121
structure of, 1119
Epigenesis, theory of, 1152
Epilepsy, cortical stimulation producing, 308
Equiline, nature of, 1111
Equivalent temperature, nature of, 1047
Erection, mechanism of, 1120
nerve centre of, 1128
Erector penis, action of, 1127
Erepsin, action of, 39
nature of, 889
Ergosterol, vitamin D relation to, **823**
Ergotamine, adrenaline actions affected by, 1066
sympathetic system affected by, 647
Ergotoxine, sympathetic system affected by, 351

Erythroblast, nature of, 519
Erythrocytes, average data of, 500
blood viscosity affected by number of, **619**
buffering power of, 733
chemistry of, 510
composition of, **505**
formation, uric acid excretion affected by, 938
fragility of, 509
gases solubility in, **727**
hæmolysin action on, **705**
high altitude effect on, **777**
life history of, 517
number of, 493
osmotic pressure measurement by use of, 59
permeability of, 16, 81
size of, 507
specific gravity of, 501
splenectomy effect on, 682
sugar content of, 953
volume of, 496
Erythro-dextrin, nature of, 843
Eserine, action of, 351, 362
curare antagonised by, 188
eye affected by, 391
mode of action of, 589
Ether, pulmonary circulation time measurement by, 623
Ethereal sulphates, excretion of, 932
Eupathioscope, use of, 1047
Eustachian canal, nature of, 452
Evaporation, heat loss by, 1040
Eve's rocker, use of, 719
Excitability, temperature effect on, 126
time factor in, 111
Excitation, membrane permeability affected by, 87
Exercise, body temperature affected by, 1035
capillary area in muscle with, **742**
cardiac nerves importance in, 584
circulatory changes in, 673–678
creatinine excretion affected by, 934
foodstuffs used in, **943**
lactic acid production in, 150–**151**
lymph flow affected by, 691
mechanical efficiency of, 155
metabolic changes in, 804
oxygen consumption in, 150–**152**
protein requirements in, 806
respiratory changes in, **674**
respiratory quotient during 153–154
second wind in, 769
skeletal muscle capillary area increase in, 638
glycogen changes ni, 960
spleen affected by, 682
sweating induced by, 1031
sympathetic system removal effect on, 350
uric acid excretion affected by, 938
ventilation rate affected by, 768
white cell count in, 524
Exophthalmic goitre, nature of, **1075**
Exotoxins, body reaction to, 701
Expiration, muscles used in, 711
Expiratory centre, location of, 750
Expired air, composition of, 723
measurement of, 722
Expression, function of, 472
Extensor muscles, chronaxie of, 194
Extensor reflex, ipsilateral, 266
nature of, **230,** 231
nociceptive stimulus inhibition of, **264**
recruitment in, **261**

Extensor reflex, spinal cord section in man affecting, 234
Extensor thrust reflex, nature of, 231
Exteroceptor, definition of, 216
Extinction, conditioned reflexes showing, 326
  motor cortex showing, 307
Extracellular fluid, water in, 810
Extra-pyramidal paths, lesions of, 315
  motor cortex and, 309, 311
Extra-systole, nature of, **547**
Eye, accommodation in, 389
  adaptation in, 429
  chromatic aberration of, **393**
  colour responses of, 445
  focal length of, 387
  labyrinth reflexes affecting, 279
  optical system of, 383
  parasympathetic nerve supply to, 350
  peripheral aberrations of, 395
  pupil changes with convergence of, 378
  refraction of, 392
  refractive indices of media of, **387**
  resolving power of, **419**
  righting reflexes dependent on, **282**
  sections through, **384**
  sensation curve in, **425**, 426
  spherical aberration of, 394
  sympathetic nerve supply to, 347
  visual field of, 409, **410**
  X-ray measurements of, **399**
Eye movements, cortical control of, **299**, 300, 306
  control of, 374
  superior colliculi concerned in, 289
Eye muscles, innervation of, **375**
Eye reflexes, nervous pathways of, 289
Eyeball, blood supply to, **381**
  length, posterior nodal distance relation to, **401**
  muscles of, 373
  nerve supply to, **378**
Eyelids, structure of, 379
Eye-strain, hypermetropia causing, 397

Facilitation, cerebral cortex stimulation effecting, 321
  extra-pyramidal paths concerned in, **313**
  internuncial action potentials and, 247
  motoneurone showing, **243, 244**
  motor cortex showing, 307
Fæces, calcium in, 814
  composition of, 899
Fainting, cause of, 656
Fallopian tube, ciliary movement in, 169
  fertilisation in 1128
  ovum passage in, 1107
False vocal cords, function of, 465
Faraday-Tyndall phenomenon, nature of, 72
Faradic stimulation, effects of, 111
Fat, analysis of, 27
  bile secretion affected by, 884
  calorific value of, **791**
  carbohydrate formation from, 944
    in diabetes from, 967
  composition of, 25–26
  daily requirements of, 835
  emulsification of, 887
  essential in diet, 810
  gastric digestion of, 862
  glucose producing, 955
  growth needs of, **789**
Fat, heart usage of, 607
  intestinal absorption of, 909
  metabolism of, 939
    phospholipides function in, 950
    pituitary action on, 1087
    respiratory quotient showing amount of, **805**
    starvation effect on, 797
  oxidation of, 944
  pancreatic digestion of, 881
  placenta containing, 1135
  properties of, 26–27
  specific dynamic action of, 803
  starvation effect on usage of, **799**
  stomach emptying time affected by, 873
  thermal conductance of, 1039
Fat absorption, changes during, 951
Fatigue, skeletal muscle showing, **135**–136
  spinal reflexes showing, 262
Fatty acid, hydrotropy and intestinal absorption of, 909
  iodine values in different tissues of, **950**
  oxidation of, 944
Fatty degeneration, nature of, 949
Fechner's law, nature of, **370**, 371
Feet, temperature effect on temperature of, **1035**
  sweating on, 1031
Female, androgens effect on, 1126
  reproductive organs of, 1105
Femoral pulse, brachial comparison with, 635
Fenn effect, nature of, 126
Ferret, ovulation in, 1106
Ferri-porphyrins, nature of, 516
Ferritin, nature of, 520
Ferro-porphyrins, nature of, 516
Fertilisation, events in, 1099
Fertility, menstrual cycle and time of, 1130
Fever, basal metabolic rate affected by, 795
  course of events in, 1052
  thyroid gland activity in, 1072
  uric acid excretion affected by, 938
Fibrillation, nature of, 554
Fibrin network, structure of, **493**
Fibrin, properties of, 506
Fibrinogen, characters of, 529
  hæmorrhage effect on, 532
  properties of, 46, 506
Fibroin, nature of, 51
Fibrous protein, nature of, **43**
Fick principle, cardiac output measurement by, 568
Fillet, composition of, **285**
Filtration fraction, nature of, 1003
Final common path, nature of, **208**
Finger plethysmograph, pulse volume record by, **636**
Fish, accommodation in eye of, 388
  circulation arrangement in, 537
  lens in eye of, 388
Fixation reflex, nature of, 374, 376
Flavine adenine dinucleotide, action of, **99**
  co-enzyme action of, **94**
Flavine enzyme system, E_h of, 101
Flavo-protein, lactate to pyruvate reaction involving, 748
Fleisch differential stromuhr, principle of, **625,** 626
Flexor muscles, chronaxie of, 194
  cortical control of, 307
Flexor reflex, characteristics of, 250
  extensor reflex compared with, **261**–262

Flexor reflex, nature of, **230**
reflex arc concerned in, **213**
reticular formation stimulation effect on, **312**
spinal cord section in man affecting, 234
Flicker, cause of, 427
cortical potentials relation to, **321,** 322
light intensity affecting, 421
Flour, vitamin B_1 content of, 826
Fluoride, action on muscle of, 149
blood clotting affected by, 534
Focal length, X-ray measurement in eye of, **400**
Fœtal blood, oxygen content of, 1137
oxygen dissociation curve of, **1138**
Fœtal circulation, maternal circulation relation to, **1139**
Fœtus, blood cell formation in, 517
blood specific gravity in, 501
blood supply with growth of, 1135
circulation in, **1136**
glycogen storage in, 957
iodine value of fat in, 940
oxygen supply to, 1137
respiration in, 1139
Folic acid, extrinsic factor and, 520
nature of, 830
Food, alcohol absorption affected by, **840**
cardiac output affected by taking of, 573
gall bladder affected by, 885
urea and uric acid excretion following ingestion of, **939**
Food rationing, introduction of, 836
Foodstuffs, absorption of, 903
body storage of, **796**
calorific value of, **791**
composition of, 784
isodynamic replacement of, 806
percentage absorption of, 833
protein metabolism affected by, 800
vitamin A content of various, 822
vitamin content of, **829**
Foramen ovale, fœtal circulation through, 1137
Fovea, light intensity effect on vision at, **442**
spectral coefficient curves for, **444**
structure of, 404, **405**
structure of image at, 395
Foveal luminosity curves, notches in, **443**
Fractionation, reflex response showing, 255
Fragility, red blood cells showing, 509
Free energy, nature of, 67
Free-martin, nature of, 1157
Freezing point depression, osmotic pressure measurement by, 59
Frequency diagram, use of, **7**
Frog, circulation arrangement in, 537
heart anatomy in, 542
kidney, vascular supply to, **1007**
skin, permeability of, 82
urine formation in, **1005**
vago-sympathetic nerve stimulation in, **590**
Fröhlich's syndrome, nature of, **1084**
Frontal lobe, functions of, 300, **301**
Fructose, blood containing, 952
glycogen formation from, 959, 960
properties of, 32–33
semen containing, 1123
F.S.H., nature of, 1113
testis affected by, 1126
Fugacity, nature of, 101
Fumaric acid, structure of, **31**
Furane, nature of, **34**
Fuscin, function in vision of, 407

Galactose, properties of, 33
Gall bladder, food effect on, 885
function of, 882
Galvanic stimulation, effects of, 110
Galvani's experiment, nature of, **117**
Gametokinetic hormone, nature of, 1121
Gastric acidity, regulation of, 874
Gastric acids, determination of, 861
Gastric contents, emptying time and volume of, **873**
sampling of, 859
Gastric juice, actions of, 861
composition of, 859
composition of different types of, 868
humoral secretion of, 866
pernicious anæmia affecting, 520
secretion of, 862
Gastric movements, digestion and, 870
Gastric mucosa, electric potential of, 863
Gastric secretion, normal course of, 867
Gastrin, nature of, 867
Gastro-colic reflex, nature of, 897
Gastro-ileal reflex, nature of, 895
Gelatin, amino-acids in, 44
amino-acids lacking in, 808
iso-electric *p*H of, 74
properties of, 70
Gels, properties of, 70
Genes, independent association of, 1155
physical basis of, 19
Gennari, line of, 297, 304
Germ cells, formation of, 1095
Germinal vesicle, nature of, 1106
Gigantism, nature of, **1083**
Glass electrode, use of, 65
Glaucoma, causes of, 383
hypermetropia causing, 397
Gliadin, amino-acids in, 44
Globe thermometer, use of, 1047
Globin, amino-acids in, 44
properties of, 513
Globoglycoid, nature of, 507
Globular protein, structure of, 43
Globulin, electrolyte nature of, 76
properties of, 46
Globulin X, nature of, 139
Globus pallidus, functions of, 313, **314**
Glomerular capillary pressure, magnitude of, 1000
Glomerular filtrate, factors affecting rate of, 999
Glomerular filtration rate, measurement of, 1002
Glomerular fluid, composition of, 996
Glomeruli, function of, 995
structure of, 990
Glottis, nature of, 465
Glucoascorbic acid, action of, 830
Glucosamine, nature of, 34
Glucose, absorption rate from intestine of, 907
alkali action on, 35–36
body content of, 953
brain usage of, 670, 746
energy in oxidation of, 67
heart usage of, 607
metabolic fate of, **962**
oxidation of, 144
properties of, 32
red blood cell usage of, 510
renal threshold of, 963
skin storage of, 1032
T*m*, value of, **1009**

Glucose, tolerance curve, diet effect on, 972
    diabetes mellitus effect on, **977**
    nature of, **953**
  usage, diabetes effect on, 967
Glucose-1-phosphate, formation from glycogen of, **97**
Glucosides, varieties of, 35
Glucuronic acid, excretion of, 988
  nature of, 35
Glutamic acid, metabolism of, 930
  structure of, 41
Glutaminase, action of, 932
Glutamine, amino-acid synthesis from, 923
Glycerol, structure of, **30**
Glycerophosphoric acid, nature of, 25
Glycine, buffer action of, 65
  creatine formation and, 933
  structure of, 40
Glycocholic acid, nature of, 883
Glycocyamine, creatine formation and, 933
Glycogen, enzymic synthesis of, 94
  metabolic fate of, **962**
  phosphorylation of, **97**
  placenta containing, 1135
  properties of, 38, 957
  Purkinje fibres containing, 553
  skeletal muscle containing, 139
    contraction and disappearance of, 142
  sparing action on protein in starvation, 798
  tissue storage of, 957
Glycogenolysis, nature of, 958
Glycolipides, nature of, 30
Glycolysis, definition of, 142
  mechanism of, 955
  normal occurrence in blood of, 150
  reactions concerned in, 144
Glyconeogenesis, adrenal cortical hormone effect on, **973**
  anterior pituitary hormone effect on, 971
  nature of, 958
Glycoproteins, structure of, 50
Glycosides, nature of, 35
Glycosuria, causes of, 963
  diabetes mellitus causing, 977
  nature of, 955
G : N ratio, diabetes and, 944, 967
  phlorrhizin glycosuria and, 964
Goitre, causes of, 1074
Golgi apparatus, fat absorption and, 912
  nature of, **13**
  spermatozoa maturation and, 1099
Golgi cells, cerebellum containing, **333, 334**
  distribution in spinal cord of, 222
  types of, **202**, 204
Golgi network, nature of, **203**, 204
Goll and Burdach, composition of columns of, 224–**225**
Gonadotropic hormones, discovery of, 1087
  ovary affected by, **1112**
  pregnancy effect on excretion of, 1132
Gonads, adrenal action on, 1093
  adrenal gland relation to, 1063
  anterior pituitary interaction with, 1092
  thyroid interaction with 1093
"Goose-skin," nature of, 1028
Göthlin's fragility test, nature of, 639
Graafian follicle, structure of, **1105**
Granit's micro-electrode apparatus, **438**
Granulocytes, characters of, 523
Gravity, circulation affected by, 641, 683
Grey rami communicantes, composition of, 345
Growth, factors controlling, 21
Growth, food materials retained during, **789**
  protein requirement in, 802
  vitamin A effect on, **819**
Growth hormone, action of, **1083**
Growth rate, milk protein relation to, **1150**
Guanase, action of, 936
Guanine, structure of, **48**

Habit, basis of, 325
Hæm, nature of, 513
  structure of, **516**
Hæm pigments, chemical relationships of, **515**
Hæmatin, nature of, 513
Hæmatocrit, use of, **496**
Hæmatoporphyrin, nature of, 513
  structure of, **515**
Hæmin, nature of, 513
Hæmochromogen, nature of, 513
Hæmoconcentration, treatment of, 811
Hæmocyanin, molecular weight of, 45, 72
  nature of, 23
Hæmocytoblast, nature of, 517
Hæmocytometer, use of, 496
Hæmofuscin, nature of, 682
Hæmoglobin, absorption spectrum of, 512
  buffering power of, 733
  carbon dioxide reaction with, 737
  composition of, 47
  cyanosis with amount of, 772
  determination of, 497
  erythrocyte size relation to, 509
  high altitude effect on, **777**
  iron content of, 497
  iso-electric *p*H of, 74
  molecular weight of, 72
  oxygen combination with, **728**
  properties of, 511
  rate of regeneration of, 503
Hæmoglobinometer, use of, 497
Hæmokonia, nature of, 506
Hæmolysin, formation of, 704
Hæmolysis, nature of, 16, 509
Hæmolytic jaundice, nature of, 682
Hæmophilia, nature of, 535
  sex-linked inheritance of, 1158
Hæmopoietic factor, nature of, 520
Hæmopyrroles, nature of, **515**
Hæmorrhage, blood clotting in arrest of, 531
  blood volume restitution following, 495
  circulatory changes caused by, 680
  plasma protein formation after, 918
  tissue fluid movement after, 692
Hæmorrhagic states, causes of, 535
Hæmosiderin, function of, 813
  nature of, 522
  spleen containing, 682
Hair, factors affecting growth of, 1032
  tactile sensibility relation to, 478
Hair follicle, nerve plexus on, 216, **217**
  structure of, 1028
Hair growth, thyroid gland effect on, **1071**
Haldane, blood gas apparatus of, 497, **498**
Haldane-Pembrey respiration apparatus, use of, **787**
Hales, experiment of, 609
Halometer, use of, 507
Hamburger interchange, nature of, 733
Hand, sweating on, **1030**
  temperature of, **1035**
Haploid number, nature of, 1099
Haptophore group, nature of, 702

“ **Harden-Young ester,**” structure of, **34**
Hartridge's microstimulation apparatus, **441**
    theory of visual acuity, 420
Head, body tone affected by position of, **277**
    pose, reflexes concerned in, **280**-**281**
    sympathetic nerve supply to, 347
    temperature of, 1035
Head blood supply, regulation of, 658
Hearing, central nervous pathways of, **286**
    cortical representation of, 303
    mechanism of, 454
    organ of, 450
    phenomena of, 461
    reaction time of, 319
    theories of, 456
    tympanum function in 452
    Weber's law and, 370
Heart, acid effect on, **63,** 64
    adrenaline action on, **590,** 1066
    blood flow to, 629
    β-hydroxybutyric acid utilisation by, 948
    changes in form of, 561
    compensation by, 580
    contraction of, 550
    efficiency of, **576**
    excitatory wave spread in, **566**
    fat content of, 943
        iodine values in, **950**
    glycogen formation in, 607
    H ion concentration effect on, **583**
    lactate utilisation by, 150
    law of the, 576
    muscle. *See* Cardiac muscle.
    nervous regulation of, 583
    oxygen usage of, 576
        adrenaline action on, 591
        relation to diastolic volume of, 579
    parasympathetic stimulation effect on, 350
    perfusion of, **581, 582**
    pressure measurements in, **557**
    propagation of contraction wave in, 544
    pyruvate usage by, 746
    referred pain from, 354
    reflexes in, 592
    respiration effect on filling of, 567
    starvation and loss in weight of, **797**
    structure of, 548
    sympathetic nerve supply to, 348
    systolic output of, 567
    temperature effect on, 580
    “ tone ” of, 579
    work done by, 574
        in lifetime of, 541
Heart beat, neurogenic theory of, 543
    sequence of events in, 556
Heart block, nature of, 554
Heart disease, exercise affected by, **676**
Heart rate, refractory period relation to, 546
Heart sounds, cause of, 563
    graphic recording of, 563, **564**
Heart-lung preparation, use of, **571**
Heart-lung-kidney preparation, use of, 997
Heart-oxygenator preparation, **606**
Heart volume, arterial pressure change effect on, **577**
    venous return change effect on, **578**
Heat, acclimatisation to, 1051
    balance sheet, **1042**
        and its partition, 1041
    metabolic rate affected by, 1037
Heat cramp, cause of, 1052
Heat exhaustion, nature of, 1052
Heat loss, regulation of, 1038
Heat production, heat loss balance with, 793
    measurement in muscle of, **156**
    nerve showing, 185
    regulation of, 1036
Heat radiation, measurement of, 1047
Heat-regulating centre, location of, 1053
Heat regulation, breakdown of, 1051
Heat rigor, nature of, 126
Heat spots, distribution of, **475**
Heat-stroke, cause of, 1045
    limiting climatic conditions for, **1049**
Heavy nitrogen, amino-acid metabolism studied by, 920, 923
Hecht's theory of vision, 418
Helmholtz, theory of accommodation, 389
    theory of hearing of, 456
Hemiplegia, muscle responses after, 315
Henderson-Hasselbalch equation, 504
Henle's loop, function of, 1006
Henry's law, blood gases and, 727
Heparin, action of, 532, 534
    anaphylactic shock and, 706
    chemical nature of, 50
Hepatectomy, blood sugar affected by, **958**
Hepatic artery, portal vein connections with, 669
Hepatic circulation, 668
Heredity, conditioned reflexes and, 328
    factors concerned in, 1152
Hering-Breuer reflex, nature of, 760
Hering's theory of depth perception, 448
Herpes zoster, nature of, 235, 649
Heterozygous, meaning of, 1155
Hexokinase, action of, 144
    anterior pituitary and adrenal hormones and insulin action on, 974
    glycogenolysis and action of, 957
    glycolysis and action of, 955
Hexose phosphates, varieties of, **34**
Hexoses, structure of, 31
Hibernation, respiratory quotient in, 944
High altitude, Cheyne-Stokes breathing at, 771
    oxygen pressure at, **775**
Hippuric acid, excretion of, 986
Hirudin, action of, 534
His, bundle of, **551**
Histamine, anaphylactic shock and, 706
    blood vessels affected by, 662
    bronchi affected by, 721
    calcium effect on action of, 721
    circulation time measurement by, 623
    gastric secretion and, 867, **868**
        stimulation by, 859
    histidine origin of, **97**
        relation to, 42, 931
    nasal mucosa affected by, **709**
    shock relation to, 663
    skeletal muscle contraction liberating, 149
    uterine muscle affected by, **164,** 165
Histidine, histamine formation from, **97**
    metabolism of, 931
    structure of, 41
Histiocytes, inflammation and action of, 698
    nature of, 525
Histogram, nature of, 7
Histones, properties of, 45
History of physiology, 8
Histotoxic anoxia, nature of, 771
Hofmeister series, nature of, 74
Homatropine, eye affected by, 391
Homeostasis, nature of, 4

Homogentisic acid, nature of, 929
Homozygous, meaning of, 1155
Hormones, properties of, 1057
Horopter, nature of, 445
Houssay animals, nature of, 970
H-substance, nature of, 662
Human nerve, electrical stimulation of, **193**
Humanised milk, nature of, 1151
Humoral theory of nervous action, 360
Hunger, hypoglycæmia causing, 956
  nature of, 900
Hunger diabetes, nature of, 800
Hunger pangs, cause of, 874
Hyaluronidase, discus proligerus affected by, 1128
  spermatozoa containing, 1120
Hydræmic plethora, events in, 678
  lymph formation in, **690**
Hydrohcloric acid, gastric juice containing, 860
Hydrogen, balance sheet of, **788**
Hydrogen ion concentration. *See also* *p*H.
  meaning of, 63
  measurement of, 65–66
Hydrolases, actions of, 95, 96
Hydrosols, properties of, 71–73
Hydrotropic action, nature of, 883
Hydrotropy, absorption in intestine affected by, 909
Hydroxy-acids, amino-acid synthesis from, 923
Hydroxyglutamic acid, structure of, 41
Hydroxyproline, structure of, 41
Hypercalcæmia, effects of, 1077
Hypercapnia, nature of, 755
Hypercarbia, nature of, 755
Hypermetropia, causes of, 396
Hyperpnœa, nature of, 717
Hyperpyrexia, effects of, 1052
Hypertension, nature of, 661
Hyperthyroidism, effects of, 1074
Hypertonic solution, cerebro-spinal fluid affected by, 695
Hypodynamic heart, conditions in, 579
Hypogastric nerves, action on bladder of, **1019,** 1024
  composition of, 348
Hypogastric reflex, nature of, **349**
Hypoglycæmia, effects of, 956
  pituitary dysfunction and, 1085
Hypophysectomy, carbohydrate metabolism affected by, 969
  effects of, 1080
  lactation affected by, 1144
Hypophysio-portal circulation, nature of, 1079
Hypothalamus, anti-diuretic hormone control by, 1014
  frontal lobe connections with, **301**
  functions of, 233, 357
  motor cortex connections with, 311, **312**
  nuclei and connections of, **356**
  pituitary connections with, 1080
  sleep centre in, 331
  temperature regulating centre in, 1053
Hypotonia, cerebellar ablation causing, 339
  cerebellar injury in man causing, **340,** 341
Hypoxanthine, skeletal muscle containing, 140
  structure of, **48**
Hysteresis, nature of, 70

I.C.S.H., nature of, 1113
  pregnancy and excretion of, 1132
Identical twins, nature of, 1152
Idiomuscular contraction, nature of, 136
Ileocæcal valve. *See* Ileocolic sphincter.
Ileocolic sphincter, function of, 893
Ileum, food absorption in, **919**
Imbecillitas phenylpyruvica, nature of, 929
Imbibition, nature of, 70
Iminazol ring, structure of, **49**
Immunity, development of, 701
Impedance, nature of, 110
Inanition, basal metabolic rate affected by, 795
  metabolic rate affected by protein intake, 802
Incus, malleus relation to, **451**
Indican, excretion of, 987
  formation of, 930
Indicator yellow, nature of, 406
Indicators, *p*H measurement by, 65–**66**
Indol, formation of, 930
Inertia fly-wheel, use of, **134**
Infant, food intake of adult compared with, 1150
Infection, leucocyte action in, 699
Inflammation, course of events in, 697
  leucocytes function in, 525
Infra-red rays, eye insensitive to, 422
Inheritance, agglutinogens and, 502
  laws of, 1154
  morphology of, 1153
Inhibition, conditioned reflexes showing, 326
  cortical area concerned in, 328
  extra-pyramidal paths concerned in, **313**
  internuncial action potentials and, 247
  motonurones showing, 245
  recruitment and after-discharge in, **262**
  reflex response showing, 256, **257**
  theories of mechanism of, **260**
Injury, macrophage activity after, 697
Inosine, nature of, 936
Inositol, nature of, 140
Insensible perspiration, nature of, 1029
  water loss in, 811
Inspiration, muscles used in, 711
Inspiratory centre, location of, 750
Instinct, nature of, 323
Insulin, actions of, 968
  anterior pituitary extract effect on reactions to, **970**
  blood sugar effect on output of, 975
  mechanism of action of, 974
  molecular weight of, 45
Intercostal muscles, action in respiration of, 712
Intermittent claudication, nature of, 678
Internal capsule, basal ganglia relation to, **309**
  composition of, 309
  lesions in, 315
Internal inhibition, nature of, 327
Internuncial cells, action potentials in spinal cord of, **246–247**
Internuncial paths, types of, **242**
Interoceptor, definition of, 216
Intestinal blood vessels, adrenaline action on, 1065
Intestinal circulation, foodstuffs absorption and, **904**
Intestinal gas, formation of, 900
Intestinal juice, properties of, 888
Intestinal mucosa, enzymes in, 889
  phospholipides in, 950
Intestine, blood flow to, 629
  parasympathetic stimulation effect on, 350
  sympathetic stimulation effect on, 348
  See also Large and Small intestine.

Intra-abdominal pressure, respiration effect on, 715
Intra-auricular pressure, cardiac cycle and changes in, **561**
Intracellular fluid, water in, 810
Intracortical neurones, types of, **296–298**
Intracranial pressure, factors affecting, 671
Intra-ocular pressure, constancy of, 383
Intra-pleural pressure, cause of, 714
Intrathoracic pressure, cause of, 714
Intra-uterine pressure, parturition effect on, **1142**
Intravascular clotting, production of, 533
Intraventricular pressure changes,
  measurement of, 558
Intrinsic factor, anæmia and, 862
Inulin clearance, value of, 1003
Inulin, nature of, 38
Invertase, action of, 36
  fructose effect on, 92
Invertebrate hearts, structure of, 548
Involuntary muscle. *See* Plain muscle.
Iodine, daily requirement of, **812**
  thyroid gland uptake of, 1072
Iodine lack, thyroid gland affected by, 1073
Iodine value, body fat variation in, 939
Iodised casein, thyroxine formation from, 1072
Iodoacetate, action on muscle of, 148, 149
  fat absorption affected by, 913
  heart affected by, **607**
Ionophoresis, nature of, 1031
Iris, functions of, 377
  light sensitivity in some species, 377–378
Iron, absorption of, 895
  balance sheet of, **812**
  functions of, 23
  hæmoglobin containing, 497, 511
Iron wire model, nerve impulse and, 195
Irradiation, conditioned reflexes showing, 325
  flexor reflex showing, 251–252
  reflex action showing, 214
Ischæmic pain, nature of, 678
Islets of Længerhans, diabetes mellitus and, 978
  nervous control of, 1094
  structure of, **966**
Isochronism, law of, 115
Iso-citric acid, structure of, **31**
Isocortex, nature of, 293
Isodynamic replacement, foodstuffs and, 806
Iso-electric *p*H, proteins showing, 74
Iso-electric point, nature of, 40
Isohæmopyrrole, nature of, **515**
Isoleucine, structure of, 40
Isomerases, actions of, 96, 101
Isometric contraction, fibril changes with, **107**
  heat production in, 158
  nature of, **123–124**
Isosmotic solutions, definition of, 59
Isotonic contraction, fibril changes with, **107**
  heat production in, 158
  nature of, 121–**122**
Isotonic solutions, definition of, 59
sotopes, metabolic studies with, 920
Jaundice, blood clotting in, 535
  red blood cell fragility affected by, 509
  types of, 887
Jejunem, food absorption in, **919**
Joint movement, respiration affected by, 769
Joint, structure of, 818
Jugular pulse, heart block effect on, **554**
  heart sounds relation to, **564**
  radial pulse and electrocardiogram with, **565**
Jugular pulse, recording of, **640**
Jugular vein, pressure in, 639
Juxtamedullary glomeruli, nature of, 992

Kaes, line of, 303
Kallikrein, shock due to, 664
Katabolism, definition of, 3
Kephalin, structure of, 30
Kephir, nature of, 1148
Keratin, amino-acids in, 44
  properties of, 51
  structure of, **43**
Keto-acids, amino-acid metabolism and, 927
  amino-acid synthesis from, 923
  transamination and, 923
Ketogenic amino-acids, nature of, 928
Ketogenic hormone, action of, 1087
Ketoglutaric acid, structure of, **31**
Ketone bodies, metabolism of, 947
Ketosis, cause of, 946, 965
Kidney, adaptation to reduction of tissue of, 1011
  adrenal cortical deficiency effect on, 1060
  ammonia formation by, 932
  blood flow to, 629
  efficiency in diuresis of, 1012
  endocrine organs effect on, 1010
  fat iodine values in, **950**
  pituitrin action on, 1088
  structure of, **990**
  temperature effect on, **997**
  work done by, 994
Kinæsthetic impulses, nervous pathways for, **225**
Kinæsthetic sensation, central nervous
    pathways for, 284
  unconscious nervous pathways of, 292
Knee-jerk, cerebellar injury effect on, **340,** 341
  facilitation of, 265
  nature of, 230
  reflex arc concerned in, **213**
  reticular formation stimulation effect on, **312**
  vagus stimulation effect on, **359**
Knipping recording spirometer, use of, **786**
Korotkov sounds, nature of, 613
Krause's end bulb, function of, **481**
  nature of, 216, **217**
Krause's membrane, nature of, 106
Kupffer cells, nature of, 526
Kynurenic acid, nature of, 930

Labour pains, nature of, **1142**
Labyrinth, functions of, 217, 270
  structure of, **267**
Labyrinth reflexes, nature of, **278**
Labyrinthectomy, effects of, 270
Labyrinthine righting reflexes, head pose and, **280**
Lachrymal gland, nerve supply to, 350
  secretion of, **380**
Lactalbumin, milk containing, 1149
  molecular weight of, 45
Lactase, action of, 37
  galactose effect on, 92
  kinetics of action of, **91**–92
Lactation, control of, 1144
  reflex factors in, 1145
Lacteals, nature of, 686
Lactic acid, excretion of, 988
  exercise and production of, 150–**151**

Lactic acid, fatigue in muscle due to, 136
  gastric contents containing, 860
  heart usage of, 607
  liver removal of, 959
  pyruvate formation from, 748
  reduction rate of arterial blood affected by, **743**
  skeletal muscle containing, 139
    contraction and production of, 141
    heat production and changes in, 159
  structure of, **30**
  sweat containing, 1029
  vasomotor centre affected by, 652
Lactic acid cycle, isolated muscle and, 147
  nature of, 142
Lactic dehydrogenase, action of, **98**
  biliverdin affected by, 522
Lactoflavin, actions of, 827
Lactogenic hormone, action of, 1087
Lactoglobulin, milk containing, 1149
  molecular weight of, 45
Lactone ring, carbohydrates and, 33
Lactose, mammary gland synthesis of, 1147
  properties of, 37
  whey containing, 1149
Lævocardiogram, nature of, 566
Lanoline, nature of, 1028
Large intestine, functions of, 894
  innervation of, **896**
  movements of, 896
Laryngoscope, use of, 467
Larynx, anatomical mechanism of, 465
  deglutition and movement of, **855**
Latent addition, nerve showing, 180
  of excitation, plain muscle showing, 166
Latent period, plain muscle showing, 166
  reflex response showing, **252, 253**
  skeletal muscle showing, **122–123**
Lateral geniculate body, retinal area representation in, **288**
Lateral lemniscus, composition of, **286**
Law of forward direction, nature of, 205, **207**
  the heart, 576
  isochronism, nature of, 115
  plurality of connections, neurones and, **242**
  reciprocity of connections, neurones and, **242**
  specific irritability, 369
Lead poisoning, parathyroid effect on, 1078
Lecithin, fat absorption affected by, 912
  function in tissues of, 949
  structure of, **29**
Leech muscle, acetylcholine action on, **363**
Leg circulation, posture effect on, 641
Legumin, properties of, 46
Lengthening reaction, decerebrate preparation showing, 265
Lens, diffraction pattern formed by, 392
  focal length of, 387
  metabolism of, 385
  radius of, 386
  refractive power of, **385**
  structure of, 383
  suspension of, **384**
Lens capsule, thickness of, **390**
Lenticular nucleus, cortical connections with, 313, **314**
Leucine, structure of, 40
Leucocytes, amœboid movement of, 169
  chemiotaxis and, 3
  formation of, 524
  functions of, 525
  inflammation and action of, **698**
Leucocytes, number of, 493
  types of, 523
Leucotomy, results of, 301
Leukotaxin, nature of, 3, 699
L.H., nature of, 1113
Light, gonads stimulation by, 1113
  intensity threshold for, 413
  physical properties of, 372
  visual acuity affected by intensity of, 416
Light reflex, nature of, **290,** 377
Lillie's model, nerve impulse and, 195
Limb volume, adrenaline action on, **1065**
Limulus heart, structure of, 548
Linkage, heredity and, 1157
Linking, conditioned reflexes showing, 326
Linoleic acid, essential nature of, 949
  essential in diet, 810
Lipase, action of, 881
  bile salts action on, 887
Lipides, classification of, 25
Lipocaic, action of, 949
Lipoid, plasma membrane containing, **86**
Lipomicrons, nature of, 943
Lipotropic action, choline showing, 949
Liquor folliculi, nature of, 1106
Liver, adrenaline action on, 1066
  adrenaline inactivation by, 1068
  alcohol metabolism and, **841**
  amino-acid synthesis in, 923
  amino-acid uptake by, 916
  arginase, hormonal action on, 1086
  bile secretion in, 883
  blood flow to, 629
  capillary permeability in, 687
  choline action on, 949
  circulation in, 668
  deamination in, 926
  extirpation of, 669
  fat, glycogen relation to, 965
    iodine values of, **950**
    metabolism of, 947
  fatty degeneration of, 949
  fibrinogen formation in, 506
  function, test of, 882
  glycogen, adrenal cortical hormone effect on, **973**
    adrenaline action on, **961**
    bilirubin formation affected by, 522
    factors regulating, 976
    lactate as source of, 151
    regulation of, 956
  hæmopoietic factor of, 520
  insulin action on, 974
  jaundice in absence of, 887
  nervous control of, 963
  nucleic acid metabolism in, 937
  prothrombin formation in, 530
  serum proteins formation in, 506
  size, factors affecting, 881
  specific dynamic action of protein in, 803
  sugar output by, **959**
  sympathetic stimulation effect on, 348
  thyroxine formation by, 1073
  urea formation in, 926
  vitamin A content of, 821
  vitamin K action on, 825
Local excitatory state, nature of, 180
Local sign, nature of, 479
Locomotor ataxy, nature of, 316
Long sight. *See* Hypermetropia.
Loudness, scale of, 464

Loudness spectrum, outer and inner ear comparison, **461**
Lower motor neurone, acetylcholine synthesis in, 364
  effects of lesions of, 315
Lumbar cord, defæcation centre in, 899
Lumbar puncture, nature of, 693
Luminosity curve, light intensity effect on, **413**
Lung capillaries, distensibility of, 665
Lung inflation, respiration affected by, 759
Lungs, blood glycolysis in, 605
  dust removal in, 779
  gas exchange in, 738
  glycolysis in, 955
  glycolytic action of, 150
  oxygen diffusion in, 740
  oxygen uptake by blood in, 730
  respiratory movements of, 712
  speech control by, 471
  structure of, **708**
  sympathetic nerve supply to, 348
  volume of, 716
  water loss from, 811
Luteal cells, nature of, 1107
Lutein, nature of, 1107
Lymphagogues, action of, 689
Lymphatic system, blood relation to, **685**
  fat absorption by, 910
Lymphatic vessels, valves in, **691**
Lymph, composition of, **686**
  formation of, 685
  history of, 488
  movement of, 690
  plasma protein content comparison with, **687**
Lymph glands, functions of, 691
  lymphocyte formation in, 525
Lymphocytes, characters of, 524
  infection and action of, 700
Lysine, structure of, 41
Lysins, formation of, 704
Lysozyme, nature of, 697

Macrophage, action of, 697
Macula lutea, cortical representation of, 305
Maculæ acousticæ, nature of, 268, 402
Magnesium, acetylcholine synthesis and, 364
  balance sheet of, **812**
  excretion of, 985
  function in diet of, 813
  phosphatase affected by, 818
Magnesium sulphate, blood clotting affected by, 534
Male, œstrogens effect on, 1126
  reproductive organs of, 1119
Malic acid, structure of, **31**
Malleus, incus relation to, **451**
Malphighian body, nature of, 990
Malphighian follicles, nature of, 681
Maltase, action of, 36, 89
  pancreatic juice containing, 881
Maltose, properties of, 36
Mammary gland, corpus luteum effect on, 1113
  hormonal control of, 1104
  œstrogens effect on, 1111
  pituitary action on, 1087
  pregnancy effect on, 1144
Mammogen, nature of, 1144
Man, composition of, **789**
Manganese, function in diet of, 813
Mannose, properties of, 33
Marey's law, nature of, 595
" **Mark-time** " reflex, mechanism of, 260–**261**
Mass peristalsis, nature of, 897
Mass reflex, nature of, 234
Mast cells, characters of, **524**
  heparin formation in, 533
Mastication, process of, 852
  reflex nature of, 261
Mayer waves, nature of, 653
Meat, composition of, 835
  gastric secretion response to, 869
Mechanical efficiency, exercise and, 804
Mechanism, meaning of, 6
Medulla, electric potentials in, 321
  respiratory centres in, 749
  structure of, 210, **211**
Medullary sheath, structure of, 172
Megakaryocyte, nature of, 527
Megaloblast, nature of, 519
Meiosis, cancer cells showing, 1153
  nature of, **1097**
Meissner's corpuscle, function of, **481**
  nature of, 216, **217**
Melanin, skin containing, 1028
Melanophores, pituitary action on, 1088
Membrana granulosa, nature of, 1106
Membrane manometer, endocardiac pressure measurement by, **557**
Membrane equilibria, factors concerned in, 82–84
Membrane, permeability of, 80–82
Membrane potentials, nature of, 85
Mendel's laws, 1154
Menopause, changes at, 1119
  gonadotropic hormone excretion following, 1133
Menstrual cycle, events during, **1116**
  fertile period in, 1130
Menstruation, causation of, 1116, 1118
  nature of, 1115
  olfactory sense affected by, 487
Mercurial manometer, use of, **610**
Mercury, skin absorption of, 1031
Mesial lemniscus, composition of, 284, **285**
Metabolic rate, exercise effect on, **804**
  protein intake effect on, 802
  starvation effect on, **797**
  vitamin requirements relation to, 820
Metabolism, definition of, 3
  history of, 782
  specific dynamic action in, 802
Metachronal wave, nature of, 170
Metallo-porphyrins, nature of, 516
Metals, colloidal solutions of, 69
Metaproteins, nature of, 46–47
Methæmalbumin, nature of, 523
  properties of, 512
Methionine, creatine formation and, 933
  liver affected by, 808
  lipotropic action of, 949
  metabolism of, 931
  structure of, 40
Methylene blue, tissue respiration and, 747
Methylglyoxal, structure of, **30**
Meynert, giant pyramidal cells of, 304
Microcalorimeter, muscle heat production measurement by, **157**
Micro-manipulator, use of, **12**
Micro-pipette, glomerular fluid sampling by, 996
  tubular fluid sampling by, **1004**
Microrespirometer, use of, **145–146**
Microrespirometry, use of, 745

Microtonometer, blood gas pressures measurement by, 739
Micturition, physiology of, 1016
  spinal cord section affecting, 234
Mid-brain animal, brain section producing, **273**
Mid-brain, micturition centre in, 1025
Milk, clotting of, 1149
  composition of, 1148
  cow and human comparison, **1151**
  fat, composition of, 26
   origin of, 940, 1147
  gastric juice action on, 862
  pancreatic juice action on, 880
  protein, young growth rate relation to, **1150**
  secretion of, **1147**
  vitamin A content of, 822
Miner's cramp, cause of, 812
Mitochondria, nature of, **12,** 13
  spermatozoa maturation and, 1099
Mitotic division, process of, **1095**
Mitral valve, structure of, 550
Modiolus, nature of, 453
" **Modulator,"** nature in vision of, **440**
Molecular weight, glomerular membrane permeability and, 998
Monocular depth perception, 446
Monocytes, characters of, 524
Mono-molecular film, nature of, 79
Monophasic action potential, cause of, 119
Morgagni, ventricle of, 465
Morphine, pupil affected by, 379
  vagal tone affected by, 588
Morula, nature of, 1130
Moss fibres, origin of, 335
Motoneurone pool, nature of, 250
Motoneurones, constant current stimulation of, 247, **248**
  facilitation in, **243, 244**
  transmission at, **240–241**
  volley rate of, 246
Motor areas, ablation of, 308
  location of, 305
  localisation in, **299,** 300
  stimulation of, 306
Motor cortex, extra-pyramidal paths from, 309
  hypothalamic stimulation effect on response to stimulation of, **312**
  suppressor strip effect on, **314**
Motor end plate, transmission at, **196**
  structure of, **106,** 108
Motor nerve, composition of, 108
  terminations of, 108
Motor paths, lesions in man of, 315
Motor point, stimulation of, 193
Motor unit, functioning of, 130
  nature of, 204
  size of, 172–173, 250
   in different muscles of, 306
Mountain sickness, nature of, 774
Mouth, digestion of, 842
  speech affected by muscles of, 471
  temperature in, 1035
Movement, nervous pathways for conscious sensation of, 224–**225**
Mucin, gastric digestion of, 862
  properties of, 50
Mucinogen, salivary gland containing, 851
Mucoid, properties of, 51
Mucoitin, nature of, 50
Mucus, gastric secretion of, 868
Müller, retina containing fibres of, 404
Müller's muscle, nerve supply to, 348
Multiple chain, neurone action and, 244–245
Multiple cone hypothesis of colour vision, 437
Murmur, physical cause of, 617
Muscarine, action of, 351
Muscular movements, afferent impulses affecting co-ordination of, 316
  cortical stimulation giving, 306
Muscular tone, semi-circular canals concerned in, 272
  utricle concerned in, 271
Musculus vocalis, action of, 467
Music, vibration frequencies used in, 463
Mutarotation, nature of, 33
Mutases, action of, 101
Mutation, heredity and, 1159
Myasthenia gravis, nature of, 197
  thymus in, 1091
Myelin sheath, structure and function of, 172, 173
Myenteric reflex, nature of, **891**
Mylohyoid muscle, preparation of, 105
Myofibril, structure of, **107**
Myogen, properties of, 46, 138–139
Myoglobin, function of, 107
  oxygen dissociation curve of, **744**
Myopia, causes of, 398
Myosin, adenosine triphosphatase and, 148
  muscle contraction effected by, **160**–161
  physical properties of, 107–108
  properties of, 46, 139
Myxœdema, nature of, 1070

Narcotics, nerve affected by, 186
Nasal fossæ, olfactory epithelium in, **486**
Nasal passages, factors affecting diameter of, **709**
Neck, sympathetic nerve supply to, 347
Neck reflexes, eye movements affected by, 280
  righting reflexes and, **281**
  types of, **277**
Necturus, urine formation in, **1005**
Negative successive induction, nature of, 254
  spinal reflexes showing, 260
Neocerebellum, composition of, **332, 333**
  effects of injury in man to, **341**
  effects of removal and stimulation of, 339
Nerve, accommodation time factor in, 192
  action potentials in, **120, 175**
  block, excitability changes in nerve below, **187**
  conduction, electrotonic changes in, 189
  conductivity, factors affecting, 186
  degeneration of, 173
  electrotonic potentials in, 190–**191**
  electrotonus in, **189–190**
  excitability, electrotonic changes in, 189–**190**
   parathyroidectomy effect on, 1076
   temperature effect on, 181
  excitation of, 174
  fibres, classification of, 183
  history of, 103
  impulse, acetylcholine concerned in, 365
   all-or-none character of, 180
   chemical changes accompanying, 185
   frequency of, 178
   frequency, reflex contraction and, 246
   heat production in passage of, 185
   nature of, **194**–195
   train, nature of, 178
   transmission speed of, 177, **182**

Nerve, impulse, velocity in different fibres of, 177, **183**
volley, nature of, 178
interaction between adjacent fibres of, **184**
refractory period of, **179**
regeneration of, 173
structure of, **171**
terminations of, **202,** 204
theory of impulse transmission in, 185
unfatiguability of, 187–**188**
velocity of impulse in different fibres of, 177, **183**
Nerve centre, definition of, 212
Nerve tracks, spinal cord section and degeneration of, **222,** 223
Nerve-muscle preparation, chronaxie of, 114
use of, 105
Nervi erigentes, functions of, 350
large intestine secretion control by, 895
Nervous system, chemical transmission in, 360
“ **Neuberg ester,**” structure of, **34**
Neurilemma, nature of, 172
nerve regeneration and, 173
Neurocyton, structure of, **203**
Neurofibrils, nerve cells containing, **203,** 204
Neurokeratin, properties of, 51
Neurology, conditioned reflexes relation to, 329
Neuro-muscular conduction, thymus effect on, 1091
Neuro-muscular spindle, response to stimulation, 219–**220**
structure of, **217–218**
Neurone pool, nature of, **211,** 212
Neurone, types of, **202–203**
Neurosis, experimental development of, 327
New-born, composition of, **789**
renal function in, 1011
Niacin, actions of, 827
Nicotinamide, actions of, 827
Nicotine, sympathetic ganglia affected by, 345, 351, 645
sympathetic ganglia potentials affected by, 240
Nicotinic acid, actions of, 828
Nictitating membrane, nature of, 381
sympathetic nerve supply to, 347
sympathetic ganglion stimulation effect on, 238
Night-blindness, causes of, 434
vitamin A concerned in, 407
vitamin A, effect on, 821
Nissl bodies, nature of, **203**
Nitric oxide, hæmoglobin reaction with, 511
Nitrogen, absorption coefficient of, **726**
balance sheet of, **788**
excretion, starvation effect on, **799**
fixation of, 22–23
solubility in tissues of, 778
Nitrogenous equilibrium, factors affecting, 800
intravenous amino-acids injection and, 915
nature of, **785**
Nociceptive stimulus, prepotent influence of, **258**
Node of Ranvier, nature of, 172
Nomogram, effective temperature from, **1048**
serum calcium and protein, **814**
Non-polarisable electrodes, use of, 116, **117**
Non-protein respiratory quotient, carbohydrate and fat utilisation shown by, **805**
fat and carbohydrate usage measurement by, **798**
Nor-adrenaline, actions of, 1065
sympathin comparison with, 361
vasoconstriction action of, 659
Norleucine, structure of, 40
“ **Normal,**” definition of, 6
“ **Normal saline,**” definition of, 61
Normoblast, nature of, 519
Norvaline, structure of, 40
Novocaine, nerve affected by, 186
Nuclear delay, nature of, 243
Nuclease, action of, 935
Nucleic acid, breakdown of, 935, **937**
composition of, 48
molecular weight of, 72
Nucleins, composition of, 47
formation in body of, 935
properties of, 48
Nucleoproteins, composition of, 47
gastric digestion of, 862
metabolism of, 935
molecular weight of, 50
properties of, 48
Nucleosidase, action of, 936
Nucleoside, structure of, 49
Nucleotidase, action of, 935
Nucleotide, structure of, 49
Nucleus, cell division affecting, 1096
composition of, 17, **18**
effect of damage to, **18, 19**
structure of, **9,** 12
Nucleus cuneatus, function of, 284
Nucleus gracilis, function of, 284
Nutrition, history of, 781
Nystagmus, cerebellar lesions causing, 341
rotatory movement of head producing, 283
semi-circular canal stimulation inducing, 27

Obesity, chylomicrograph affected by, **910**
Occipital cortex. *See* Visual cortex.
Occipital lobe, functions of, 301
Occlusion, reflex response showing, **256**
Occlusion test, nature of, 662
Oculo-motor nerve, effect of injury to, 375
Oculo-motor neurones, transmission at, **240–241**
Oculo-motor nuclei, connections of, **375**
Œdema, cause of, 689
Œsophagus, deglutition and action of, **857**
parasympathetic stimulation effect on, 350
Œstradiol, structure of, **1110**
Œstriol, structure of, **1110**
Œstrogens, anterior pituitary affected by, 109
capon’s comb affected by, **1124**
male excretion of, 1126
mammary gland affected by, 1144
menstrual cycle effect on excretion of, 111
nature of, 1110
parturition effected by, 1141
placenta formation of, 1134
pregnancy effect on excretion of, **1133**
prostate affected by, 1122
Œstrone, pregnancy test by injection of, 113
structure of, **28, 1110**
Œstrus, causation of, 1109
vaginal changes in, **1108**
Œstrus cycle, course of, **1108**
Ohm’s law, sound analysis and, 463
Oleic acid, body synthesis of, 949
depôt fat containing, 939
nature of, 26
Olfactometry, use of, 487

lfactory epithelium, structure of, 486
lfactory sensation, 485
live, cerebellar connections with, 335
livo-cerebellar tracts, connections of, 292
ögenesis, process of, 1099
‘ **Opening tetanus,**’’ nature of, 189
perative temperature, nature of, 1040
phthalmoscope, use of, **411**
psonins, nature of, 705
ptic disc, appearance of, 411, **412**
ptic nerve, composition of, 287–288
ptic paths, course of, **287**
ptic radiation, blindness resulting from damage to, 289
Optic tract, blindness resulting from damage to, 289
Orchidectomy, effects of, 1103
Organ of Corti, nature of, **455**
“ **Organiser,**” nature of, 21
Orgasm, nature of, 1127
Ornithine, structure of, 41
  urea formation and, **927**
Orthopnœa, nature of, 717
Oscillograph, use of, **118,** 119
Osmometer, colloid osmotic pressure measurement by, **71**
Osmoreceptors, nature of, 1014
Osmosis, absorption from intestine effected by, 906
Osmotic diuretics, action of, 1006
Osmotic pressure, measurement of, 58–**61**
  nature of, **57**
Ossein, nature of, 815
Osteoclast, nature of, 526
  parathyroid effect on, 1078
Otolith organ, nature of, 268, **271**
Ovariectomy, effects of, 1103
Ovary, history of, 1056
  menstrual cycle changes in, **1117**
  pregnancy effect on, **1131**
  structure of, **1106**
Over-ventilation, apnœa following, 767, **770**
Ovulation, process of, 1105
  time of, 1117
Ovum, fertilisation effect on activity of, 1101
  fertilisation of, 1128, 1130
  formation of, 1099
  maturation of, 1106
Oxalate, blood clotting affected by, 528
Oxalic acid, excretion of, 987
Oxalo-acetic acid, fat metabolism and, 947
  pyruvic acid oxidation and, **143**
  structure of, **31**
Oxalosuccinic acid, structure of, **31**
Oxidases, actions of, 96, 99
  high oxygen pressure effect on, 774
Oxidation-reduction potentials, nature of, 101
Oxidising enzymes, action of, 98
Oxoisomerase, action of, 101
Oxycalorimeter, use of, **790**
Oxygen, absorption coefficient of, **726**
  blood content and saturation with, 500
  calories per litre of, **791**
  carbon dioxide dissociation curve affected by, **734**
  coefficient of utilisation in exercise, 676
  diffusion constant of, 740
  Fick principle use of, 569
  red blood cell formation affected by pressure of, 520
  tissue usage of, 745
Oxygen consumption, exercise affecting, **152**
Oxygen consumption, exercise effect on, 673
  isolated muscle showing, **146**
  of heart, work effect on, **576**
  protein meal effect on, **916**
  temperature effect on, 1037
Oxygen debt, exercise and, 152–**153**
  isolated muscle showing, 146
Oxygen dissociation curve, carbon dioxide effect on, **728**
  carbon monoxide effect on, 779
Oxygen insufflation, efficacy of, 719
Oxygen lack. *See* Anoxia.
Oxygen pressure, air and blood comparison, **740**
  effects of high, 773
  high altitude effect on, **775**
Oxyhæmoglobin, crystals of, **511**
  factors affecting dissociation of, **743**
  formation of, 511
  iso-electric pH of, 74
Oxyntic cells, composition of secretion by, 868
  secretion by, 863
Oxytocin, action of, 1088
  lactation affected by, 1146
  parturition effected by, 1141
  uterus and cervix affected by, 1141

Pace-maker, action of, **553**
  nature of, 543
Pacinian corpuscle, function of, **481**
  nature of, 216, **217**
  vasodilator reflex from stimulation of, 656
Pain, central nervous pathways for, 284
  pupil size in, 379
  nerve tracts concerned in sense of, **225,** 226
  sense of, 480
  spino-thalamic tract section and, 235
Palæocerebellum, composition of, **332,** 333
  effects of injury in man to, **340**
  effects of removal of, 339
Palm, sweat secretion on, **1030**
Palmitic acid, nature of, 26
p-**aminobenzoic** acid, sulphanilamide competition with, 820
p-**aminohippuric** acid Tm, value of, 1009
Pancreas, blood sugar action on, 1091
  blood sugar effect on insulin secretion by, 975
  diabetogenic hormone action on, 971
  insulin content of, 969
  parasympathetic stimulation effect on, 350
  zymogen granules in, **878**
Pancreatectomy, effects of, 965
  hypophysectomy effect on results of, 970
Pancreatic diabetes, nature of, 965
Pancreatic fistula, nature of, 875
Pancreatic juice, diet effect on composition of, **881**
  properties of, 878
  secretion of, 875
Pancreatic secretion, histological changes with, **878**
Pancreozymin, nature of, 877
Pantothenic action, nature of, 827
Papillary muscles, function of, 550
Paracasein, nature of, 1149
Paraffin, intestinal absorption of, 910
Paraganglia, nature of, 1060
Parallax, monocular depth perception use of, 447
Paralytic ileus, nature of, 893
Paraplegia, types of, 234

Parasympathetic nerve stimulation, salivary gland response to, **847**, 851
Parasympathetic system, chemical transmission in, 361
  composition of, 350
  hypothalamic stimulation effect on, 357
  irradiation in, **359**
  sympathetic comparison with, 351
Parasympathetic vasodilator nerves, 646
Parathyroid glands, function of, 1076
  history of, 1055
  lactation affected by, 1145
Parathormone, effects of injection of, 1077
Paraxanthine, thyroid gland affected by, 1076
Parietal cortex, structure of, **297**
Parietal lobe, functions of, 300
Parkinson's disease, nervous pathways affected in, 313
Parthogenesis, nature of, 1101
Partitional calorimetry, nature of, 1041
Parturition, events in, 1140
  nerve centre for, 1142
  oxytocin function in, 1090
"Past-pointing test," nature of, 272
Patellar reflex, hypothalamic stimulation effect on, **312**
Pavlov pouch, use of, **864**
Pecten, accommodation in eye of, 388
Pecten muscle, " catch action " of, 165
Pectin, absorption of, 894
Pellagra, nature of, 827
Pelvic visceral nerves, action on bladder of, **1019**, 1024
Penis, coitus and action of, 1127
  function of, 1120
Pentose, nucleic acid containing, 49
  structure of, **31**
Pepsin, action of, 39, 861
Pepsinogen, histamine and vagal stimulation effect on, **869**
  properties of, 863
Peptic cells, secretion by, 863
Peptide, synthesis of, 42
Peptide linkage, nature of, 42
Peptone, blood clotting affected by, 534
  feeding, blood amino-acids after, **917**
  properties of, 47
Pericardial fluid, coagubility of, 534
  effect of excess of, 567
  function of, 550
  plasma composition comparison with, **692**
  serum composition comparison with, **687**
Pericardial pressure, respiration effect on, 668
Pericardium, function of, 550, 567
Perimeter, visual fields measurement by, **409**
Perineuronal spaces, nature of, 695
Peripheral resistance, measurement of, 617
Peripheral vision, extent of, 409
Peristaltic movement, mechanism of, **891**
Peritoneal cavity, fluid absorption from, 692
Peritoneal fluid, plasma composition comparison with, **692**
Peritoneum, referred pain from, 354
Perivascular spaces, function of, 694
Pernicious anæmia, gastric juice in, 860
  treatment of, 520
Peroxidases, action of, 100
Personality, cortical areas concerned in, 301
Petechiæ, nature of, 639
P-factor, ischæmic pain and, 678
"Pfluger's law of contraction," nature of, **190**
*p***H**, definition of, 63
*p***H**, nerve affected by, 186
  plain muscle affected by, **164**, 166
  red blood cell fragility affected by, 509
  respiratory centre affected by, 765
Phagocytosis, nature of, 525, 697
Pharynx, deglutition and movements of, **855**
Phase contrast, use of, 11
Phenol red, renal secretion of, 1007
Phenylalanine metabolism of, 928
  structure of, 40
Philippson's reflex, nature of, **265**
Phlorrhizin, action on kidney of, **1005**, 1010
Phlorrhizin glycosuria, mechanism of, 964
Phosphatase, bone formation and, **817**
  fat absorption in intestine affected by, 909, 912
Phosphate, bone formation and, 816
  buffer action of, 64
  daily requirement of, **812**
  energy-rich bond of, 52
  excretion of, 895, 985
  fat formation from carbohydrate and, 941
  glucose absorption from intestine affected by, 907
  metabolism, parathyroid effect on, 1078
    vitamin D action on, 823
Phosphoacetic acid, structure of, **53**
Phosphoglucomutase, glycogenolysis and action of, 957
Phosphoglyceric acid, structure of, **31**
Phospholipides, function in tissues of, 949
  nature of, 29
Phosphoproteins, properties of, 47
Phospho-pyridino-nucleotides, co-enzyme action of, 93
Phospho-pyruvic acid, structure of, **30**, **53**
Phosphorus, functions of, 23
Phosphorylases, actions of, 95, **97**
  glycogenolysis and action of, 957
Photo-chemical reaction, types of, 373
Photo-chromatic interval, nature of, 415
Phthalate, buffer action of, 65
Phyllopyrrole, nature of, **515**
Physiology, definition of, 1
  history of, 8
  method of, 5
Physostigmine, eye affected by, 391
Phytin, nature of, 814
  rickets production by, 823
Pia mater, innervation of vessels in, 671
  nature of, 693
Piezometric circulation, nature of, **618**
Pilocarpine, action of, 351
Pilomotor nerves, course of, 346
Pinnaglobulin, nature of, 24
Piqûre glycosuria, mechanism of, 964
Pituicytes, nature of, 1079
Pituitary basophilism, signs of, **1086**
Pituitary body, structure of, **1079**
Pituitary gland, history of, 1055
  nervous control of, 1093
Pitressin, coronary vessels affected by, 602
  nature of, 1088
Pituitrin, actions of, 1087
  sweating effected by, 1031
Placenta, functions of, 1134
  mammary glands affected by, 1144
  œstrogen formation by, 1111
  pregnancy maintenance by, 1141
  uterine blood content and growth of, **1134**
Placental circulation, fœtal circulation relatio to, **1139**

“Placing reaction,” nature of, 283
Plain muscle, action potentials in, 167–**168**
  chemical agents affecting, **164**, 166
  chronaxie of, 114
  contraction, chemistry of, 169
  pituitrin action on, 1088
  propagation of excitatory state in, 168
  properties of, 162
  stimulation of nerve to, **165**
  temperature effect on oxygen usage by, 1036
  tonus in, 163–165
Plantar reflex, spinal segments concerned in, 215
Plasma, carbon dioxide dissociation curve of, **732**
  carbon dioxide solubility in, **727**
  clearance, meaning of, 1002
  composition of, **505**
  definition of, 493
  globulin, agglutination and, 501
  osmotic pressure, red blood cell fragility affected by, 509
  oxygen solubility in, **727**
  potassium, storage of blood effect on, 510
  proteins of, 506
    glomerular filtration affected by concentration of, 1002
    protein metabolism and, 917
    renal excretion of, 998
    starvation effect on, 800
  urine composition compared with, **995**
  vitamin A content of, 821
  volume of, 496
  water of body in, 810
Plasmapheresis, nature of, 918
Plasmolysis, nature of, 15, **16**
  osmotic pressure measurement by, 59
Plastein, nature of, 94
Platelets, characters of, **526**
  number of, 493
Plethora, events in, 678
Plethysmograph, blood flow measurement by, 627, **644**
  pulse volume measurement by, **636**
Pleura, referred pain from, 354
  structure of, 708
Pleural cavity, gas absorption from, 741
  fluid absorption from, 692
Pleural fluid, coagubility of, 534
P.M.S., nature of, 1133
Pneumotaxic centre, action of, **753**
  nature of, 751
Pneumothorax, nature of, 714
Poiseuille's formula, blood flow and, 616
Polar body, nature of, 1099
Polarisation, nature of, 80
  nerve impulse and, 185
Polarising current, nature of, 189
Polar stimulation, nature of, **110**
Polocyte, nature of, 1099
Polychromatic theory of colour vision, 439
Polygraph, use of, **632**
Polypeptides, properties of, 47
  trypsin action on, 880
Polysaccharides, nature of, 37
Pons, structure of, **211**–212
Porphin, structure of, 515
Porphyrin derivatives, skeletal muscle containing, 140
Porphyrins, excretion of, 987
  structure of, **515**
Portal pressure, exercise effect on, 680
Portal pressure, plethora effect on, **679**
Portal reservoir, factors affecting, 669
Portal vein, pressure in, 668
Posterior root ganglion, autonomic cells in, **352**
Post-ganglionic fibre, composition of, 345
Post-pituitary gland, functions of, 1089
  hormones secreted by, 1087
  nervous connections of, **357**
  water excretion regulation by, 1013
Postural albuminuria, nature of, 998
Postural reflexes, nature of, 274
Postural tonus, cerebellar lesions effect on, 340
  nerve paths concerned in, **274**
Posture, alveolar air composition affected by, 724
  blood volume variation with, 495
  cardiac output affected by, 573
  circulation changes with, 684
  factors concerned in, 267
  leg circulation affected by, 641
  stretch reflex importance in, 264
  systems concerned in, **275**
  tissue fluid formation affected by, 688
Potassium, acetylcholine release affected by 366
  acetylcholine synthesis and, 364
  adrenal cortex affected by, 1062
  cardiac muscle affected by, **581**
  cell content of, 81–**82**
  daily requirement of, **812**
  excretion of, 985
  nerve affected by, 186
  nerve impulse and, 195
  skeletal muscle affected by, 138
    containing, 140
  starvation effect on excretion of, 799
P-P factor, actions of, 827
Precipitin, formation of, 704
Pre-ganglionic fibre, composition of, 345
Pregnancy, blood sedimentation rate affected by, 501
  blood oxygen dissociation curve affected by, **1138**
  course of, 1130
  hormone factors in, 1132
  hormonal events in, 1104
  ovariectomy effect on, 1115
  oxytocin action affected by, 1088
  pituitary changes during, 1079
  placenta functions in, 1134
  test for, 1132
  white cell count in, 524
Pregnancy urine, œstrogens in, 1110
Pregnandiol, placenta formation of, 1134
  pregnancy effect on excretion of, 1133
  structure of, **1114**
Presbyopia, nature of, 391
Pressor reflex, nature of, 654
Pressure diuresis, nature of, 1012
Presystolic bruit, cause of, 564
Primordial follicles, nature of, 1106
Probable error, definition of, 7
Progeria, nature of, **1081**
Progesterone, adrenal cortex containing, 1061
  mammary gland affected by, 1144
  menstrual cycle effect on excretion of, 1118
  pregnancy maintenance by, 1141
  structure of, **1114**
Progression, stato-kinetic reflexes concerned in, 283
Prolactin, action of, 1087
  lactation control by, 1145

Prolactin, mammary glands affected by, 1144
  œstrogen stimulation to formation of, 1134
Proline, metabolism of, 930
  structure of, 41
Pro-œstrus, vaginal changes in, **1108**
Proprioceptive impulses, cerebellar recording of, 335–**337**
Proprioceptive reflex, cerebellar injury effect on, 340
  characteristics of, 263–**264**
Proprioceptors, nature of, 216–**218**
Prostate, androgens effect on, **1125**
  secretion of, 1122
  structure of, 1119
Prostigmine, nature of, 197
Protein, amino-acids in, 43–44
  bile secretion affected by, 884
  biological value of, 807
  buffer action of, 65
  calorific value of, **791**
  catabolism of, 924
  chemical nature of, 38
  denaturation of, 77
  electrical charge on, 73
  electrolyte nature of, 76
  fat formation from, 942
  functions in diet of, 807
  growth needs of, **789**
  intestinal absorption of, 914
  lens containing, 385
  lipotropic action of, 949
  metabolism, dietary protein effect on, 800
    exercise effect on, 805
    growth hormone effect on, 1084
    plasma proteins action in, 918
    starvation effect on 797
  minimum requirements for, 834
  molecular weight of, 44–45
  pepsin action on, 861
  physiological heat value of, 791
  rate of intestinal absorption of, **916**
  renal excretion of, 998
  sparing action of glycogen in starvation, **798**
  specific dynamic action of, 802
  specificity of, 51
  storage in body of, **799, 801**
  synthesis in body of, 922
  ultra structure of, **43**
Proteoses, properties of, 47
Prothrombin, characters of, 529
  vitamin K effect on formation of, 825
Protamines, properties of, 45
Protopathic sensation, nature of, 481
Protoporphyrin, nature of, 516
Protoplasm, chemical constituents of, 22–24
  nature of, 10
  physical structure of, 14
  ultrastructure of, 12
  water content of, 54
Pseudohermaphrodites, nature of, 1157
Pseudo-parturition, nature of, 1141
Pseudo-pregnancy, nature of, 1113
Ptyalin, action of, 843
  speed of action of, 88
P.U., nature of, 1132
  placenta formation of, 1134
Puberty, female development at, 1115
  nature of, 1103
  spermatogenesis at, 1120
Pudic nerve, bladder emptying control by, 1024
Puerperium, events in, **1143**
  milk secretion in, **1146**
Pulmonary arterial pressure, magnitude of, **538**
Pulmonary artery, afferent impulses from, 593
  stretch receptors in, 767
Pulmonary circulation, 665–668
  exercise effect on, 673
Pulmonary veins, afferent impulses from, 593
Pulmonary ventilation, **716**
Pulmonary vessels, innervation of, 666
  pressures in, 665
Pulmonary pulse pressure, 666
Pulse, central and peripheral, **633**
  pressure, measurement of, **611**
  rate, average value of, 599
    exercise effect on, **675**
    reduced barometric pressure effect on, **776**
    respiration effect on, **600**
  reflected waves in, 634
  tracing, comparison of different arterial, **633**
  volume, measurement of, **636**
  wave, cause of, 629
    velocity of, 631
    velocity, measurement of, 635
Pulsus paradoxus, nature of, 567
Pupil, causes of constriction, 377
  cortical control of constriction of, 306
  diameter, depth of focus affected by, 393
  dilatation, causes of, 379
  innervation of, 289
  sympathetic control of, 227
Pupillary reflex, nature of, 289, **290**
Purine bases, excretion of, 899
Purines, composition of, 48
  metabolism of, 936
Purkinjé cells, cerebellum containing, **333, 334**
Purkinjé fibres, nature of, **553**
Purkinjé's figures, nature of, **412**
Purpura, causes of, 535
Pus cells, nature of, 524
Pus, formation of, 699
Putrescine, nature of, 97
Pyloric canal, movements of, 870
Pyloric sphincter, afferent nerve fibres from **353, 354**
  stomach emptying and, 872
Pyramidal cells, connections of, 295
Pyramidal tracts, composition of, 226
  effects of section of, 315
  origin and course of, 309–311
Pyrane, nature of, **34**
Pyranose, nature of, 33
Pyrexia, heat regulation in, 1052
Pyridine, blood platelet formation and, 527
Pyridoxol, transamination and, 924
Pyrimidine bases, structure of, **49**
Pyrimidine nucleus, nature of, **49**
Pyrimidines, metabolism of, 938
Pyrithiamine, nature of, 827
Pyruvic acid, alanine metabolism and, 927
  brain usage of, 746
  fat formation from carbohydrate and, 941
  fat metabolism and, 947
  heart usage of, 607, 746
  lactate formation from, 748
  oxidation of, **142, 143**
  structure of, **30**
Pyruvic carboxylase, vitamin B_1 action on, 826

Quantal summation, nature of, 130
Quinidine, heart affected by, 556
Quinine, skeletal muscle affected by, 138
QO_2, definition of, 745
  meaning of, 922

- **Rabbit**, ovulation in, 1106
- **Radial** pulse, jugular pulse and electrocardiogram with, **565**
  - record of, **634**
- **Radiation,** heat loss by, 1039
- **Radioactive** iodine, use of, 1073
- **Radioactive P,** blood volume measurement by use of, 495
  - metabolic studies with, 920
- **Radioactive** substance, circulation time measurement by, 623
- **Rami** communicantes, nature of, 343
- **Rationed** food, composition of, **837**
- **Reaction** of degeneration, nature of, 194
- **Reaction** time, measurement of, 318
- **Reactive** hyperæmia, nature of, 659
- **Rebound,** spinal reflexes showing, 260, **261**
- **Recessive** character, nature of, 1154
- **Reciprocal** innervation, eye muscles showing, 375
  - flexor reflex showing, **251,** 252
  - motor area stimulation and, 306–307
  - spinal reflexes and, 256–**257**
  - theory of mechanism of, 259–**260**
- **Recklinghausen** capsule, capillary pressure measurement by, 638
- **Recruitment,** extensor reflex showing, **261**
  - mechanism of, 262
- **Rectum,** defæcation and action of, 898
  - temperature in, **1035**
- **Red** cell count, nature of, 496
- **Red** nucleus, cerebellar connections with, 338
  - decerebrate rigidity and, 273
- **Reducing** enzymes, action of, 98
- **Reduction** division, nature of, **1097**
- **Reflex** action, characteristics of, 250
  - nature of, **212**
- **Reflex** arc, nature of, **213**
- **Reflex** contraction, frequency of nerve impulses in, 246
- **Reflex** figures, nature of, **232,** 233
- **Reflex** stance, factors concerned in, 277
- **Refraction,** factors concerned in, **385**
- **Refractory** period, cardiac muscle showing, 545
  - motoneurone showing, 241
  - nerve impulses and, 178
  - nerve showing, **179**
  - reflex response showing, **255**
  - skeletal muscle showing, 130
  - spinal flexor arc showing, 245–246
  - sympathetic ganglion showing, 238
- **Reinforcement,** conditioned reflexes showing, 326
  - spinal reflexes showing, 258
- **Reissner's** membrane, nature of, **454**
- **Remak's** ganglion, site of, 542
- **Renal** arterioles, urine flow regulation by tone of, 999
- **Renal** blood flow, glomerular filtration rate relation to, 999
  - measurement of, 1010
- **Renal** circulation, anatomy of, 991
- **Renal** function, history of, 980
- **Renal** glycosuria, nature of, 963
- **Renal** secretion, theories of, 994
- **Renal** tubules, function of, 1003
  - reabsorption from, 1004
  - secretion into, 1006
  - structure of, **991**
- **Renin,** action of, 1015
  - nature of, 661
  - site of production of, 991
- **Rennin,** action of, 862
- **Repetitive** discharge, motoneurones showing, 245
- **Reproduction,** history of, 1056
  - vitamin E effect on, 824
- **Reproductive** organs, hormonal influences on, 1103
- **Residual** air, measurement of, **717**
  - value of, **716**
- **Resonance** theory of hearing, 456
- **Respiration,** arterial pressure effect on, **766**
  - arterial pressure variation with, 667
  - artificial, 718
  - barometric pressure increase effect on, 778
  - bronchial movements in, 722
  - chemistry of, 722
  - diastolic filling of heart affected by, 567
  - glossopharyngeal nerve stimulation effect on, **858**
  - high altitude effect on, 775
  - history of, 490
  - lymph flow affected by, 691
  - mechanics of, 708
  - portal vein pressure affected by, 668
  - pulmonary pressures variation with, 666
  - pulse rate variation in, 600
  - reflex regulation of, 758
  - speech effect on, 471
  - of swallowing, nature of, 854, 859
  - vocal cords movement in, 468
- **Respiration** apparatus, use of, **785,** 791
- **Respiration** pump, types of, 718
- **Respiratory** centre, acetylcholine action on, 364
  - automaticity of, 753
  - carbon dioxide action on, 757
  - cardio-inhibitory centre affected by, **600**
  - location of, 749
- **Respiratory** exchange, exercise effect on, 804
  - measurement of, **785**
- **Respiratory** movements, chemical regulation of, 754
  - mechanics of, 708
  - methods of measurement of, **713**
  - regulation of, 749
- **Respiratory** quotient, calorific value of oxygen variation with, 792
  - definition of, 150
  - diabetes and, 967
  - exercise effect of, 153, 806, **943**
  - hibernation effect on, 944
  - measurement of, 788
  - nature of, 724
- **Restiform** body, afferent fibres in, 335
- **Rete** mucosum, structure of, **1027**
- "**Retention** of action current," nature of, 185–186
- **Reticular** cell, nature of, 525
- **Reticular** formation, motor cortex connections with, 311
- **Reticulocyte,** nature of, 519
- **Reticulo-endothelial** cells, red blood cell destruction by, 521
- **Reticulo-endothelial** system, function of, 525
  - jaundice and, 887
- **Reticulo-spinal** tract, function of, 227, **313**
- **Retina,** central connections of, 411
  - directional sensitivity of, **414**
  - electrical changes in, **406**
  - fatigue in, 429
  - lateral geniculate representation of, **288**
  - structure of, 402
- **Retinal** vessels, position of, **412**

Retinene, nature of, 406
  pigments formed from, 440
Retino-motor fibres, function of, 405
Retinoscopy, method of, 396
Retractor penis, action of, 1129
  innervation of, **162**
Retrograde degeneration, nature of, 224
Reverbatory circuits, cerebral cortex containing **298,** 299
Reverberation, speech affected by, 470
Reversion spectroscope, carboxyhæmoglobin determination by, 512
Rh factor, nature of, 503
Rheobase, nature of, 114
Rheotome, use of, **113**
Rhinomanometry, use of, 709
Rhodopsin. *See* Visual purple.
Riboflavin, actions of, 827
  hæmoglobin formation affected by, 521
  protein synthesis and, 923
Ribs, respiratory movements of, 711
Ricin, nature of, 701
Rickets, vitamin D relation to, 822
Righting reflexes, mechanism of, **280**
  nerve centres for, 282
Rigor mortis, factors affecting, 137
  lactic acid maximum in, 141
  muscle proteins in, 139
  nature of, 126
Ringer solutions, composition of, **62**
Ritter-Valli law, nature of, 181
"Robison ester," structure of, **34**
Rod, structure of, **404**
  theories of vision and, 437
  twilight vision and, 408
  vitamin A, effect on, 821
Room ventilation, standard conditions for, 779
Round ligaments, parturition and changes in, 1140
Rotation, reactions to, 283
Royal Air Force, respiratory tests for, 768
Rubber, gases soluble in, 81
Rubro-spinal tract, decerebrate rigidity and, 273
  function of, 227
Russell's tract, course of, **338**
Rutherford's theory of hearing, 459

Saccharin, circulation time measurement by, 623
Saccule, function of, 268, 271
Saliva, composition of, **843**
  functions of, 843
  secretion of, 844
Salivary "centre," location of, 845
Salivary duct, pressure in, 848
Salivary glands, changes during secretion in, 848
  conditioned stimulation of, 324
  innervation of, 846
  parasympathetic nerve supply to, 350
  structure of, **844**
  sympathetic nerve supply to, 347
Salivary secretion, electrical changes during, 851
  energy involved in, 852
  histological changes following, **850**
  thirst relation to, 901
  reflex arc of, **214**
Salmin, amino-acids in, 44
Salt, daily requirement of, **812**
  growth needs of, **789**
  intestinal absorption of, 906
  metabolic rate affected by lack of, 1064
  renal excretion of, 1010
  skin storage of, 1032
  sweat containing, 1029
Salt excretion, desoxycorticosterone effect on, 1062
Saponification, nature of, 27
Sarcolemma, nature of, 106
Sarcomere, nature of, **107**
Sarcoplasm, nature of, 106
Sarcoplasmatic membrane, nature of, 106
Saturation, difference threshold of, 424
Scala media, nature of, **454**
Scala tympani, nature of, **454**
Scala vestibuli, nature of, **454**
Schafer's method of artificial respiration, 719
Schiff-Sherrington phenomenon, nature of, 230
Sclero-proteins, nature of, 51
Scratch reflex, latent period of, 254
  nature of, **231**
  nociceptive stimulus inhibition of, **258**
Scopolamine, eye affected by, 391
Scurvy, capillary fragility in, 639
  vitamin C effect on, 828
Sebaceous glands, secretion of, 1028
  secretion, nature of, 27
Sebum, composition of, 1028
Secondary sexual characters, adrenal cortex effect on, 1063
"Second wind," nature of, 153, 769
Secretin, bile secretion affected by, 884
  nature of, 876
Segmenting movements, small intestine showing, **890**
Semen, composition of, 1123
Semi-circular canals, arrangement of, **268**
  function of, 271–272
Semi-lunar valves, heart response to damage to, 580
  structure of, 550
Seminal vesicle, androgens effect on, **1125**
  structure of, 1119
  sympathetic nerve stimulation effect on, 1129
Semi-permeable membrane, nature of, 57
Sensation, stimulus relationship to, 369
Sense organs, classification of, 368
Sense receptors, properties of, 219–**220**
Sensory nerve, vasodilator action of, **649**
Sensory paralysis, nature of, 316
Serum, bacteria affected by, 700
  calcium, protein affecting ionic state of, **814**
  colloid osmotic pressure of, 57
  composition of, 505
  definition of, 493
  phosphate, glucose absorption effect on, 907
  proteins of, 506
  protein, calcium ionisation relation to, **814**
    intestinal absorption of, 914
    osmotic pressure of, 71
  specific gravity of, 501
Serum albumin, amino-acids in, 44
  blood clotting affected by, 532
  iso-electric *p*H of, 74
  molecular weight of, 72
  properties of, 45, 506
Serum globulin, antibody formation and, 704
  blood clotting affected by, 530
  iso-electric *p*H of, 74

Serum globulin, molecular weight of, 45, 72
  properties of, 46, 507
Serine, structure of, 40
Sex, blood composition affected by, 500
  determination of, 1155
  hair growth affected by, 1032
  metabolic rate variation with, 832
  temperature difference in, 1035
  temperature regulation differences in, 1038
Sex chromosomes, nature of, **1156**
Sex hormones, specificity of, 1126
Sex-linked characters, nature of, 1156
Sham feeding, gastric secretion affected by, **860, 865**
Sham rage, hypothalamic stimulation causing, 358
  nature of, 233
Sheep, blood sugar value in, 954
Shingles, nature of, 235
Shivering, reflex nature of, 1054
  temperature regulation and, 1038
Shock, adrenal cortical hormones effect in, 1062
  events in, 663
  spinal transection in man causing, 234
  vascular changes in, 621
Shortening reaction, decerebrate preparation showing, 265
Short sight. *See* Myopia.
Simmond's disease, nature of, **1081**
Simultaneous contrast, nature of, 430
Singing, vocal cords action in, 468
Single-cone hypothesis of colour vision, 438
Sino-auricular node, structure of, 552
  vagus nerve stimulation effect on, 586
Sinus arrhythmia, nature of, 600
Sinus venosus, modification of, 552
Skatol, formation of, 930
Skeletal muscle, adrenaline action on, 1066
  aerobic metabolism of, 142
  all-or-none rule in, 127–**128**
  blood flow in resting, 629
  capillary area in, **742**
  capillary bed on exercise of, 675
  chemical composition of, 138
  chronaxie after nerve degeneration, 194
  chronaxie of, 114
  contraction, A.T.P. changes in, 148
    chemical changes in, 140
    chemical and heat changes in, 159
    mechanical efficiency of, 159
    mechanical energy of, 133–**134**
    pH changes in, 149
    physical changes associated with, 160
    physical changes in fibrils during, 107
    temperature effect on, 126
    theories of, **160**–161
  contractures in, 136–137
  creatine storage in, 933
  drugs acting on, 138
  electrical and mechanical responses of, 120, **131**
  enzyme systems in pyruvate formation in, **143**
  excitability of, 109
  exercise effect on blood flow in, 674
  fat content of, 943
  fatigue in, **135**–136
  glycogen storage in, 960
  heat production in, 155
  history of, 103
  initial length effect on contraction of, **124,** 125
Skeletal muscle, iodoacetate action on, 148
  isometric contraction of, **123–124**
  isotonic contraction of, **122**
  latent period of, **122–123**
  maximum work of, **134**–135
  myoglobin function in, 744
  neuro-muscular spindles in, **217–218**
  optimal rate of contraction of, 135
  oxygen usage of, 145
  potassium and sodium content in, 81–**82**
  propagation of contraction in, 127
  reaction of degeneration in, 194
  red, postural reflexes and, **279**
  refractory period of, 130
  relaxation, nervous connections effect on, 316
  starvation and loss in weight of, **797**
  tetanus of, 128–**129**
  tone, afferent impulses concerned in, 316
    cerebellum removal effect on, 339
    mechanism of, **131**
    sleep and, 329, 330
  thyroxine formation by, 1073
  twitch, recording of, **121–122**
  types of, 264
  vasodilatation, fainting due to, 656
  vasodilator nerves to, **647**
  viscosity, athletes and, 155
  voluntary contraction of, 132–**133**
Skin, absorption by, 1031
  blood flow to, 629
  blood supply at different temperatures to, 1044
  blood vessels, heat regulation effected by, 1043
    temperature sense relation to, 476
  clothing effect on heat loss by, 1046
  history of, 981
  reflex vaso-motor response to temperature change in, 1053
  sensations in, 474
    spinal cord tracts for, 224–**225**
  storage functions of, 1032
  structure of, **1027**
  temperature variation in, **1035**
    reflex responses to change in, 1053
  vascular reactions of, 662
  vessels, hæmorrhage effect on, 680
    vasodilator nerves to, 647
  water loss from, 811
Sleep, hypothalamic lesions causing, 358
  pupil size in, 378
  state of, 329
Sloth, muscle tonus in, 274
Small intestine, absorption from, 903
  digestion in, 875
  movements of, **890**
Smell, nervous pathways of, 290
  sense of, 485
Smell centre, location of, 305
Smooth muscle. *See* Plain muscle.
Sodium, cardiac muscle affected by, **581**
  daily requirement of, **812**
  movement to and from intestine of, 908
  red blood cell treatment of, 510
  skeletal muscle affected by, 138
Soft palate, deglutition and movement of, **855**
Sole, sweat secretion on, 1031
Solubility product, bone calcification and, 817
Somæsthetic area, functions of, 302
Sound, localisation of, 463
Sound pattern theory of hearing, 459

Specific dynamic action, cause of,803
  intimate nature of, 928
  protein showing, **916**
Specificity, conditioned reflexes showing, 325
Spectral colours, properties of, 372
Spectroscope test, colour blindness detection by, 435
Speech, acoustics of, 469
  neurology of, 470
Spermatid, nature of, 1098
Spermatocyte, nature of, 1098
Spermatogenesis, hormonal control of, 1120
  process of, 1098
Spermatozoa, fertilisation by, **1100**
  maturation of, 1099
  movement in female tract of, 1128
  numbers in semen of, 1123
  properties of, 1122
Spherical aberration, eye showing, 394
Sphincter of Oddi, function of, 885
  nature of, 882
Sphincter vesicæ, action of, 1017
Sphygmograph, use of, 632
Sphygmomanometer, use of, **612**
Spike-potential, nature of, **177**
Spinal animal, brain section producing, **273**
  properties of, 229
Spinal autonomic afferent fibres, path of, **352**
Spinal cord, acetylcholine synthesis in parts of, 364
  action potentials in, **246**, **247**
  afferent paths in, 224
  autonomic centres in, 355
  efferent paths in, 226
  micturition centres in, 1025
  nerve tracks in, 223, **225**
  section. *See* Spinal transection.
  structure of, 209, 222
  transmission in, 245
  trophic functions of, 234
Spinal cord canal, ciliary movement in, 169
Spinal cord lesions, micturition affected by, **1023**
Spinal flexor arc, refractory period of, 245–246
Spinal frog, properties of, 214
Spinal lemniscus, composition of, 284, **285**
Spinal nerve, composition of, **345**
Spinal reflex, algebraic summation of excitation and inhibition in, 259
  characteristics of, 250
  hypothalamic stimulation effect on, 357
  nature of, **230**
  vagus stimulation effect on, **359**
Spinal roots, action potentials in, 247, **248**
Spinal root section, effects of, 228
Spinal shock, nature of, 230
Spinal transection, blood pressure affected by, 642
  effects of, 227, 229
  effects in man of, 233
Spinal vasomotor centres, action of, 653
Spino-cerebellar tracts, composition of, **225**, 226
  destination of, 335–337
  functions of, 292
Spino-thalamic tract, composition of, 224
  pain relief by section of, 235
Spireme, nature of, 1096
Spirometer, lung volumes determined by, **717**
  respiratory exchange measurement by, **786**
Splanchnic nerve, composition of, 346, 646
Spleen, blood platelets affected by, 535
  circulation in, 681
Spleen, contractions of, **681**
  functions of, 682
  monocyte formation in, 525
  sympathetic stimulation effect on, 348
Splenectomy, red blood cell fragility affected by, 509
Spongin, nature of, 51
Spongioblasts, retina containing, **403**
Squid nerve, action potentials in, **176**
Stagnant anoxia, nature of, 771
Staircase effect, nature of, **545**
Standard deviation, definition of, 7
Stannius ligatures, nature of, 542
Stapedius, function of, 452
Starch, properties of, 37
  salivary digestion of, **843**
Starvation, bile secretion during, 885
  blood amino-acids in, **917**
  blood lipides affected by, 911
  fat usage in, 943
  glucose tolerance curve affected by, 972
  liver glycogen in, 957
  metabolic rate affected by food intake, 802
  metabolism in, 796
Static ataxy, nature of, 316
Static reflexes, types of, 276
Statistics, use of, 7
Stato-kinetic reflexes, types of, 282
"Steady state," nature of, 151
Stearic acid, nature of, 26
Stellate ganglion, composition of, 343
Stenopœic aperture, use of, 396
Stephan's law, nature of, 1039
Stepping reflex, negative successive induction in, 254
Stercobilin, nature of, 883
Stereognosis, cortical areas for, 303
Stereoscopic vision, factors in, **447**
Sterno-cutaneous muscle, strength-duration curves from, **115**
Sterols, metabolism of, 952
  structure of, 27–29
Stethograph, use of, **713**
Stilbœstrol, structure of, **1111**
Stomach, absorption from, 903
  alcohol action on, 839
  deglutition effect on, 858
  distension, gastric secretion from, 867
  emptying of, 871
  hæmopoietin formation in, 520
  hormone secretion by, 866
  movements of, 870
    vomiting effect on, 874
  nerve stimulation effect on movement of, **165**, 166
  parasympathetic stimulation effect on, 350
  pressure in, 874
  salivary digestion in, 844
  sympathetic stimulation effect on, 348
Strabismus, causes of, 375
  hypermetropia causing, 397
Stratum pigmenti, function of, 403
Strength-duration curve, *a* and *γ* components of, **115**
  nature of, **113**, 114
Stretch receptors, structure of, **217–218**
Stretch reflexes, characteristics of, 263–**264**
  muscle contractions in, **131**
String galvanometer, principle of, 118
Stroke volume, exercise effect on, **675**
Stromuhr, types of, **624**
Strophanthin, heart affected by, 579

Strychnine, motor area stimulation after, 307
  spinal cord affected by, 263
Sturin, amino-acids in, 44
Sub-arachnoid cisternæ, nature of, 693
Subcutaneous fat, composition of, 939
Subcutaneous tissue, gas pressures in, 743
Subliminal excitation, motoneurones showing, 243
Subliminal fringe, nature of, 253, **254**
Substrate, definition of, 89
Successive contrast, nature of, 430
Successive spinal induction, nature of, 254
Succinic acid, heart usage of, 747
  structure of, **31**
Succinic dehydrogenase, action of, **99**
Succus entericus, secretion of, 888
Suckling, uterine movements affected by, **1143,** 1148
Sucrose, properties of, 36
Sulphæmoglobin, formation of, 512
Sulphanilamide, *p*-aminobenzoic acid competition with, 820
Sulphate, urine containing, 984
Sulphonal, urine affected by, 987
Sulphur, amino-acids containing, 931
  enzymes containing, 90
  equilibrium, nature of, **785**
  metabolism of, 23, 931
Summation, central inhibitory state showing, 259
  conditioned reflexes showing, 325
  nerve and types of, 178
  reflex response showing, **253–254**
Summation of contractions, plain muscle showing, **164,** 166
  skeletal muscle showing, 128–**129**
Summation of stimuli, cardiac muscle showing, 545
  nature of, 115
  plain muscle showing, 166
  sympathetic ganglia showing, 239
Superior cervical ganglion ratio, of pre- and postganglionic fibres in, 349
  transmission in, 237
Superior colliculi, visual functions of, 289
Supplemental air, value of, **716**
Supporting reactions, nature of, 277
Suppressor bands, electrical activity of cortex affected by stimulation of, 321
Suppressor strips, location of, 308
  mode of action of, **314**
Supra-optic nucleus, function of, 358
Supra-opticohypophyseal tract, function of, **1089**
Surface tension, hydrotropy and, 909
  nature of, 66
Suspensoid, definition of, 70
Suspensory ligament, action in accommodation of, **390**
  action in eye of, 388
Swallowing, pulse rate affected by, 600
  respiration affected by, 767
Sweat, climate effect on output of, **1049**
  composition of, **1029**
Sweat glands, nerve supply to, 347
  structure of, 1029
Sweating, acclimatisation effect on, 1051
  factors affecting, **1030**
  skin temperature affected by, 1045
  temperature effect on, 1040
Sympathetic chain, composition of, 343
Sympathetic efferent paths, course of, 227
Sympathetic ganglia, acetylcholine formation in, **363**
  chemical transmission in, 361
  distribution of, 343
  transmission in, 237
Sympathetic nerve stimulation, adrenal medulla affected by, 1067
  gastric secretion with, 864
  heart affected by, **589**
  intestinal movements affected by, **893**
  lung volume affected by, **721**
  salivary glands affected by, 847, 851
Sympathetic nerves, distribution of, 346
  sweat glands supplied by, 1031
Sympathetic nervous system, afferent fibres of, **352**
  chemical transmission in, 360
  composition of, 343
  heart innervation by, **585**
  hypothalamic stimulation effect on, 357
  irradiation in, 359
  para-sympathetic comparison with, 351
Sympathetic plexuses, nature of, 346
Sympathetic vasoconstrictor nerves, tonic action of, 642
Sympathetic vasodilator nerves, 646
Sympathin, nature of, 167, 360
Synapse, conduction at, 236–**237**
  definition of, 195
  structure of, 205
Synapsis, nature of, 1099
Synaptic block, nature of, 207
Synaptic conduction, nature of, 236–**237**
Synaptic delay, nature of, 207
  sympathetic ganglion showing, 238
Synaptic knobs, nature of, 205, **206**
  neurone stimulation and, **242,** 243
Synaptic potential, nature of, 240
Synaptolemma, nature of, 205
Syngamy, nature of, 1099
Synovial fluid, composition of, 818
Systole, cardiac events in, 556
  pressure changes in heart in, **559**
Systolic murmur, cause of, 563
Systolic pressure, measurement of, **611**
  measurement in man of, **612**

Tachypnœa, nature of, 754
Tactile sensibility, test for, **477**
Talbot Plateau law, nature of, 422
Taste-buds, structure of, **484**
Taste centre, location of, 305
Taste, nervous pathways of, 290
  sense of, 483
Taurine, cysteine relation to, 931
  nature of, 883
Taurocholic acid, nature of, 883
Tear fluid, secretion of, **380,** 381
Tectorial membrane, function of, **454**
Tecto-spinal tract, function of, 227
Teeth, vitamin C effect on growth of, 829
  vitamin D effect on formation of, 823
Telephone theory of hearing, 459
Temperature, blood clotting affected by, 528, 534
  heart affected by changes in, 580
  nasal mucosa affected by changes in, **709**
  nerve conductivity affected by, 186
  nerve excitability affected by, 181
  oxygen dissociation curve affected by, 729
  plain muscle affected by, 169

Temperature, pulse rate affected by, 599
  red blood cell fragility affected by, 509
  renal secretion affected by, **997**
  sense of, 474
  skin temperature affected by, **1035**
  spermatozoa affected by, 1122
  sweating response to rise in, **1030**
Temperature regulation, nervous control of, 1053
Temperature sense, central nervous pathways for, **225**, 226, 284
  receptors for, 216, **217**
Temporal lobe, functions of, 300
Tendon receptors, function of, 218
Tendon reflexes, characteristics of, 264–265
Tendril fibres, origin of, 335
Tension receptors, nature of, 218
Tension-length relationship, resting and contracted muscle, 125–**126**
Tensor tympani, function of 451,
Test meal, nature of, 859
Testis, anterior pituitary effect on, 1125
  history of, 1056
  structure of, 1119
Testosterone, adrenal cortical hormones and action of, 1062
  structure of, 28, 1123
Tetanus, genesis of, 128–**129**
Tetanus toxin, species variation in susceptibility to, 701
Tetany, parathyroid glands and, 1076
Tetrahydro-β-naphthylamine, actions of, 1038
Thalamus, acetylcholine synthesis in, 364
  frontal lobe connections with, **301**
  functions of, 291
  hypothalamic connections with, 356
  motor cortex connections with, 311
Thalamus animal, brain section producing, **273**
Theobromine, structure of, 48
Thermal anhidrosis, nature of, 1052
Thermal interchange, temperature effect on, **1043**
Thermopile, use of, **156**
Thermostromuhr, principle of, 624
Thiamin, actions of, 826
Thiamine pyrophosphate, co-enzyme action of, **94**
Thiocyanate, formation and excretion of, 843
  thyroid gland affected by, 1076
Thiosulphate, excretion of, 1003
Thiouracil, thyroid gland affected by, 1075
Thiry-Vella fistula, nature of, 888
Thirst, cause of, 901
Thorax, respiratory movements of, 711
Threonine, structure of, 40
Threshold substance, nature of, 1004
Threshold values, method of, 367, 369
Thrombin, characters of, 529
Thrombocytes, nature of, 526
Thrombogen, nature of, 535
Thrombokinase, action of, 530
Thromboplastin, action of, 530
Thrombozym, nature of, 535
Thymine, structure of, **49**
Thymus gland, castration effect on, 1104
  function of, 1091
Thyro-arytenoid muscle, action of, 466
Thyroglobulin, nature of, 1072
Thyroid deficiency, effects of, 1069
Thyroid extract, diuretic action of, 1090
Thyroid feeding, effect of, **1071**
Thyroid gland, anterior pituitary interacti with, 1093
  blood flow to, 629
  carbohydrate metabolism affected by, 974
  functions of, 1069
  gonads interaction with, 1093
    relation to, 1104
  history of, 1055
  lactation affected by, 1145
  nerve supply to, 348
  temperature effect on, 1038
  thyrotropic hormone action on, 1085
Thyroid secretion, basal metabolic ra affected by, 795
Thyroidectomy, pituitary changes followin 1079
Thyrotropic hormone, action of, 1075, 1085
Thyroxine, actions of, 1073
  hair growth affected by, 1032
  milk secretion affected by, 1146
  structure of, 40, **1072**
  tyrosine relation to, 928
Tidal air, expired air composition affected 725
  value of, **716**
Tissue culture, method of, 12
Tissue fluid, factors affecting formation of, 6
Tissue regeneration, power of, 1153
Tissue respiration, factors concerned in, 74
  history of, 783
Tissue slice, measurement of metabolism 745
  metabolism of, **921**
Tissues, oxygen diffusion into, 741
T*m*, determination of, 1009
Tocopherol, structure of, **825**
Tongue, drugs action on, 484
  deglutition and action of, 854
Tortoise, heart anatomy in, 542
Touch, central nervous pathways for, 284
  cortical representation of, 303
  localisation of, 479
  reaction time of, 319
  receptors for, 216, **217**
    adaptation in, 220
  sense of, 476
  spinal cord tracts for 224–225
Touch corpuscles, location of, **1027**
Toxins, lymph absorption of, 692
  types of, 701
Toxophore group, nature of, 702
Trace conditioned reflex, nature of, 326
Trachea, air dust removal by, 779
Training, muscular performance affected 677
Transamination, nature of, 923
Transferring enzymes, action of, 101
  groups of, **96**
Transitional cells, characters of, 524
Transmethylation, nature of, 931
Transneuronal degeneration, nature of, 2
Transphosphatase, action of, 101
Traube-Hering waves, nature of, 652
Tricarboxylic acid cycle, fat oxidation an nature of, **143**
Tricuspid valve, structure of, 550
Trigeminal lemniscus, connections of, 28
Trioses, structure of, 30
Triple response, nature of, 662
Trochlear nerve, effect of injury to, 375
Trophic lesions, spinal cord section causin
Trophoblast, nature of, **1132**

Voluntary eye movements, control of, 376
Voluntary movement, cerebellar injury affecting, **341**
Voluntary muscular contraction, fatigue in, 136
  mechanism of, 132–**133**
Vomiting centre, action of, 875
Vomiting, intestinal secretion affected by, 888
  mechanism, of, 874
Vowels, frequency of components of, **469**
ulpian-Heidenhain-Sherrington phenomenon mechanism of, 136–137

Wallerian degeneration, nature of, 173
Warburg manometer, use of, **921**
War, diets affected by, 836
Wasserman reaction, nature of, 705
Water, absorption in intestine of, 905
  balance, pituitrin action on, 1088
  distribution in body of, 810
  diuresis, mechanism of, 1013
  large intestine absorption of, 895
  passage through membranes of, 79
  regulation, factors concerned in, 1090
  skin and lungs loss of, 1029
  skin storage of, 1032
‘ **Water-hammer** ” pulse, nature of, 629
Wave summation, nature of, 130
Weber's law, difference threshold of intensity in eye following, 423
  nature of, 371
  touch and, 478
Wedensky inhibition, nature of, 180, 196
ight-testing, Weber's law and, 370
eiss's laws, chronaxie and, **113**
ever and Bray effect, nature of, 455, 457
hey, nature of, 1149
hirling psychrometer, use of, 1047

White rami communicantes, composition of, 345
White light, composition of, 372
Widal test, nature of, 704
Wiggers manometer, use of, **557**, **558**

Xanthine oxidase, action of, **99**
Xanthine, structure of, **48**
X-chromosome, nature of, 1156
Xerophthalmia, vitamin A relation to, 821
X-ray, colon filling shown by, **897**
  deglutition movements followed by, 853
  fœtal circulation examined by, 1137
  intestinal movements shown by, **890**
  measurements on living eye by, **399**
  mutations induced by, 1159
  ovaries affected by, 1109
  renal circulation studied by, **993**
X-zone, nature of, 1059

Y-chromosome, nature of, 1156
Yeast, vitamin B_1 content of, 826
Yolk sac, blood cell formation in, **518**
Young's hypothesis of colour vision, 437
